An occlusive dressing is placed using sterile antibiotic ointment or petrolatum over the ostomy site. The exiting catheter and torso are then wrapped gently but securely with gauze and tape for further protection. A stockinette can also be used to cover the entire area. The end of the catheter should be exposed near the dorsum of the animal's back, and the rest of the catheter should be covered to prevent its being damaged or dislodged.

Methods of Pleural Space Evacuation

The open end of the tube must be attached to one of the following: 1) a Heimlich valve (Bard-Parker, Rutherford, NJ) or another one-way egress valve; 2) a three-way stopcock; 3) an underwater seal; 4) an underwater seal with controlled continuous, low-vacuum suction drainage (high-volume or low-volume types depend on the rate of air or fluid-blood accumulation); 5) an underwater seal with controlled, intermittent low-vacuum suction drainage; or 6) under emergency conditions, a regular suction unit with a side hole cut into the connective tubing to control the suction pressure. The choice of device depends on the size of the patient, the size of the air leak, the nature of the pleural fluid, and the patient's tractability. All attachments to the chest tube should be secured with tape placed in a criss-cross fashion. This allows the inside of the tubing or attachment to be visualized. If the attachment is inadvertently pulled, the tape will tighten and prevent loosening or detachment.

Heimlich Valve

The Heimlich valve consists of a rubber one-way flutter valve that is enclosed in a clear plastic tube open at each end (Figure 27-29). The end of the chest tube is attached to the wide end of the flutter valve and is an excellent device for evacuating air. It is a good temporary device for evacuating blood and other fluids; however, the valve should be replaced frequently during drainage of blood or other tenacious fluids because the rubber valve becomes sticky and does not open freely. The end of a Heimlich valve has a fitting that accommodates a syringe in case manual suction is required. Although the valve has been used with success in animals weighing less than 15 kg, some smaller patients may not be able to generate sufficient increases in intrapleural pressure during expiration to open the valve and to allow evacuation. One-way valves are especially useful in the initial management of tension pneumothorax in patients weighing more than 15 kg if an underwater seal and suction system is not immediately available.

Stopcock

A stopcock attached to the end of a catheter prevents air or fluid from moving either in or out without manual operation. Its use is recommended in animals weighing less than 15 kg and in animals that are not accumulating air or fluid rapidly in their pleural cavity. The rate of fluid or air evacuation is determined by the size of the stopcock because the stopcock is of a smaller diameter than the chest tube. A large syringe is used for periodic aspiration by opening and closing the valve as needed to accomplish thoracentesis. The syringe plunger should be pulled back gently with only sufficient pressure applied to evacuate the fluid. Excessive pressure (greater than 30 cm H_2O) can lead to lung injury or ineffective evacuation caused by the aspiration of mediastinal tissue.

Temporary Emergency Underwater Seal and Suction System

A disposable plastic intravenous administration set can be used to facilitate emergency drainage of large quantities of pleural

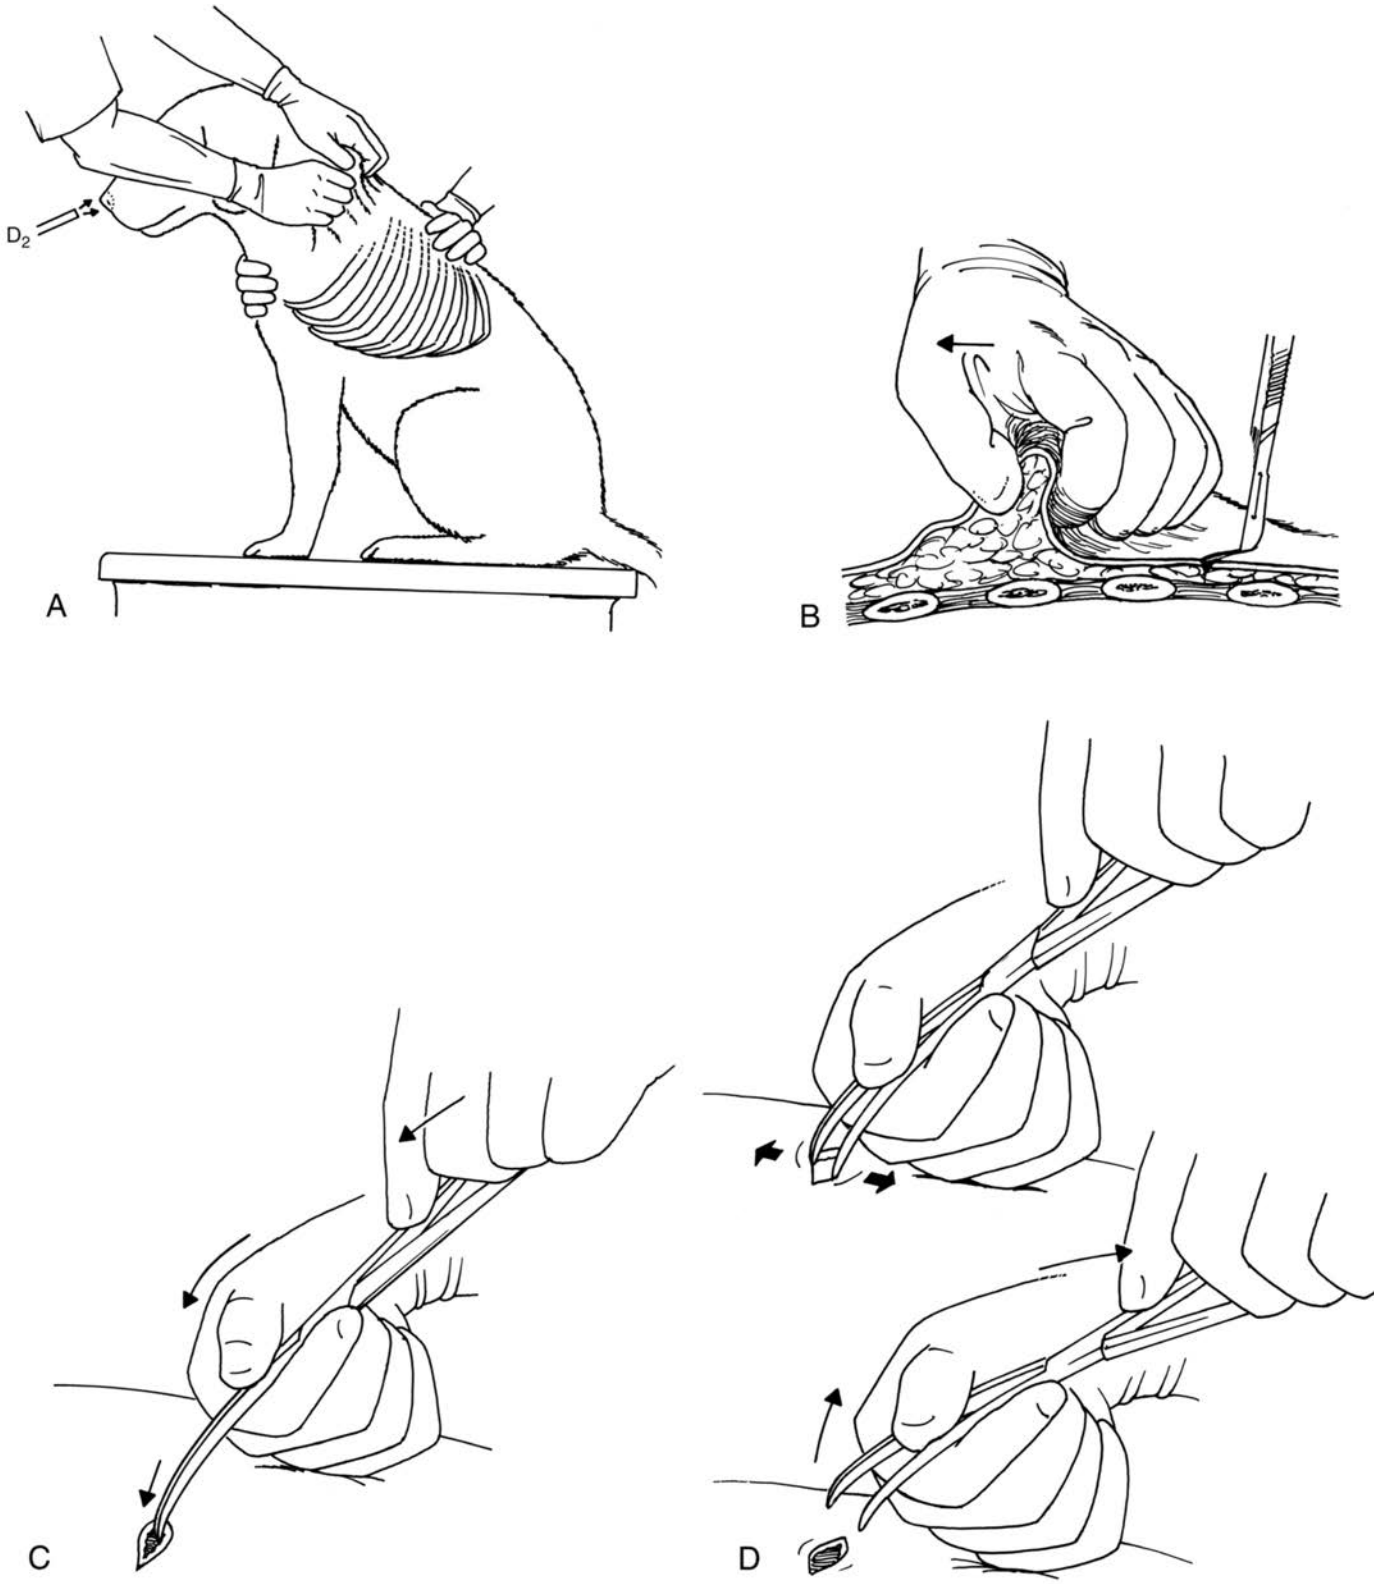

Figure 27-27. A-F. Placement of a chest tube with the skin pulled as far forward as possible that creates a flap when the tube is inserted and the skin is released.

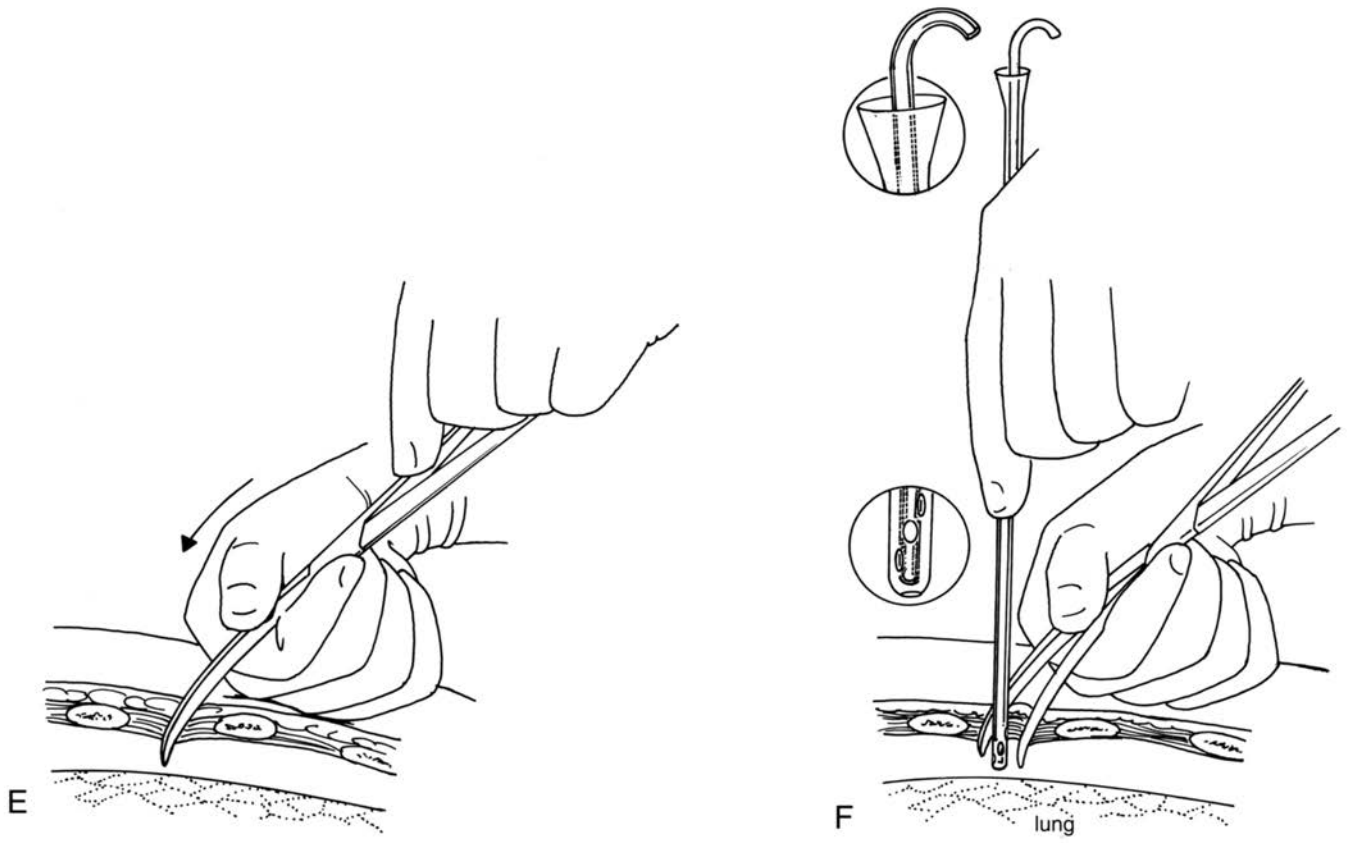

Figure 27-27. A-F. *(continued)*

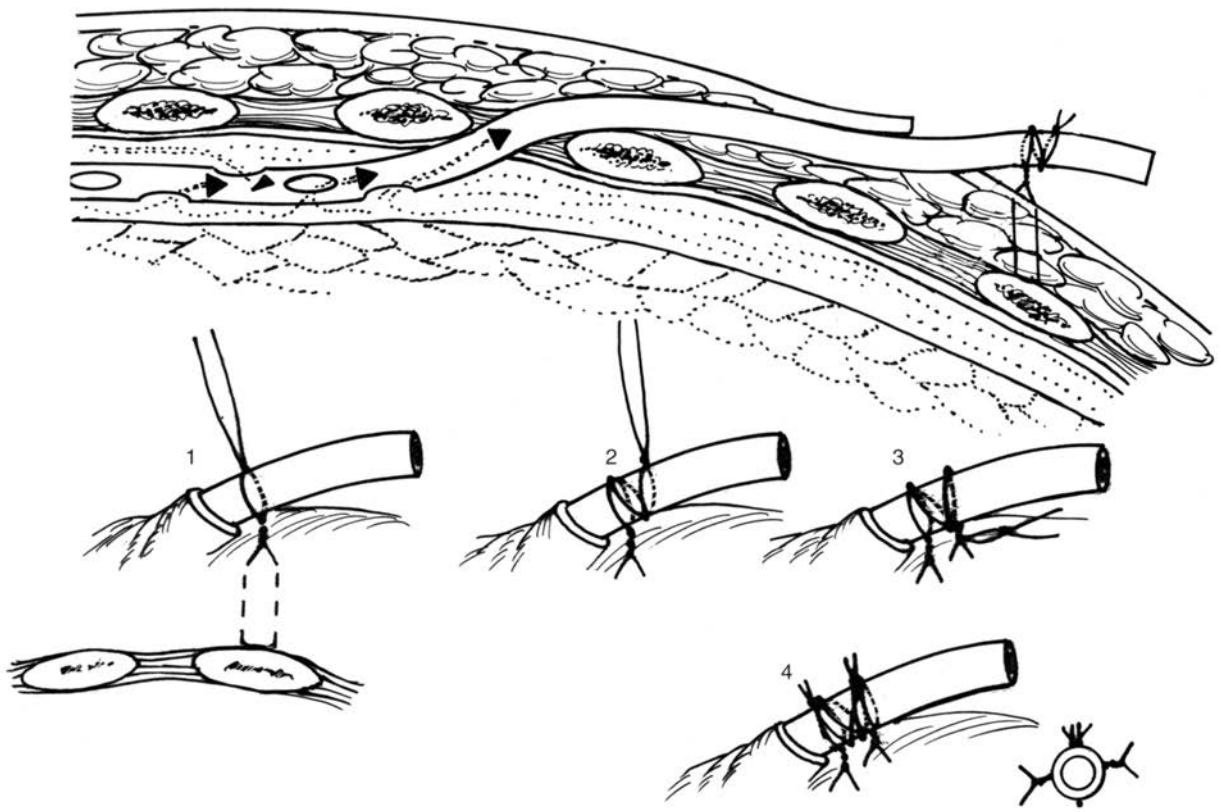

Figure 27-28. When the skin is allowed to return to normal position, a tunnel is created that helps to prevent air from migrating into the pleural space. Note the position of some of the side holes in the tube that allow air and fluid to drain from the pleural space as the lung reexpands *(1 to 4)*.

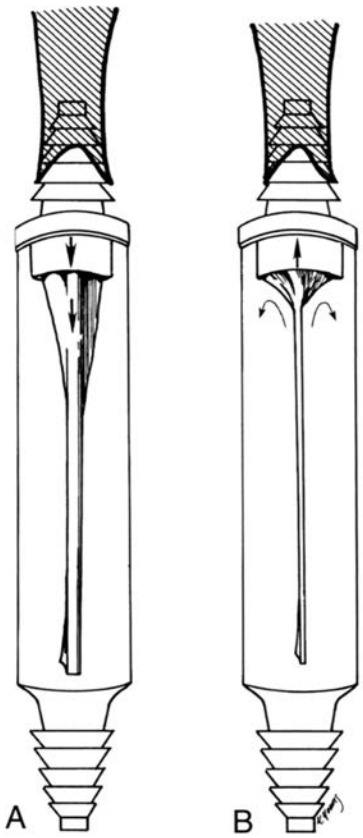

Figure 27-29. These diagrams demonstrate the function of the Heimlich flutter valves. **A.** During inspiration, the valve stays closed, and no air can enter the thoracic cavity. **B.** During expiration, as intrapleural pressure increases, the air or fluid is forced out of the pleural space through the chest tube and one-way valve. (From Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea & Febiger, 1983.)

effusion. The male end of the plastic tubing is fitted to the side arm of the stopcock, and the drip chamber is cut from the other end and is placed underwater. When the side arm tubing is filled and the stopcock is opened, drainage of the pleural space to a collecting vessel is possible by siphon action. To make and use an underwater seal, a length of tubing connected to the chest catheter is placed 1 to 2 cm below the fluid's surface in a bowl or bottle containing 2 to 3 cm of sterile saline solution. This useful, quickly made underwater seal and one-way valve are recommended as a temporary measure when no other instruments or one-way valves are available and when time does not permit delayed action. The device can also be used for patients that need a vent if pleural fluid or air accumulates. When using this technique, care is taken to make sure that the tube stays submerged because, if the seal is broken, pneumothorax rapidly develops. Constant observation of this temporary device is mandatory.

Underwater Seal and Suction Drainage

Underwater seal and suction drainage of the pleura can be easily accomplished using several systems. Both two-bottle (Figure 27-30) and three-bottle (Figure 27-31) systems are adaptable to veterinary practice, and the equipment is unsophisticated and reusable. With a two-bottle suction drainage system, the chest

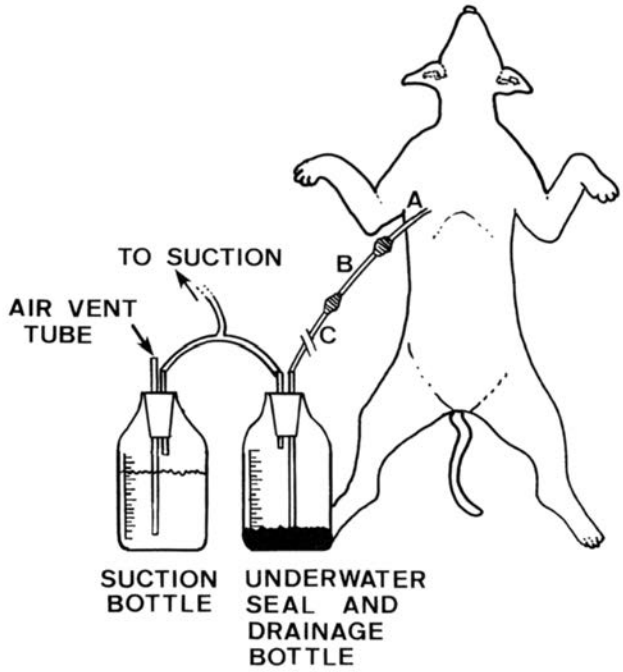

Figure 27-30. Two-bottle suction drainage: *A,* Distal end of the chest tube exiting from the bandaged thorax: *B,* gum-rubber tubing (approximately half an inch in diameter) to allow "stripping" of the chest tube, about 3 feet long (see text): *C,* polyvinyl chloride "bubble" tubing. (From Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea & Febiger, 1983.)

catheter is connected to a 500- to 2000-mL sterile glass bottle containing enough sterile saline solution to fill it to a level of 2 to 3 cm from the bottom. The tube within the bottle is placed 1 to 2 cm below the surface of the saline solution. The bottle acts as both a collection reservoir and an underwater seal system to prevent air from being aspirated into the pleural space. A second bottle is partially filled with sterile saline solution and is connected to the first. A rigid plastic vent tube is open to room air, so it permits air to be aspirated into the bottle as vacuum is applied. Thus, by raising or lowering the tube in the second bottle, the amount of vacuum applied to the catheter extending into the patient's chest can be controlled. If the vacuum regulation tube is submerged to 10 cm, the patient will not experience more than 20 cm water transpleural suction pressure.

Experimental and clinical studies have shown that a continuous 15 to 20 cm negative pressure effectively aspirates tension pneumothorax and allows pulmonary visceral and parietal pleural surfaces to be approximated and to remain approximated. This pressure has proved to be key to the successful, spontaneous sealing of large defects in the lungs of human and animal patients. With the use of suction drainage, many pneumothoraces close, and the need for thoracotomy is thus obviated. This finding is in contrast to drainage without suction, experimental and clinical studies of which have shown that large leaks either do not seal or seal slowly.

With a three-bottle suction drainage system, the first bottle is connected to the chest catheter and acts as a fluid trap. Such a system is particularly useful if hemorrhage or hydrothorax is voluminous. If traumatic hemorrhage is severe, autotransfusion

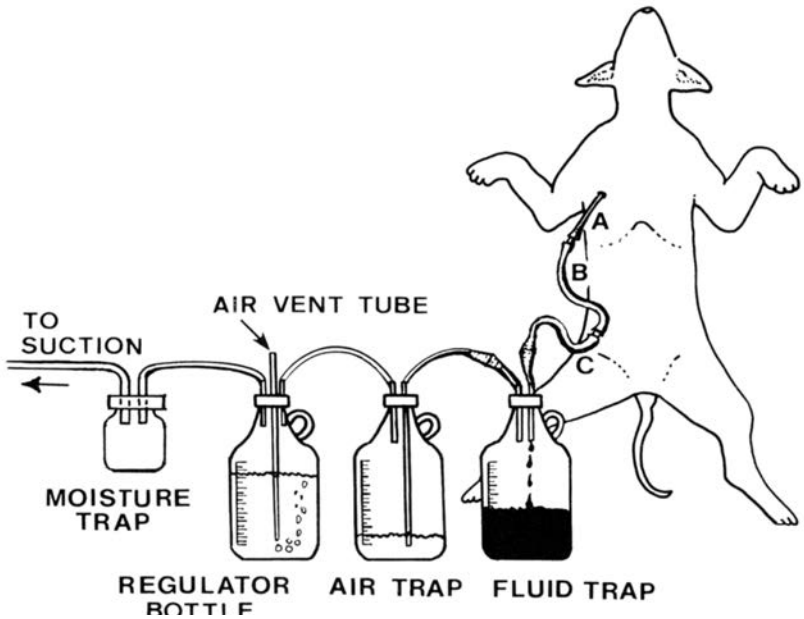

Figure 27-31. Three-bottle suction drainage: *A,* Distal end of the chest tube exiting from the bandaged thorax; *B,* gum-rubber tubing (approximately half an inch in diameter) to allow "stripping" of the tube, about 3 feet in length (see text); *C,* polyvinyl chloride "bubble" tubing. (From Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea& Febiger, 1983.)

may be considered from this vessel. In this case, approximately 50 to 75 mL anticoagulant solution is initially added to the bottle. When 500 to 1000 mL blood has been aspirated, a second fluid-trap bottle containing anticoagulant is substituted for the first bottle, and autotransfusion is begun. The second bottle of the three-bottle system is connected to the first bottle and acts as the underwater seal. Its function and filling are similar to those of the first bottle of a two-bottle system. The third bottle is connected to the second and again acts as suction regulator.

For the underwater seal and suction drainage system, at least the first 3 feet of the tubing leading from the chest catheter to the underwater seal should be made of gum rubber (Tomac amber latex intravenous tubing, American Hospital Supply Corp., McGaw Park, IL). Any animal whose chest catheter is connected to an underwater seal device by a tube must be watched carefully because knocking over of the bottles and detachment or chewing of the tubing can lead to massive pneumothorax. This possibility is the major drawback of the use of bottle suction systems in many small animal practices in which staff coverage is not available on a 24-hour basis. If an intensive care unit, hospital with 24-hour staff coverage, or emergency practice is available, however, continuous suction and drainage may be accomplished and continued for as long as necessary.

With several alternatives available, selection of a drainage system depends on the following criteria: 1) the patient's size; 2) the type of material drained and its rate of accumulation within the pleural space; 3) the facilities and staff available for monitoring; and 4) economic considerations. Without question, the underwater seal and suction drainage system is the most effective. A three-bottle system is no longer available, but one may buy a two-bottle and a one-bottle system and combine them (American Hospital Supply Corp.). The Pleur-evac chest drainage unit (Deknatel, Inc., Fall River, MA) is a commercially available underwater seal system that is in essence a three-bottle system. This also has an autotransfusion system that can be attached for collecting blood for autotransfusion. The Pleur-evac does require the use of a suction unit to generate the vacuum powering the system. The AN50 Thorovac (H. W. Andersen Products, Inc., Haw River, NC) is a commercial example of a two-bottle system. This is an electrically driven underwater seal suction system. Up to 20 cm of water pressure can be generated; however, in patients with large leaks, the unit may not be able to evacuate rapidly enough. It is generally useful if the air leak from a pneumothorax is less than 500 mL per hour.

Troubleshooting and Tube Stripping

When using any form of continuous underwater suction system, the chest tube should be intermittently stripped and, in some cases, hand suctioned using a stopcock and syringe to ensure that the system is working adequately. The best way to hand suction using a stopcock is to attach a "Y" connector (Abbott Laboratories, Chicago) to the chest tube. A red rubber tube (Sovereign, Sherwood Medical Products) is used to connect the stopcock to the Y connector. The other end of the Y connector is attached to the suction tubing (Figure 27-32). A clamp is placed across the section of tubing not being used. This method allows either continuous suctioning or syringe aspiration without disruption of the connections.

With continuous-suction systems, leaks and generation of inadequate suction pressure are the two most common complications. Leaks can occur anywhere along the system from the ostomy site to the suction unit. If the tube was not tunneled at least two spaces, the tube may start to leak at the ostomy site. This is more likely to occur the longer the tube is in place because the skin edges retract around the ostomy site, thereby creating a larger hole. If the tube backs out of the chest, holes in the tube may communicate with the environment.

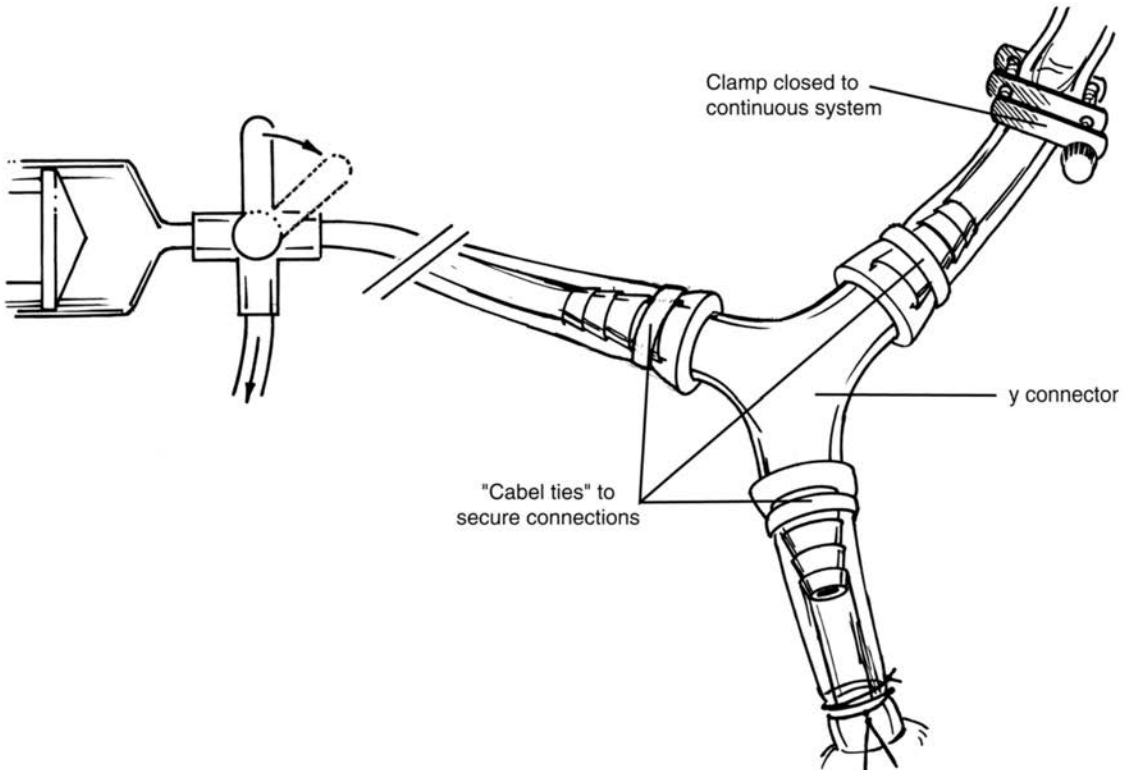

Figure 27-32. Y connecter attached to a chest tube to allow a continuous-suction system to be connected as well as a stopcock to aspirate intermittently, to ensure function of the continuous system and to act as a "fail safe" for evacuation of the pleural space if the system stops working properly.

The pressure generated at the chest tube should be checked periodically. This can be done by placing a manometer near the chest tube and monitoring the pressure as the suction is applied. A commercial manometer (Vital Signs Inc., Totawa, NJ) can be used for this purpose, or tubing can be placed in a bottle of sterile saline. A column of saline pulled upward into the tubing should be between 15 and 20 cm above the surface of the saline. The pressure indicated at the suction unit itself is always less than the pressure generated at the chest tube because of resistance within the tubing. This problem worsens in proportion to the length and collapsibility of the tubing.

Fluid accumulations within the suction tubing also interfere with operation of the system. Stripping is required to keep the fluid from accumulating. By grasping the tubing as near to the patient as possible and by pinching it closed, a stripping motion (a sliding motion, with the tube pinched off) is applied along the length of the tube for 20 to 40 cm (Figure 27-33). The stripping action creates a sudden, high negative pressure inside the tube past the area where the tube has been pinched closed. At the end of each stripping action, the pinch is released, and a surge of negative pressure is transferred to the thoracic catheter. The high negative pressure generated also loosens and evacuates fibrin clots and debris inside the catheter. This stripping should be done every hour when a significant amount of blood or other viscous or sticky fluid is encountered. The frequency of stripping may be decreased as the amount of fluid removed decreases. Generally, by the second day, stripping is only necessary every 4 to 8 hours.

Special Considerations for the Rapid Accumulation of Fluid or Air

Currently, an underwater seal and suction drainage system attached to the chest tube is the recommended method of treatment for trauma or disease conditions involving the continuous or rapid accumulation of air or fluid in the pleural space. In these situations, a Heimlich valve should only be used as a temporary means of evacuating the chest if the patient's weight exceeds 15 kg, such as when transporting the patient from the emergency treatment area to the intensive care unit. For patients under 15 kg, use of a three-way stopcock and syringe is the only method recommended for the drainage of rapid accumulation of air or fluid other than underwater seal and suction systems.

Under emergency conditions, if an underwater seal and suction system is not immediately available, a regular suction unit can be used. The vacuum is reduced to 20 to 30 cm H_2O by one of three methods: 1) cutting a small hole in the side of the tubing; 2) partially clamping the tubing; and, 3) opening the "escape" valve or using the control valve on the suction unit.

Analgesia

The presence of chest tubes can be painful for the patient, and analgesia should be administered on a regular basis as required. Intercostal nerve blocks can be provided with 0.25 to 1.0 mL of 0.25% bupivacaine through intermittent injections or with the use of an indwelling catheter. Intrapleural analgesia is best provided with 0.25 to 0.5% bupivacaine (up to 2 mg/kg) administered into

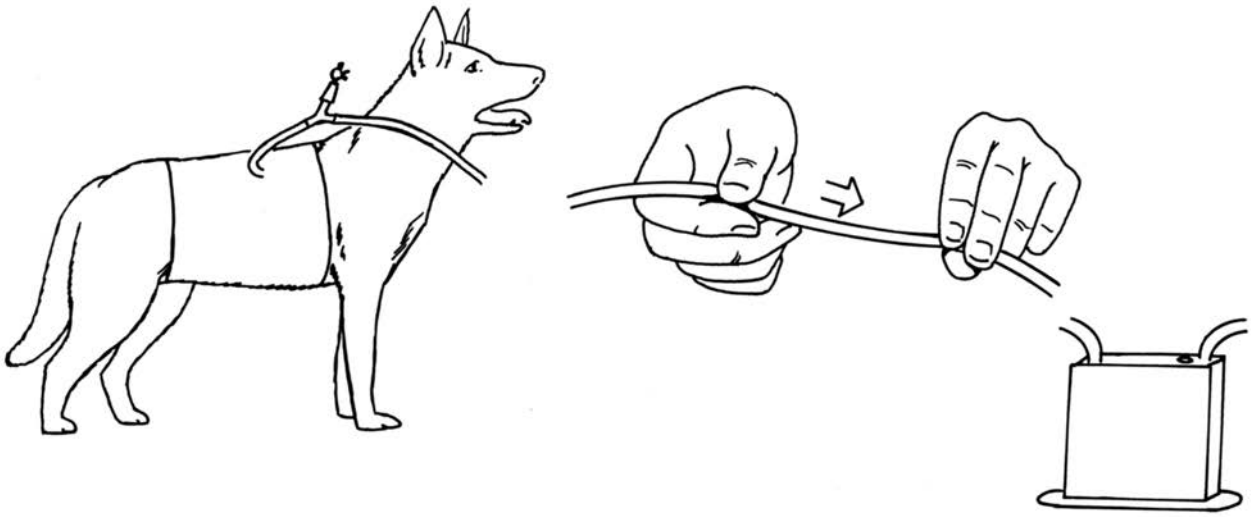

Figure 27-33. Chest tube stripping done by a nurse every 6 to 8 hours to keep the tubing and the tube patent. The left hand pinches the tubing (made of gum rubber) shut, and the right hand is used to strip the tube, by pinching and then sliding using the thumb and index finger, which are lubricated with water or petroleum jelly. When the right hand meets the left, the tube in the left hand is allowed to snap open, creating a sudden popping of air.

the chest tube. The addition of sodium bicarbonate (one-third sodium bicarbonate to two-thirds bupivacaine) to the local anesthetic helps to decrease the irritation from the acidity of the drug. Warming the medication to body temperature and administering the drugs slowly also provide less discomfort. Systemic administration of a neuroleptanalgesic is also recommended in combination with local analgesia.

Tube Removal

The chest drain should be removed whenever it is no longer needed. This time may range from the immediate postoperative period to more than a week. Suction should be continued until no air has been removed for 12 to 24 hours or until fluid accumulations are less than 1 to 2 mL/kg per day. If any question exists concerning the safe removal of the chest tube, it should be clamped for 24 hours. The patient should be closely monitored during this time, and the tube should be suctioned if the patient has any evidence of respiratory compromise. The tube is aspirated after the 24-hour period, and radiographs are then taken to determine whether any intrapleural accumulation of air or fluid is present. If no accumulation is present, the tube may be safely removed.

When the surgeon determines that the tube is no longer needed, the bandage and sutures are removed, and the tube is quickly removed using traction. The hole is covered with a gauze dressing impregnated with an antibiotic ointment. The gauze is held in place with a torso bandage. Complete sealing of the wound generally occurs in 2 or 3 days. Until then, the dressing is changed as required to maintain a clean, dry, and occlusive (with ointment) environment.

Complications

As previously mentioned, whenever the patient must be left unattended, the entire chest catheter and attached apparatus must be covered completely under a well-secured dressing to prevent disturbance or dis-lodgment. If disconnection occurs in the patient with a large-bore chest tube, death can occur within 5 to 10 minutes because of the effects of a progressive pneumothorax.

An occasional problem is the accumulation of fibrin clots, especially when a small-lumen-diameter catheter (smaller than 20 French) is used or when a large amount of fibrin, blood, or other proteinaceous material is drained. Blockage is prevented by frequent stripping of the tubing. When using a three-way stopcock on the end of the chest catheter, a small amount of sterile heparinized saline solution can be infused every few hours; when using the Heimlich valve or other one-way rubber valve, it may be necessary to change the valve frequently.

Reexpansion pulmonary edema has been occasionally reported in patients with chronic cases of atelectasis when the lung is reinflated rapidly after rapid removal of pleural fluid or air. In general, this complication is not seen until the lungs have been atelectatic for longer than 3 days.

Another reported complication is subcutaneous emphysema as the result of a large hole in the chest wall that is not completely occluded by the presence of the drainage tube. An occlusive dressing applied around the exit site helps to minimize this problem. Lung tissue entrapment and subsequent infarction by vigorous chest suction have been reported. This complication may be considered whenever a radiographic pulmonary infiltrate appears near a side or end hole of the chest tube. Unregulated, high vacuum levels, as in operating room or portable suction units (80 to 120 mm Hg), should not be used. All active suction must be regulated by a two- or three-bottle system, the emergency system mentioned earlier, or, if one is aspirating with a syringe, it should be done gently.

Although infection can occur whenever any indwelling catheter is used, this problem is minimized by careful tube placement and care. In a randomized study of 120 human patients with indwelling chest drains, half were treated with prophylactic antibiotics,

and the other half were given a placebo. Those patients given antibiotics had the higher infection rate. Our clinical results with the use of chest drains in dogs and cats also seem to indicate similar conclusions. Proper wound care at the site where the drainage catheter enters the chest and strict attention to aseptic technique and suction drainage remain the most important factors in preventing serious infection of the pleural cavity and subcutaneous tissue. If any concerns exists, the evacuated fluid should undergo periodic cytologic assessment, and Gram staining and culture should be performed as indicated. Culture of tips of the tubes on removal should be considered in any tubes that have been in place for an extended period.

A rare complication of chest tubes is phrenic nerve irritation and palsy. This problem may be severe enough to cause diaphragmatic paresis. If the tube rubs the pericardium or the heart after pericardi-ectomy, arrhythmias may occur. These are generally self-limiting.

If the tube has been in place for several days, adhesions may have formed, and mild intrathoracic bleeding may occur when the tube is removed. Rarely, bleeding may persist to the point that surgical exploration and vessel ligation are required.

Comments

Often, animals suffering from multiple injuries, including fractures, have a pneumothorax. Mild pneumothoraces do not cause respiratory distress, but they are readily diagnosed by chest radiographs. If anesthesia is necessary for fracture repair, a chest tube should be inserted to aid resolution of the pneumothorax, to help in lung healing, and to allow earlier and safer use of anesthesia. Positive-pressure ventilation during anesthesia may predispose the healing lung or bronchus to rupture. Without a chest tube in place, a tension pneumothorax can rapidly develop and can prove fatal. The placement of prophylactic chest tubes is also indicated in patients with lung injury that require positive-pressure ventilation.

Bilateral chest tubes may be required to permit adequate evacuation of the pleural space. In many trauma patients, the mediastinum ruptures, thus allowing both sides of the thorax to be evacuated with a unilateral tube. However, the mediastinum may seal, and a second tube may be required. In many patients with bilateral fluid accumulations, chest tubes may be required on both sides of the thorax to provide effective drainage because the mediastinum is intact and is often thicker than normal.

Chest tubes can be used as a method of core re-warming of the severely hypothermic patient. In such cases, through-and-through lavage is done with warm sterile saline. Instillation of sterile saline or lactated Ringer's solution into the pleural cavity using chest tubes can also be used for the treatment of uremia, similar to peritoneal dialysis.

Chapter 28

Thoracic Wall

Thoracic Wall Neoplasia

Dennis Olsen

Biology of Thoracic Wall Neoplasia

Tumors of the thoracic wall are considered uncommon and can originate from skeletal or soft tissues structures. The tissue of origin and tumor type determine biologic behavior and behavior dictates the degree of surgical intervention. Benign soft tissue tumors (e.g. lipoma) can often be removed without wide margins or aggressive excision. However, malignant tumors, regardless of tissue of origin, should be removed with a variable margin of normal tissue dictated by the type of tumor. Those tumors that have a high probability of recurrence should have large borders of normal tissue removed three dimensionally around the tumor.[1] This degree of surgical excision often comprises the full thickness of the thoracic wall which, may affect function as well as dictate the type of closure or reconstruction required to restore integrity of the thoracic wall. Variations in surgical therapy recommendations emphasize the need for accurate differentiation between benign and malignant tumors before appropriate therapy can be planned and initiated.

Primary tumors affecting the skeletal structures of the thoracic wall are malignant more often than they are benign.[2-7] Most authors report that osteosarcoma is the most common type of malignant rib tumor followed by chondrosarcoma[1,3-7] however, at least one report has this order reversed.[7] Skeletal tumors often occur at the costochondral junction of the ribs and more rarely the sternum.[2,3,5,7] These tumors are often firmly attached to soft tissues of the thorax making them relatively immobile. This characteristic may be an indication of malignancy.[6] Young to middle aged dogs are most commonly diagnosed with these tumors.[2,5,7,8] The occurrence of skeletal tumors in this location in the cat is very rare.[7]

Clinically, dogs with osteosarcoma of the thorax are presented with a palpable mass of the ribs or sternum that may be painful,[9,10] although some authors describe them as nonpainful.[5,7] Dyspnea due to pulmonary impingment from intrathoracic extension of the tumor, pleural effusion, and pulmonary metastasis has been reported[2,5,7,9] but another source states that respiratory signs due to these conditions are not commonly seen.[10] One characteristic that is generally agreed upon is that the biologic behavior of osteosarcoma in the rib is similar to other locations. Locally, osteosarcoma is aggressive with lysis and production of bone and replacement with neoplastic tissue.[10] Early metastasis is a trait of osteosarcoma with the lungs as the primary location for tumor spread and this characteristic is responsible for the poor prognosis for animals with osteosarcoma.[4,7,10] *En bloc* resection of the tumor including wide margins of normal tissue with adjunctive radiation and or chemotherapy are recommended. The median survival times for cases treated by *en bloc* excision and excision plus adjunctive chemotherapy are three and eight months respectively.[9,11,12] The poor prognosis emphasizes the need for accurate diagnosis particularly when compared to chondrosarcoma.

Chondrosarcoma has a predilection for flat bones where it occurs 61% of the time.[10] In the canine, occurrence of chondrosarcoma on the ribs ranges from 6% to as high as 33%.[7] In cats common locations near the thorax are the scapula and vertebrae and rarely the ribs or sternum.[7] Biologically, chondrosarcomas are less malignant than osteosarcoma, however this tumor may attain large dimensions prior to diagnosis. It invades local tissues, the pleural space, and may cause pleural effusion.[7] Metastasis is reported to be slower than with osteosarcoma and the prognosis is somewhat better if early diagnosis and aggressive surgical resection is performed.[7,9] The reported median survival times for dogs with chondrosarcoma of the ribs are quite variable but are considerably longer than osteosarcoma with some authors reporting up to1080 days.[9,12] Therapy for chondrosarcoma is also *en bloc* resection of the tumor with reconstruction of the thoracic wall if needed.

Metastatic neoplasms of the thoracic wall have been described and the ribs are considered a common site while the sternum is rarely affected.[2,9] When metastasis to the ribs occurs, the diaphyseal area near the nutrient foramen is the common location.[7,9] The incidence of metastasis of appendicular osteosarcoma to other bones such as the ribs may be increased following chemotherapy regimens.[10]

Primary tumors of thoracic soft tissues include various sarcomas (e.g. fibrosarcoma, hemangiosarcoma, hemangiopericytoma, and malignant fibrous histiocytoma) and occasional discrete cell tumors (i.e. mast cell tumor).[3,6,12,15] Wide three dimensional surgical excision is recommended for these tumors. If removal requires *en bloc* excision of the thoracic wall, reconstruction may be required.

En Bloc Resection Technique

Prior to considering *en bloc* excision, the patient should be evaluated for the presence of distant metastasis. If regional lymph nodes are accessible, palpation followed by fine needle aspiration of the nodes should be performed. Three-view radiographs of the thorax should be obtained to evaluate for the presence of pulmonary metastasis.[10] Right and left laterally recumbent and either a dorsoventral or ventrodorsal views should be obtained. Ultrasound examination of the abdomen can be performed to check for metastasis or other concurrent disease that may be important prognostically. The presence of distant metastasis should be carefully considered prior to surgical therapy.

A plan for surgical treatment of thoracic tumors is developed by recognizing the extent of the neoplasm. While the external extent may be apparent, the internal extent may be more difficult to define. Diagnostic imaging studies that may include radiography, ultrasonography, computed tomography, and/or magnetic resonance imaging, should be performed to further define the extent of the disease. Once the extent of disease is determined, the excisional boundaries can be planned. It is generally accepted that wide excision is the method of choice for thoracic wall malignancies. Wide excision is defined as removing normal tissue

margins in excess of one centimeter. Two to three centimeters are regarded as standard margins in a wide excision.[1] When *en bloc* excision of thoracic wall malignancies is performed, one extra rib on each side of the mass is often taken in an attempt to obtain adequate margins.[4] Using this as a guideline along with knowledge of tumor extent allows estimation of surgical boundaries. This will allow the surgeon to determine the potential closure or reconstructive techniques that may be necessary after thoracic wall excision. When the excisional area involves only one rib and the surrounding tissues, standard soft tissue closure techniques can be utilized. When two or more ribs are excised with surrounding tissues, thoracic wall reconstruction techniques are required. Boundaries involving six ribs is considered the upper limit of surgical excision.[4-6] Reconstruction is also indicated when a part of or the entire sternum is removed.[5,6] It should be noted that altering the planned surgical boundaries in an effort to simplify closure of the thoracic defect may increase the potential for incomplete removal of the tumor. The planned closure of the defect should not influence the surgical excision plan. Rather, the excision should dictate the closure technique.

A centimeter ruler can be used to measure an appropriate distance around the periphery of the tumor. After this boundary is determined, it can be converted to an elliptical or fusiform shape to simplify cutaneous closure but the wide borders around the mass are maintained. If a previous biopsy has been performed, it is important to include the entire biopsy site within the surgical excision. The skin and subcutaneous tissues are incised along the planned boundary. As the dissection progresses, there is a tendency to get closer to the mass compromising margins and this should be avoided. The thoracic musculature is also incised widely around the mass (Figure 28-1). Hemostasis is best achieved through judicious use of electrocautery and ligation of larger vessels. Positive pressure ventilation should be initiated prior to the thoracic cavity being entered. As the external intercostal muscles and ribs are encountered, the ribs are cut dorsal and ventral to the mass. Circumcostal sutures that incorporate the intercostal vasculature caudal to each rib can be preplaced around each rib involved in the resection to decrease hemorrhage. Sutures should be placed dorsal and ventral to planned transection sites. The intercostal musculature is incised at the same level and the mass and surrounding tissues are removed (Figure 28-2). Following mass removal, surrounding soft tissues are evaluated for hemorrhage and the adjacent pleural cavity and pulmonary surfaces are inspected for evidence of damage or neoplastic invasion and these are treated as needed. A thoracostomy tube should now be placed under direct visualization to provide optimal positioning for restoration of negative pressure within the pleural space.

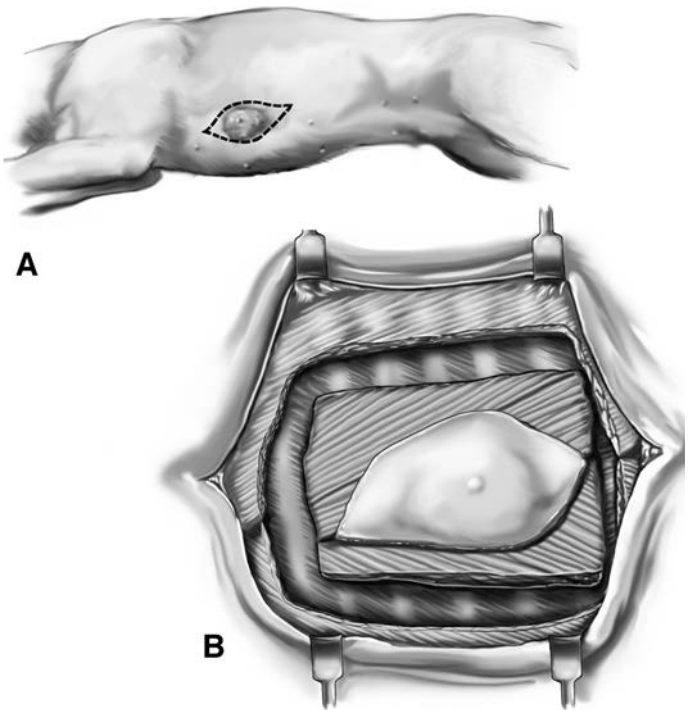

Figure 28-1. *En bloc* resection of thoracic wall tumor. **A.** Fusiform excisional boundary of a thoracic wall tumor. **B.** Wide excisional boundaries of thoracic musculature.

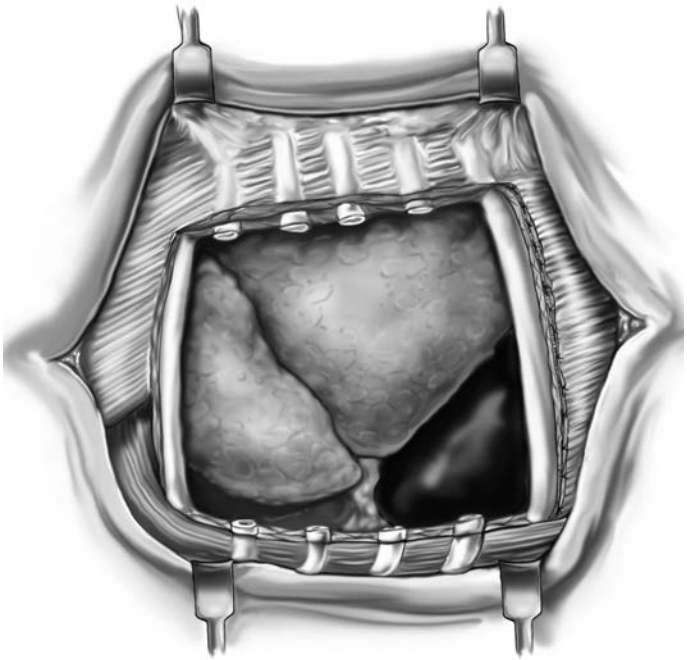

Figure 28-2. *En bloc* resection of thoracic wall tumor. All ribs involved with the tumor and one rib cranial and caudal are cut dorsally and ventrally. The intercostal musculature has been cut at the same level and the section of thoracic wall has been removed.

Thoracic Wall Reconstruction

Regardless of the technique used to close the thoracic wall, there are two general requirements that must be fulfilled during the repair. First, the repair must be relatively air tight so that negative pleural space pressure can be restored. Second, the repair should be sufficiently rigid so as to prevent excess paradoxic motion and protect thoracic organs.[5,6] Paradoxic motion involving a small section of the thoracic wall is considered a cosmetic defect and will have little effect on ventilation.

Use of autologous tissues to reconstruct thoracic wall defects is generally reserved for smaller defects. Standard soft tissue closure can be used with defects that only involve one rib and the surrounding muscles. Reconstructive muscular flaps using the latissimus dorsi and rectus abdominus muscles have been reported.[5,6] The origin of the muscles can be elevated and rotated

to cover the defect and this is followed by closure of the subcutaneous tissues and skin. When the defect is considered too large for simple closure or muscle flaps, the greater omentum can be isolated and utilized to augment wound coverage.[5,6] The greater omentum can be retrieved through a paracostal or transdiaphragmatic approach to the abdominal cavity. If the omentum can be exteriorized through the paracostal incision and manipulated through a subcutaneous tunnel to reach the defect, it is sutured over the defect and the remaining tissues are closed. When the defect cannot be reached, an omental pedicle extension flap can be prepared by previously described techniques.[13,14] The omental flap is then passed through the paracostal incision and a subcutaneous tunnel and sutured to the thoracic defect.

Larger thoracic defects may require the use of synthetic materials. Various materials are available for reconstruction such as polypropylene mesh, polymer composite struts, and combinations of synthetic materials.[4,6,10,11,16-22] When the defect is four ribs or fewer, mesh may be all that is required to cover the defect and available soft tissues are then used to cover the mesh. After the mass is excised and a thoracostomy tube is placed, a piece of mesh is cut such that it is approximately one centimeter larger than the thoracic wall defect on all sides. The edges of the mesh are folded away from the pulmonary surface and placed within the pleural cavity. This provides a double mesh layer for suturing. Along either the cranial or caudal border of the defect, non-absorbable monofilament sutures are placed around a rib and through the folded edge of the mesh implant. After the entire edge is secured, the dorsal and ventral borders are alternately sutured from the secured towards the unsecured side, engaging soft tissues and encircling the ribs or being passed through predrilled holes through the cut ends of ribs (Figure 28-3). It is important to stretch the mesh tightly and maintain even tension as the dorsal and ventral sutures are placed. The final border is now sutured in a similar manner as the initial border again stretching and maintaining tension on the mesh. At this point the superficial thoracic muscles are sutured using a four corner simple interrupted pattern to decrease the size of the defect.[4] (Figure 28-4) If the defect cannot be entirely closed using this technique the latissimus dorsi muscle can be undermined and sutured over the remaining area. If simple undermining and suturing is not sufficient then the origin of the muscle can be incised and then rotated into the defect for coverage. (Figure 28-5) Direct cutaneous vessels that perforate the caudal aspect of the muscle should be ligated and transected prior to rotation of the muscle.[4] Alternatively, other muscle flaps such as the rectus abdominus muscle can be used. The greater omentum can also be used as previously described to cover the mesh prior to muscular and/or subcutaneous and cutaneous closure.[4,13,14]

If more than four ribs have been excised, closure with mesh may not provide a stable repair and paradoxic thoracic motion may be seen. In order to prevent abnormal motion and provide protection, various devices such as synthetic, metal, or bioabsorbable plates or rib allografts have been attached to the osteotomized rib ends across the defect, over the mesh and secured with interrupted wire sutures[4,6,10,18,19] (Figure 28-6).

Bioprosthetic materials such as small intestinal submucosa may be considered for use in thoracic wall reconstruction as an adjunct to or an alternative to synthetic mesh materials. These have been used successfully in humans to reconstruct *en bloc* resections of the thoracic wall.[23,24] Reports of its use in veterinary surgery for thoracic wall reconstruction are lacking. The physiologic properties of these bioprosthetic materials have been shown to be acceptable for soft tissue augmentation and it is reasonable that this would be true for animals as well.[25]

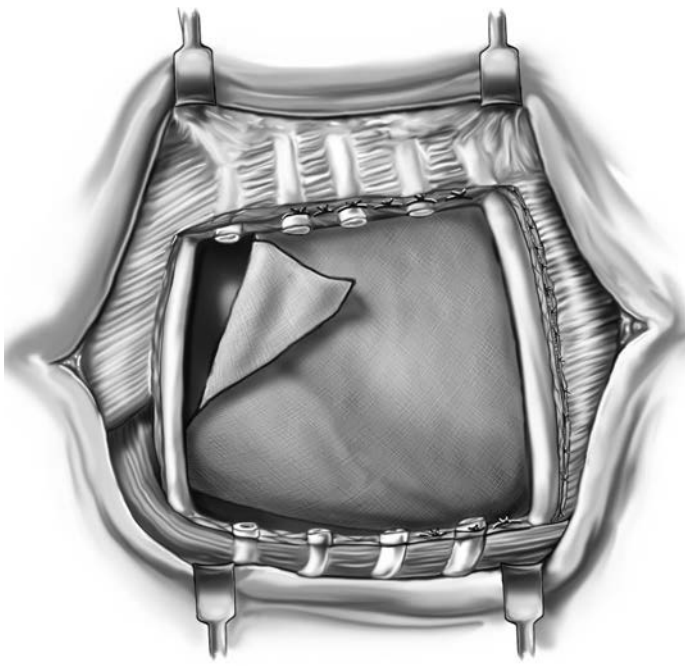

Figure 28-3. Synthetic mesh placement for thoracic wall reconstruction. The caudal edge of the mesh has been folded and sutured in place. The dorsal and ventral edges are likewise folded away from the lung and alternately sutured towards the unsecured edge.

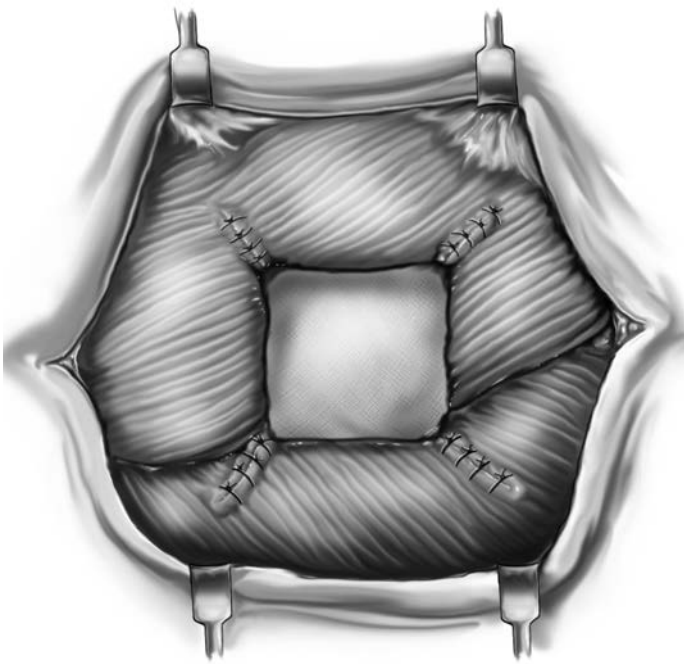

Figure 28-4. Synthetic mesh placement for thoracic wall reconstruction. Thoracic musculature is sutured in a four corner simple interrupted pattern to decrease the size of the thoracic wall defect.

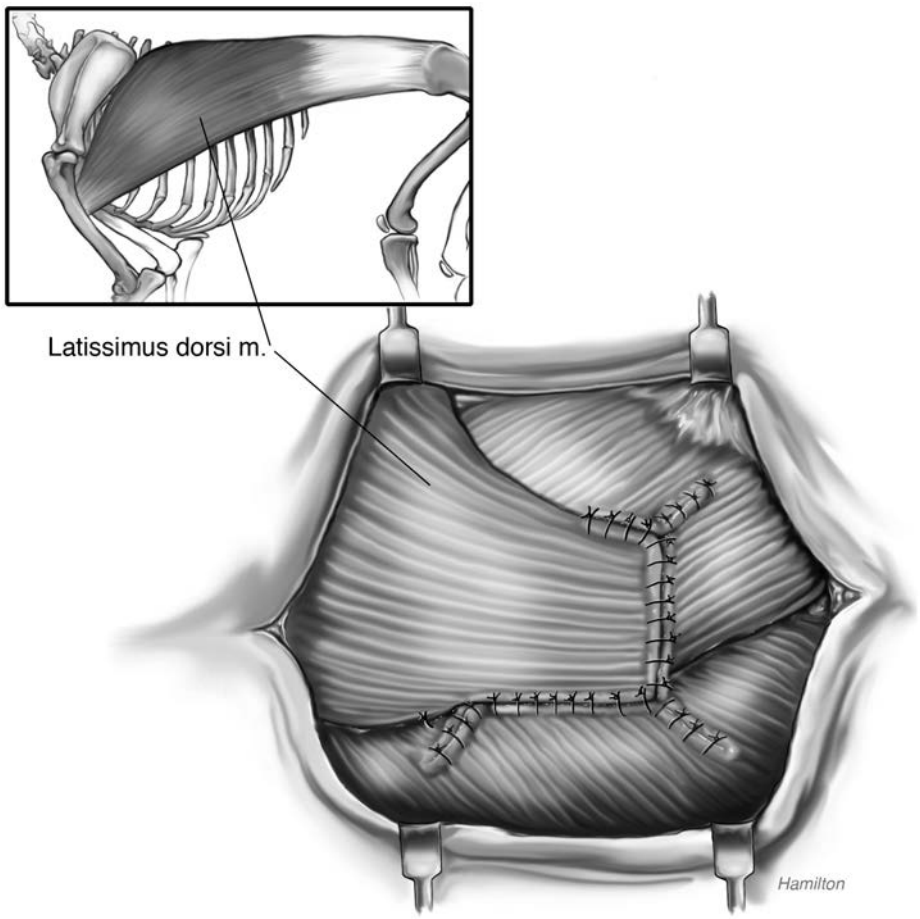

Figure 28-5. Coverage of a thoracic wall defect with a latissimus dorsi flap. The origin of the latissimus dorsi is identified and elevated and rotated to cover the thoracic wall defect and secured.

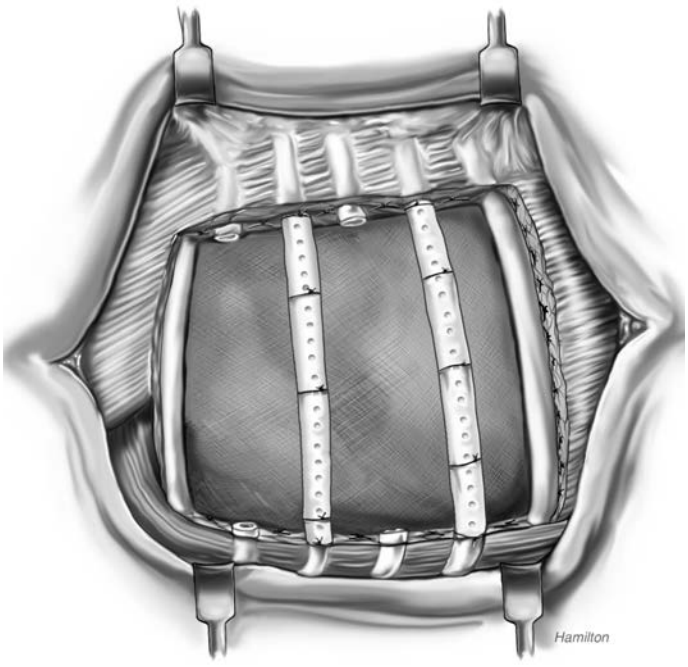

Figure 28-6. Placement of plate struts to stabilize large thoracic wall defects of 4 or more ribs. Plates have been attached to transected rib ends and secured to the underlying mesh.

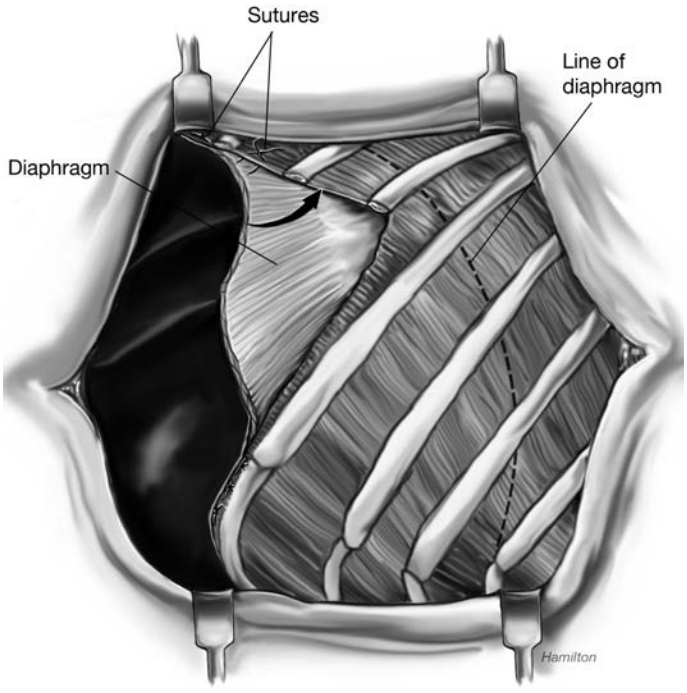

Figure 28-7. Diaphragmatic advancement for caudal thoracic wall reconstruction. The caudal diaphragm attachment is transposed cranially and sutured to the intercostal musculature, osteotomized ribs, and around the remaining caudal rib if necessary.

Diaphragmatic Advancement

If thoracic wall neoplasia involves the caudal ribs, *en bloc* excision is performed as described, however closure of the pleural space can be accomplished by diaphragmatic advancement.[4,5,6,10,26] This technique can be used when reconstruction from the eighth to the thirteenth rib is required.[26] The eighth rib articulates with the sternum and maintains thoracic stability and protection of the thoracic organs. Therefore the diaphragm can be advanced and attached to this rib. Following transection of caudal ribs and costal cartilages the line of diaphragmatic attachment will be exposed. The diaphragm is sutured to the cut edge of the thoracic wall and osteotomized ribs. (Figure 28-7) Cranial transposition of the diaphragm decreases the size of the thoracic cavity and if larger caudal thoracic resections are required for tumor resection, it may be necessary to perform a caudal lung lobectomy.[6]

Management of Flail Chest

Dennis Olsen

Pathophysiology

Flail chest exists when costal support of a section of the thoracic wall has been lost due to segmental (minimum of two) fractures, dorsal and ventral, of at least two adjacent ribs. It is also reported to occur in young animals with only dorsal fractures of adjacent ribs and pliable costal cartilages that cannot resist the interpleural pressure changes that accompany respiration.[1,2] The fractures create a section of thoracic wall that has lost not only structural but functional continuity with adjacent normal thoracic wall. The section "flails" asynchronously with normal motion of the thorax during respiration and is characterized by paradoxic inward displacement during inhalation and outward displacement during exhalation. For many years the clinical signs associated with flail chest were thought to be due, in large part, to the paradoxic movement of the flailing section.[2-8] It was thought that pendulous airflow which occurs between opposite lungs resulted from the loss of thoracic wall integrity (Pendelluft theory).[3,4,7,8] Simply stated, the air in the lung beneath the flail section would flow across to the lung in the opposite hemithorax upon inhalation and then back again during exhalation. This abnormal airflow would result in increased physiologic "dead space" and contribute to decreased vital and functional residual capacities, increased airway resistance, and hypoxemia. The end result was severe respiratory distress attributed to the erratic thoracic wall motion. Therapeutic efforts were primarily

directed at stabilizing the unstable section as soon as possible and this treatment is still recommended by some authors.[5,6,9,10] Consequently, there are many published techniques for thoracic wall stabilization, from procedures that place and maintain traction on ribs in the unstable section with braces or external fixation devices to internal fixation of the fractures in an effort to restore synchronous motion of the thoracic wall.[2,3,5,8-10]

Increased understanding of flail chest pathophysiology has revealed that paradoxic motion may produce a transient, minimum volume of pendulous airflow between lungs as well as mechanical disruption of normal thoracic movement but these problems alone seem to have little effect on ventilation.[2,11,12] These findings have redirected focus from the unstable flail section to underlying pulmonary damage, inflammatory mediators, and pain as the main contributors to respiratory dysfunction.[2-4,7,8,12-16] Pulmonary contusions are often seen in cases of thoracic trauma and are considered the most common accompanying lesion following traumatic incidents that lead to flail chest.[8,14,17-20] Pulmonary contusions are inevitable when trauma is sufficient to result in solitary rib fractures or create a flail chest.[2,3-5,7-10,12,13] The damage seen in the lungs includes rupture of alveoli, blood vessels and capillaries resulting in intraalveolar and interstitial hemorrhage. Pulmonary parenchyma is also damaged and plasma components begin leaking into the tissues and airways.[14] The alveolar damage and vascular leakage leads to obstruction of airways, decreased pulmonary compliance, and arteriovenous shunting, all of which contribute to hypoventilation and hypoxemia. In addition to structural damage, there is release of inflammatory mediators such as arachodonic acid and eicosanoids that adversely affect pulmonary function by acting as chemotactic factors for granulocytes which contribute to local tissue damage through the effects of oxygen radicals.[14,16] Although the role of pulmonary damage is more clearly understood, the dramatic appearance of a flailing chest wall in a dyspneic patient may lead to the less readily apparent pulmonary contusion being overlooked and misdirected therapy to the unstable thoracic wall.

In addition to contusions, the pulmonary parenchyma can be directly damaged by the ends of fractured ribs involved in the flail section.[2,22,23] Direct pulmonary damage can lead to leakage of air into the pleural space (pneumothorax) causing loss of negative pressure and resultant varying degrees of lung atelectasis. Leakage of air can be self-limiting as long as there is not continued pulmonary damage from fractured ribs and a fibrin seal forms over the traumatized parenchyma. Rupture of alveoli and small airways caused by the initial trauma can also lead to pneumothorax with the same negative effects on ventilation. The degree of respiratory insufficiency caused by contusions is compounded when a pneumothorax exists due to the inability of the lungs to expand. Alveolar and small airway rupture can also cause pneumomediastinum that can progress to subcutaneous emphysema as the air migrates through fascial planes at the thoracic inlet. Air can also reach the subcutaneous tissues if the pleura and intercostals muscles are disrupted. Generally, subcutaneous emphysema alone is not deleterious to the patient and therefore not of major concern.[23,24]

Pain is another recognized component in the pathophysiology of respiratory distress that accompanies flail chest.[2,3,7,9,25] Pain contributes to hypoventilation due to patient reluctance to fully expand the thoracic wall, which results in hypoxemia, pulmonary atelectasis, and also in a diminished cough reflex which leads to the accumulation of pulmonary secretions.[3,7,26,27]

Medical Treatment

The dramatic appearance of a flailing section of thoracic wall often motivates the clinician to focus therapeutic efforts on stopping the abnormal thoracic wall motion. However, it is critical to understand that trauma sufficient to cause flail chest has likely produced multisystemic problems, some of which may require more immediate therapy. Emergency triage is essential in order to identify critical abnormalities so primary therapy will focus on stabilization of the traumatized patient. Life threatening injuries are addressed as soon as they are recognized and the familiar "A, B, C" acronym provides a time proven guide for evaluation and treatment priority.

Following stabilization of conditions that are an immediate threat to life such as open pneumothorax with measures such as thoracostomy tube placement, specific therapy directed to the pathologic consequences of flail chest can be initiated. Placing the patient in lateral recumbency with the affected side down will minimize the paradoxic motion of the flail section, which will in turn decrease pain and potential further injury to the lung lobes. Severely effected animals may show hemoptysis or an accumulation of a foamy blood-tinged fluid in the airways, which can lead to airway obstruction. These cases will benefit from immediate endotracheal intubation and airway suction with a catheter placed through the tube into the mainstem bronchi and intermittent aspiration.

It should be assumed that animals with flail chest have pulmonary contusions.[28] Therapy for pulmonary contusions is considered supportive and the degree of therapy depends on the severity of the lesion.[14,28,29] Basic support begins with maintaining and/or improving oxygenation. Oxygen supplementation through an oxygen cage, hood, or nasal cannula can be used to maintain arterial oxygen saturation (SpO_2) above 92% and partial pressure of arterial oxygen (PaO_2) above 60 mm Hg.[14,28] Continued leaking of plasma components, interstitial fluid, and increasing edema can contribute to clinical deterioration and this must be closely monitored. If hypoxemia worsens as evidenced by a falling SpO_2 or a PaO_2 that is not responsive to O_2 supplementation then positive pressure ventilation may be necessary. Positive pressure ventilation provides oxygen and is effective in treating hypoxemia caused by atelectasis, pain, and blood within the airways. A progressive decrease in peak inspiratory pressure required for patient stabilization has been shown to be a sign of improving pulmonary function.[30] Positive pressure ventilation has several other advantages for the flail chest patient. It stops paradoxic motion of the flail section, decreases pain, and allows better apposition of the fractured ribs. Unfortunately, long term maintenance of a veterinary patient on positive pressure ventilation is difficult and not without complications.[14,31] Ventilatory support should also include frequent positional changes to

minimize lung lobe atelectasis. If the patient's condition permits then intermittent standing episodes or short walks can improve thoracic expansion.[14,28,31]

Pain management is an important aspect of medical therapy for flail chest. Pain contributes to reduced ventilatory efforts, which contributes to hypoxia and atelectasis. The cough response is also decreased due to pain and pulmonary secretions accumulate contributing to airway obstruction and potentially to bacterial infection. Proper pain management has become one of the major components of medical management and has been shown to improve ventilatory efforts, which decreases atelectasis, improves blood oxygen content, and enhances the ability to cough. The method of pain control selected is important and can effect patient ventilation. Some opioid analgesics are known to depress respiration and are potent antitussives. Because achieving a balance between these potentially harmful effects and effective pain control is difficult to achieve, alternative methods of pain control are available.[14] Intercostal nerve blocks using long acting local anesthetic agents such as bupivacaine hydrochloride (Marcaine, Abbott) have been shown to be effective in controlling pain and improving ventilation.[3,14,28,32] Nerve blocks are performed by injecting the local anesthetic caudal to all fractured ribs and one rib cranial and caudal to the flail section without entering the pleural space. Some authors advocate blocking the nerves dorsal to the fractures while others suggest both dorsal and ventral to the fractures[28,33] (Figure 28-8). A small gauge needle (25 to 27 g) is carefully "walked" off the caudal margin of the rib where 0.25 to 0.5 cc of the anesthetic is to be deposited (Figure 28-9). When bupivacaine hydrochloride is used the total dose should not exceed 1.5 mg/kg.[28] Gentle aspiration of the syringe will assure that injection will not be into an intercostal vessel. Since local anesthetics block motor nerves as well as sensory nerves it is important not to block excess intercostal nerves as ventilatory capability may be compromised.[28]

Another effective pain control is interpleural instillation of a local anesthetic agent. Research has shown that interpleural bupivacaine can be an effective analgesic in cases of human thoracic trauma as well as post thoracotomy in veterinary patients.[34-36]

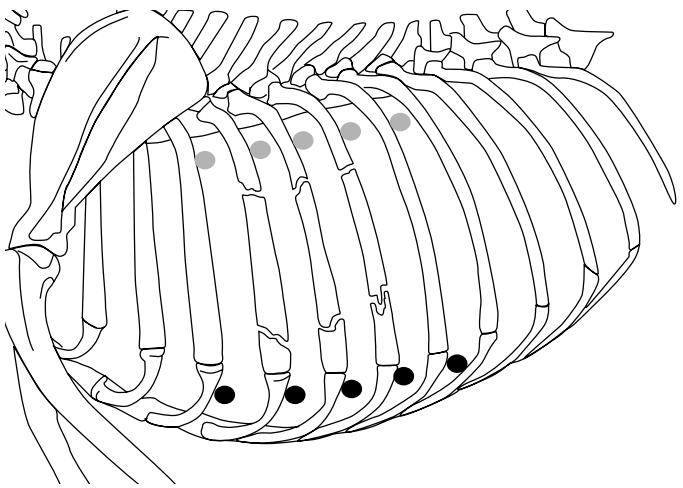

Figure 28-8. Schematic representation of the locations for placement of intercostal nerve blocks for a 3 rib flail section. Grey dots indicate dorsal location while the black dots indicate the optional ventral location.

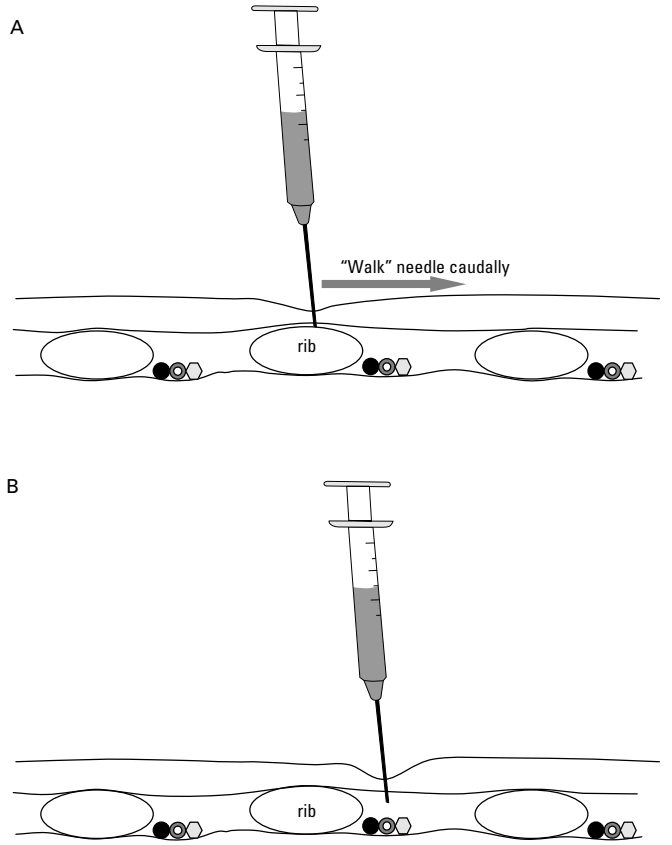

Figure 28-9. Schematic drawing of the technique for instillation of local anesthetic for intercostal nerve block. **A.** locating the rib with the hypodermic needle. **B.** Needle is "walked" off the rib in a caudal direction prior to instillation of the anesthetic.

In cases where a thoracostomy tube has been placed the drug can be instilled through the tube and the patient placed in lateral recumbency with the flail side down. This will allow the parietal pleural surface to be bathed with the local anesthetic. When a thoracostomy tube is not in place, an over the needle catheter can be introduced into the pleural space for drug instillation. Local anesthetics are mildly acidic and cause short term pain on injection. The addition of sodium bicarbonate to the local anesthetic drug increases the pH and decreases the pain on injection. In addition, it is theorized that more of the anesthetic agent molecules are converted to the nonionic form, which increases the rate of penetration and shortens the onset of anesthesia. Unfortunately, a slight increase in the pH of bupivacaine can lead to precipitation and inactivation.[37] To minimize the discomfort of interpleural instillation of bupivicaine, a preliminary dose of alkalinized lidocaine (1 cc 8.4% sodium bicarbonate in 10 cc 1% lidocaine) at 1.5 mg/kg can be instilled followed by the bupivacaine also at 1.5 mg/kg.

Epidural analgesia has also been shown to be an effective pain control method.[14,28,38] Drugs used in epidural analgesia include opioids, local anesthetics, alpha 2 agonists, and nonsteroidal anti-inflammatory drugs.[38,39] Combinations of drugs can be administered to achieve a synergistic action. As previously described, opioids can lead to respiratory depression and reduce the protective cough reflex. When opioids are administered epidurally these potentially detrimental side effects are diminished and if seen

the opioid can be easily reversed.[14] The site for epidural administration of analgesics is the lumbosacral space. The landmarks for locating the space are the ilial wings and the dorsal spinous process of L7. The site for injection is a depression on the dorsal midline caudal to the L7 dorsal spinous process on an imaginary line between the iliac crests. Once located, the area is clipped and prepared aseptically and an appropriate spinal needle is used to penetrate the skin, subcutaneous tissues, supraspinous and interspinous ligaments, and ligamentum flavum. Because the ligamentum flavum offers increased resistance to the passage of the needle a distinct "pop" may be felt indicating entry into the epidural space. Accurate placement can be verified by injecting a small amount of sterile saline or air in a separate syringe and encountering little to no resistance. When there is no resistance, the syringe containing the anesthetic agent is placed on the needle and the drug is injected. For appropriate drugs and doses to administer epidurally an appropriate anesthesia text or formulary should be consulted (See Chapter 9). Complications from epidurals are relatively uncommon and may be related to the drug and amount used.

Fluid therapy is often necessary in the initial management of flail chest cases because patients may be in shock. However, the presence of pulmonary contusions that accompany flail chest can complicate fluid therapy. It is important to maintain adequate tissue perfusion and hydration without contributing to fluid overload and pulmonary edema that could occur with high fluid rates that may be required in cases of shock.[14,22,31,40] The type of fluid, crystalloid (isotonic or hypertonic) or colloid, that should be used is a point of debate and controversy.[14,28,31] There is agreement, however, that regardless of the fluid type, the therapy should maintain cardiac performance and tissue perfusion. This can be accomplished with various fluid types but requires careful monitoring of physiologic parameters such as indicators of perfusion, arterial blood pressure, central venous pressure, urine output, and respiratory function. Therefore, whether delivering isotonic crystalloids for shock (90 ml/kg/hr in dogs, 45 to 50 ml/kg/hr in cats), hypertonic saline (4 to 5 ml/kg) followed by isotonic crystalloids, or hypertonic saline and colloid combinations, the primary aim is to maintain tissue perfusion.[14,41] The use of diuretics to decrease pulmonary edema should only be considered if generalized fluid overload occurs because the increased vascular permeability that often attends pulmonary contusions renders diuretics such as furosemide ineffective.[14,28]

Antibiotics should be administered when cases of flail chest have been caused by penetrating injury such as bite wounds. However, antibiotics are not indicated when pulmonary contusions are the primary concern because of the low incidence of bacterial pneumonia.[14,28,41] Inflammatory mediators released in trauma cases are known to exacerbate clinical signs that can accompany flail chest and one key to minimizing pulmonary injury may be to control the inflammatory cascade. The use of corticosteroids is controversial in that some studies have shown benefit while others suggest no effect or potential adverse consequences. A high dose of methylprednisolone (30 mg/kg) given within a short time of the trauma (~30 minutes) may have benefit but studies do not agree on this point.[3,14,28] Other approaches to mitigate the effects of anti-inflammatory mediators have shown promise in laboratory models and initial clinical trials but there are many that do not.[14,31,42,43] Further research is needed before general recommendations regarding anti-inflammatory therapy can be made.

Surgical Therapy

Therapeutic recommendations in veterinary medicine for many years have largely involved surgical stabilization of the flail segment but it is emphasized that surgery should only be performed when the patient has been clinically stabilized or if there is imminent risk of further trauma to thoracic organs due to motion of the flail section. Because of previous concerns relative to chest wall instability there are many methods described for stabilization.[2,3,5,6,8-10]

If flail chest has resulted in severe tissue disruption, open pneumothorax, or fracture fragments that have, or may lacerate thoracic organs, then open reduction of the fractured ribs and restoration of thoracic wall continuity is indicated as soon as the patient's condition permits. Repair of rib fractures, depending on the size of the patient, can be undertaken with appropriately sized orthopedic pins and wire or plates and screws. In addition to orthopedic repair, it is equally important to re-establish soft tissue integrity such that negative pleural space pressure can be restored. Repair of soft tissues when one intercostal space has been disrupted can be accomplished in a manner similar to closure of an intercostal thoracotomy following adequate debridement of devitalized tissues.[10] If the soft tissue integrity of multiple intercostal spaces has been disrupted it may be necessary to place a series of staggered overlapping circumcostal sutures incorporating all of the affected ribs and one rib cranial and caudal to the effected section. This creates a "basket weave" pattern and can act as a support for soft tissues mobilized to cover the defect such as the latissimus dorsi or external abdominal oblique muscles or a flap created from the greater omentum.[10] Placement of a thoracostomy tube will facilitate reestablishment of negative interpleural pressure and aid in postoperative management.

The more common methods of flail section stabilization involve the percutaneous placement of sutures that encircle the ribs of the flail section, applying traction with those sutures and attaching them to an external brace that uses the adjacent intact thoracic wall to provide counter traction for stabilization of the flail segment. Prior intercostal nerve blocks with long acting local anesthesia will facilitate placement of the external brace. One such method utilizes heat sensitive plastic or fiberglass casting material that has been molded to fit the thoracic wall over the area of the flail section. It is important that the prosthetic material extend beyond the borders of the flail section so that it rests across non-fractured ribs. Once molded and set, two holes are placed through the material in locations that will correspond to each fractured rib in the flail section. It is important to place holes sufficient for passage of two sutures per fractured rib, dorsally and ventrally positioned. This will prevent pivoting of the ribs that may occur with only one point of fixation.[3,33] The area for suture placement should be prepared aseptically and monofilament non-absorbable sutures should be passed around

each rib, dorsally and ventrally, so that the suture ends can be passed through the holes placed through the bracing material. In order to avoid interference of the brace with proper suture placement it is important to preplace all of the sutures prior to securing the brace. When passing the suture it is prudent that as the needle passes around the rib it remains immediately adjacent to the bone especially along the caudal and medial borders. This will minimize the potential of encircling the neurovascular bundle caudally and lacerating pulmonary parenchyma (Figure 28-10). It has been reported that placement of circumcostal sutures does not usually damage the underlying lung because the existing pneumothorax results in a gap between the visceral and parietal pleura, caution should none-the-less be exercised during placement.[2] After suture placement, light padding can be interposed between the thoracic wall and the bracing material. The suture ends are passed medial to lateral through the holes in the brace and secured (Figure 28-11). A light thoracic bandage can then be placed to help secure and protect the brace. The brace should be left in place for 3 to 4 weeks to allow for soft tissue healing and callus formation around the fractured ribs. The bandage should be checked on a periodic basis to assure proper position and evaluate the skin under the edges of the brace. If cutaneous lesions become evident, the padding may need to be increased around the edges of the brace.

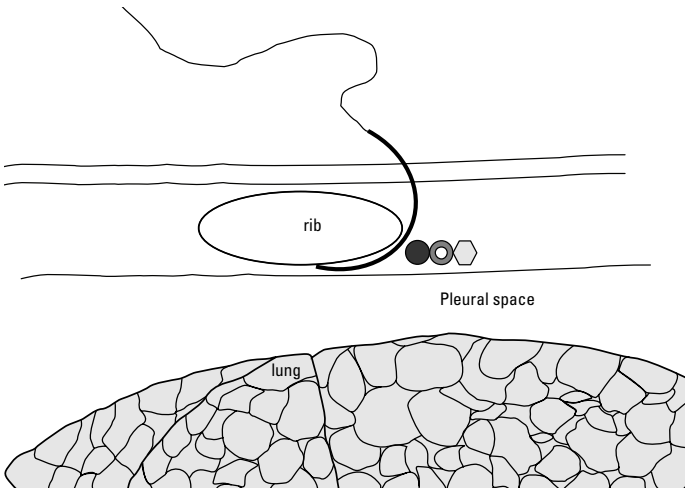

Figure 28-10. Schematic drawing of the technique for passing suture around the rib. The needle should stay adjacent to the bone to avoid the neurovascular bundle and underlying lung.

An alternative method of thoracic wall stabilization creates an external brace that is also effective at controlling abnormal motion. This method utilizes one suture passed around the midpoint of each rib in the flail section as previously described. The suture is then tied around a tongue depressor such that the long axis of the depressor lies vertically over the rib. At this point rigid counter braces, such as additional tongue depressors, are placed at the dorsal and ventral extents of the tongue depressors attached to each rib. The counter braces must rest across stable thoracic wall and are placed beneath and perpendicular (horizontally oriented) to the tongue depressors so that the flail section cannot be drawn inward. Cotton padding is placed between the tongue depressor ends and the counter braces to increase traction on the flail section for added stability. This simplified method of stabilization requires materials that are readily available and only requires the placement of one circumcostal suture[2,9] (Figure 28-12). The bracing should be protected from becoming entangled in bedding or being dislodged by covering it with a padded bandage. The brace is left in place for 3 to 4 weeks to allow osseous callus formation and soft tissue healing.

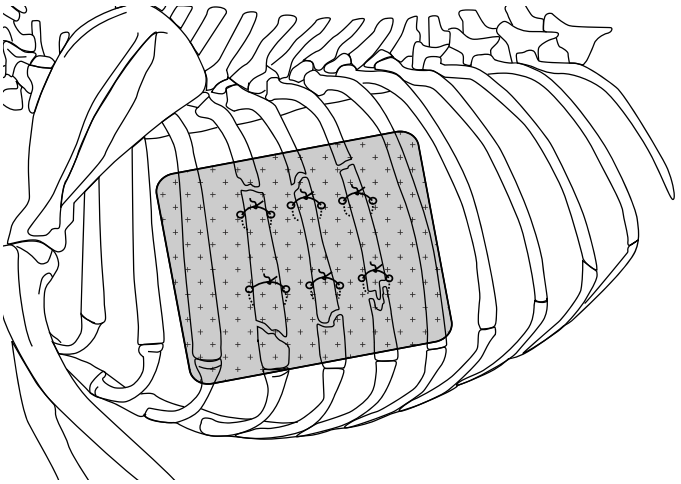

Figure 28-11. Schematic drawing of an external moldable splint for stabilization of a flail section. Two circumcostal sutures are pre-placed at the dorsal and ventral extents of each rib of the flail section and then secured to the moldable splint through appropriately placed perforations. The splint extends beyond the flail section to rest on stable thoracic wall.

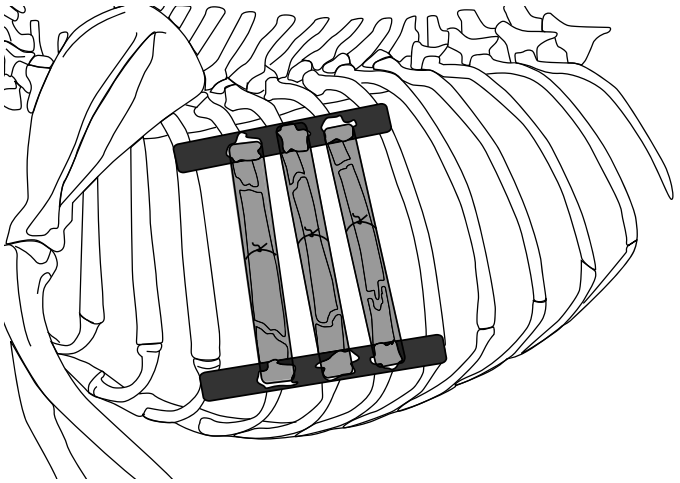

Figure 28-12. Schematic drawing of a simplified bracing of a flail section. One circumcostal suture is placed around the mid portion of each rib in the flail section and then tied around a tongue depressor. Horizontal counter braces are placed beneath the dorsal and ventral extents of the tongue depressors and cotton padding is placed between each depressor and counter brace contact point. Padding is sufficient to result in lateral traction on the flail section create stability.

Urogenital System

Chapter 29

Kidney and Ureter

Nephrectomy

Eberhard Rosin

Nephrectomy may be indicated by the following unilateral conditions: 1) solitary renal cysts causing serious renal dysfunction; 2) hydronephrosis; 3) polycystic disease of the kidney complicated by pyelonephritis refractive to medical treatment; 4) infestation by *Dioctophyma renale* with severe degenerative changes; 5) neoplasms of the kidney if metastasis has not occurred; 6) traumatic destruction of most of the renal parenchyma; 7) avulsion of the renal pedicle or uncontrolled hemorrhage; and 8) abnormal kidney drained by an ectopic ureter. The diagnosis of these conditions and assessment of adequate function of the contralateral kidney are described elsewhere.[1]

Nephrectomy is seldom performed when the architecture and vascular supply of the kidney are normal. In certain chronic pathologic states, the kidney is frequently enlarged and is extensively supplied by neovascularization. The normal renal artery and vein can be present or nonexistent. Surgical technique for nephrectomy in such instances is improvised by the veterinary surgeon and may approximate the dissection required to remove any abdominal mass. The operative technique described in the following paragraphs is based on the removal of a kidney in which the gross anatomic structure is recognizable.

Surgical Technique

The patient is anesthetized and is placed in dorsal recumbency. The abdomen is prepared for an aseptic surgical procedure. A midline abdominal incision is made from the xiphoid process through the umbilicus. The edges of the incision are protected with moist laparotomy pack, and a Balfour retractor is inserted.

The right kidney is exposed by lifting the descending portion of the duodenum and by positioning the other loops of intestine to the left of the mesoduodenum. The left kidney is similarly exposed by using the mesentery of the descending colon as a retractor to displace bowel loops to the right (Figure 29-1). The viscera are covered with moist laparotomy packs.

To mobilize the kidney to be removed, first the peritoneum over the caudal pole of the kidney is grasped with tissue forceps and is incised with scissors. The surgeon inserts a finger into the opening and gently peels the peritoneum from the kidney. Occasionally, the peritoneum adheres firmly to the kidney surface at scattered points; these attachments are severed with scissors. Bleeding generated by this reflection of the peritoneum is controlled by electrocautery. Perirenal fat is reflected from the ventromedial surface of the renal hilus to expose the renal vein and ureter. The ureter is further mobilized by dissection through the retroperitoneum, to permit ligation as close to the urinary bladder as feasible. The ureter is divided between 2-0 absorbable ligatures (Figure 29-2).

The kidney is lifted from its bed and is retracted medially to expose the perirenal fat on the dorsolateral surface of the renal hilus (See Figure 29-2). Reflection of this fat exposes the renal artery. Care must be taken to avoid transection of one or more branches of the renal artery that may be present.

The exposed renal artery and vein are separated and are independently ligated with 3-0 suture material (Figure 29-3). The artery and vein are transected distal to each ligature, and the kidney is removed. A separate suture ligature of 4-0 suture material is passed through the lumen of the renal artery and vein, distal to the first ligature, to transfix the distal ligature and to prevent retraction of the vessel from the ligature (Figure 29-4).

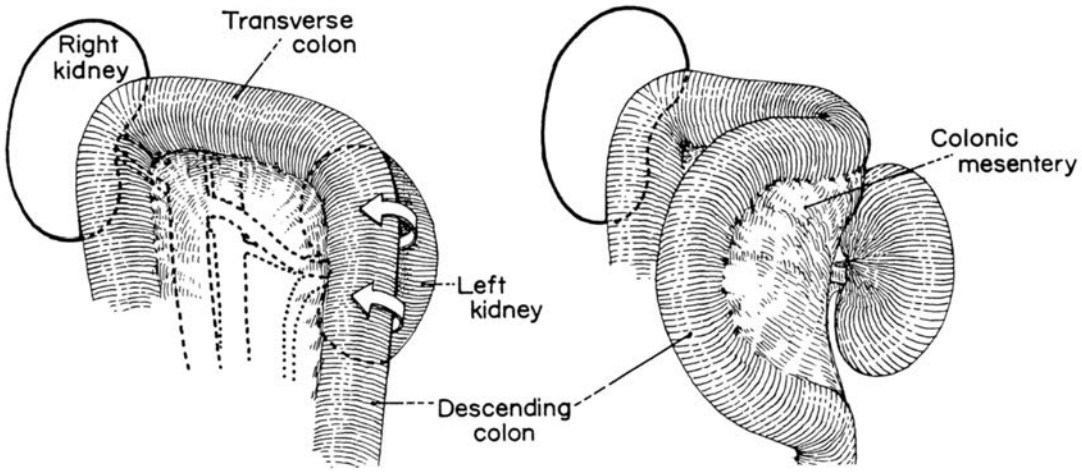

Figure 29-1. The left kidney is exposed by using the mesentery of the descending colon as a retractor for the small intestine.

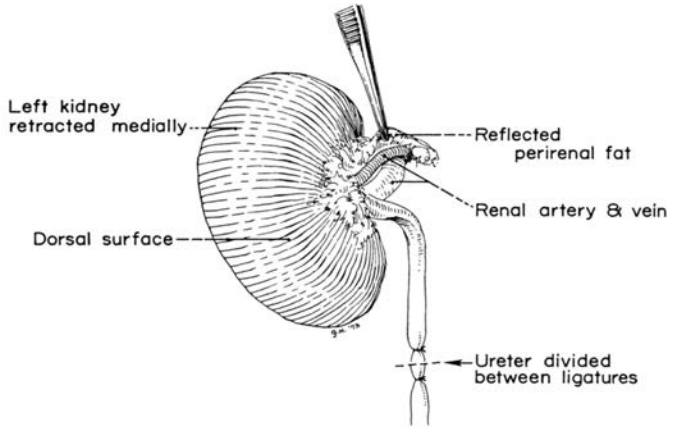

Figure 29-2. Reflection of the perirenal fat on the dorsal lateral surface of the renal hilus exposes the renal artery.

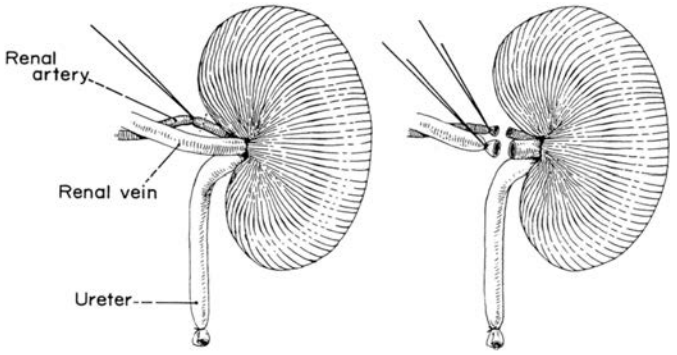

Figure 29-3. The renal artery and vein are separated, ligated individually, and transected.

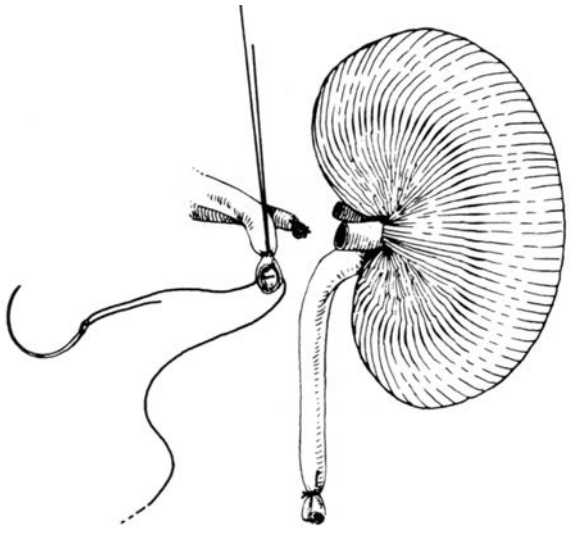

Figure 29-4. A second ligature is passed through the lumen of the renal artery and vein distal to the first ligature.

The intestines are returned to normal position, the greater omentum is repositioned over the small intestine, and the abdomen is closed in a standard manner.

Nephrotomy

Nancy Zimmerman-Pope and Michael King

Surgical Anatomy

Kidneys and ureters lie against the sublumbar muscles of the dorsolateral abdomen within the retroperitoneal space. The cranial pole of the right kidney is nestled in the renal fossa of the caudate liver lobe at the approximate level of the 13th rib (slightly cranial to the left kidney). A thin fibrous capsule envelopes each kidney. Gross appearance of the feline kidney is distinctive due to a radial network of subcapsular veins that course over the surface of the kidney toward the hilus.

The renal artery, vein, and ureter enter the concave surface of the kidney at the hilus (Figure 29-5). The primary renal artery may arborize into several branches after leaving the aorta and before entering the hilus. Arterial branching is present in 5 to 10% of dogs and cats and is most common in the left kidney. Cats may also have multiple renal veins. The left testicular or ovarian vein drains into the left renal vein rather than the caudal vena cava. Care must be taken to preserve these vessels when performing renal surgery in an intact dog or cat. The ureter is a firm tubular structure that exits the caudodorsal surface of each kidney at the hilus and courses in a caudal direction in the retroperitoneal space. The left ureter courses lateral to the aorta, but the right may be dorsal or lateral to the vena cava. In male dogs and cats, the ureter crosses dorsal to the ductus deferens and in the female it courses in the dorsal aspect of the broad ligament.[17] Each ureter traverses the respective right or left lateral ligament

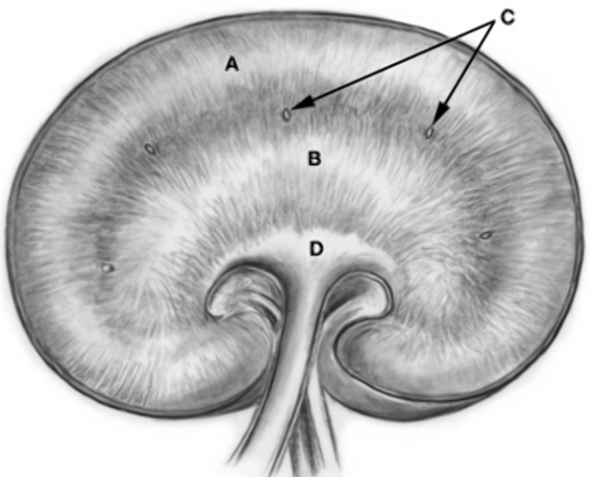

Figure 29-5. The renal cortex *A.* medulla *B.* arcuate vessels *C.* and renal pelvis *D.* are identified. The ureter originates in the renal pelvis. Calculi located in the renal pelvis may cause ureteral obstruction.

of the urinary bladder and enters the bladder on the dorsolateral mucosal surface at the trigone.

Traditional surgical approach to the kidneys and ureters is via a ventral midline celiotomy. The left kidney is exposed by grasping and retracting the colon and associated mesocolon across midline toward the right side (Figure 29-6). The right kidney is similarly exposed by grasping and retracting the duodenum and associated mesoduodenum toward the left side (Figure 29-7). Gentle retraction of the duodenum is recommended to minimize trauma to the pancreas.

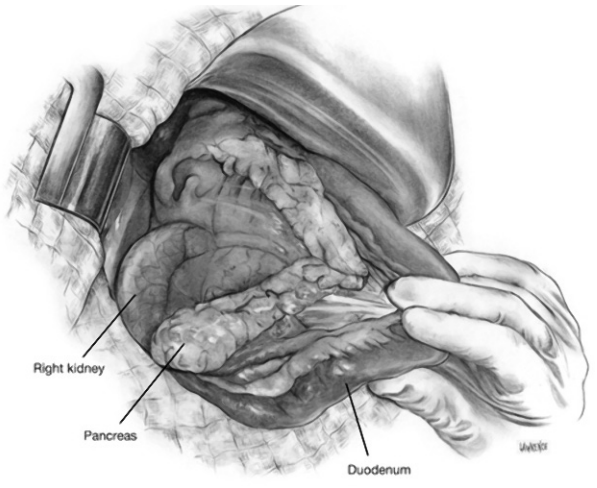

Figure 29-7. Exposure of the right canine kidney from a standard ventral midline approach.

Preoperative Assessment of Renal Function

Kidney function can be estimated from serum blood urea nitrogen (BUN) and creatinine (SCr) levels, but these biochemical markers are relatively insensitive. The BUN and SCr levels should be interpreted concurrently with a urinalysis and urine specific gravity. Urine specific gravity is most accurate when obtained prior to initiation of fluid therapy. Measurement of BUN and SCr levels are the simplest methods of evaluating renal function in the clinical patient however elevation of values beyond the normal range does not occur until severe kidney disease is present (less than 30% functional nephrons remaining). An additional limiting factor is that biochemical markers only provide information regarding total renal function and do not provide specific quantification of individual kidney function. Assessment of individual kidney function is important when trying to determine whether efforts to preserve a kidney via nephrotomy or pyelolithotomy should be considered or if nephrectomy is indicated. Determination of glomerular filtration rate (GFR) is essential in dogs and cats with underlying renal disease to guid specific treatment recommendations and provide prognostic information.

Scintigraphy is a reliable, non-invasive method of assessing total and individual kidney function in the dog and cat. Renal function is determined though measurement of GFR of labeled radioisotopes.[1] Normal total GFR in dogs is greater than 3 ml/min/kg; in cats, normal total GFR is greater than 2 ml/min/kg. Quantitative renal scintigraphy also measures individual kidney function and is sensitive enough to detect changes in function before BUN or SCr increase. Scintigraphic assessment of GFR using 99 m Technetium-diethylenetriaminepentaacetic acid (99 mTc-DTPA) correlates well with other methods of assessing renal function in the dog and cat.[2,3] The use of scintigraphy may be limited by availability and requires isolation of the patient while the radioactive material is cleared and reaches safe levels for human exposure.

Glomerular filtration rate can also be determined using contrast-enhanced computed tomography (CT). Collection of serial CT images of specific regions of interest for the kidneys and aorta permits construction of time attenuation curves that can be used to calculate GFR using graphical analysis. Tomography also provides morphologic information of the kidneys and ureters. CT use is limited by availability and the need for general anesthesia of the patient.[14-15]

Survey radiographs, excretory urography, and ultrasonography are valuable in evaluating renal and ureteral size and architecture. Location and number of urinary calculi may be determined through radiographs or ultrasound. Excretory urography can be used to evaluate the anatomy and patency of the urinary system but is not accurate in quantitative assessment of kidney function. Selection of diagnostics is based on the specific clinical problem and availability of imaging modalities.

Results of preoperative diagnostics may influence the anesthetic protocol, guide surgical planning, and aid in determining prognosis. Dogs and cats with normal renal function that receive appropriate perioperative intravenous fluids usually adjust to temporary changes in cardiovascular function and renal perfusion during anesthesia, however, patients with decreased renal function may not be able to adjust to these changes and could develop serious postoperative complications (i.e. acute renal failure). Fluid therapy should be carefully monitored, especially in cats, to avoid fluid overload. Preoperative assessment of renal function is important to reduce risk of postoperative complications and to provide the most accurate prognosis for expected outcome following surgery.

Other perioperative considerations include administration of fluids, diuretics, or vasopressors to support kidney function and maintain urine output. Intraoperative and postoperative urine output and central venous pressure monitoring should be considered especially in animals with preexisting renal disease. Electrolyte levels, body weight, and hydration status should be closely monitored.[15]

Surgical Technique

Indications for renal surgery include neoplasia, obstructive renal calculi, trauma, persistent renal hemorrhage, chronic inflammation or infection, severe hydronephrosis, renal cystic disease and in some cases, treatment of ectopic ureters.[4] Appropriate preoperative diagnostics and careful assessment of the patient will guide the clinician in formulating an overall treatment plan.

Nephrotomy

Nephrotomy is most commonly performed to remove obstructive or infected calculi but is also indicated to evaluate the renal pelvis for causes of hematuria or chronic infection, or to biopsy tumors. It is important to recognize that not all nephroliths require surgical removal. Nephrotomy or pyelolithotomy for urinary calculi is indicated when there is evidence of urinary obstruction or chronic infection. Historically, bisection nephrotomy was thought to decrease renal function by 20 to 50% in normal dogs however, more recent studies have reported that nephrotomy has no significant adverse effect on renal function in the normal dog or cat.[5-9] The effect of nephrotomy on renal function in patients with kidney disease has not been reported.

To perform nephrotomy, a ventral midline celiotomy is routinely used. A generous incision extending from the xiphoid to a few centimeters caudal to the umbilicus is recommended. Moistened laparotomy sponges are placed over the edges of the abdominal wall and self-retaining Balfour retractors are used to maintain abdominal exposure. The left or right kidney is exposed as previously described. Exposure of either kidney can be maintained or improved by use of laparotomy sponges and malleable retractors held in place by a sterile surgical assistant. Peritoneum overlying the kidney is incised and the kidney is bluntly dissected from peritoneal and fascial attachments. Perihilar fat is carefully dissected to expose the renal artery, vein, and ureter (Figure 29-8). The renal artery is often difficult to visualize since it lies craniodorsal and is intimately associated with the renal vein, however it is generally easily palpated. Careful dissection continues until the renal artery can be isolated. Once the artery is adequately exposed, it is temporarily occluded with either a Rumel tourniquet or a vascular clamp (i.e. Bulldog clamp) placed near the aorta. Successful renal arterial occlusion is confirmed by gross blanching of renal color and palpable softening of the parenchyma. The kidney is grasped gently to stabilize it as an incision is made with a scalpel blade along the convex surface (approximately one-half to two-thirds the length of the convex surface). Blunt and sharp dissection of the renal parenchyma is continued to the pelvis (Figure 29-9). Arcuate vessels located within the parenchyma can be ligated if necessary, but bleeding is usually minimal if all branches of the renal artery have been occluded. Once the renal pelvis is exposed, samples can be collected as indicated for histopathology, culture, and mineral analysis. A 3.5 or 5.0 Fr red rubber catheter can be passed normograde into the proximal ureter and gently flushed with warm sterile saline to confirm ureteral patency (Figure 29-10). Once all samples have been collected and/or calculi removed, the bisected renal parenchyma is held gently but firmly in apposition as the capsule is closed.

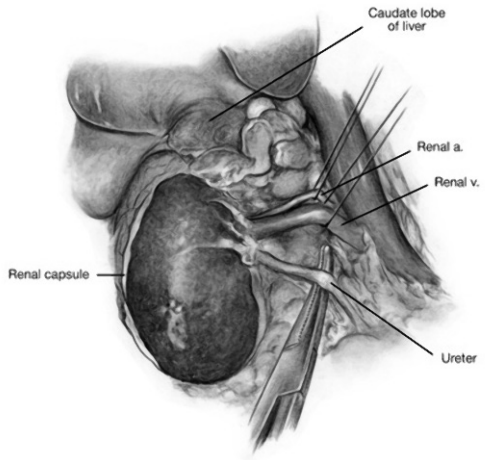

Figure 29-8. Appearance of the right canine kidney in situ, with renal vessels and ureter identified. The peritoneal attachments and renal capsule have been incised to aid in mobilization of the kidney. Isolation of the renal vessels is by blunt dissection.

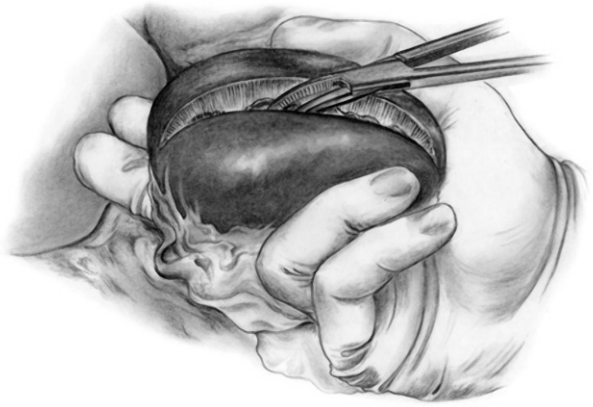

Figure 29-9. The kidney is held to expose the convex surface as an incision is made about 2/3 the length of the kidney. A blunt instrument (i.e. hemostat or scalpel handle) can be utilized to dissect to the level of the renal pelvis.

A simple continuous pattern using 4-0 or 5-0 monofilament absorbable suture on a taper needle is generally effective at providing satisfactory closure and hemostasis. Sutures bites are placed 2-3 mm apart in the fibrous capsule to minimize tension and tearing. Renal cortical tissue is occasionally included in suture placement if the capsule tears or does not hold suture adequately (Figure 29-11). Once the capsule is closed, the vascular occlusion device is removed and normal kidney color and parenchymal consistency promptly return. Total vascular occlusion of the kidney during nephrotomy should not exceed 15 to 20 minutes.[10] If hemorrhage occurs from the sutured incision it can be controlled with direct digital pressure

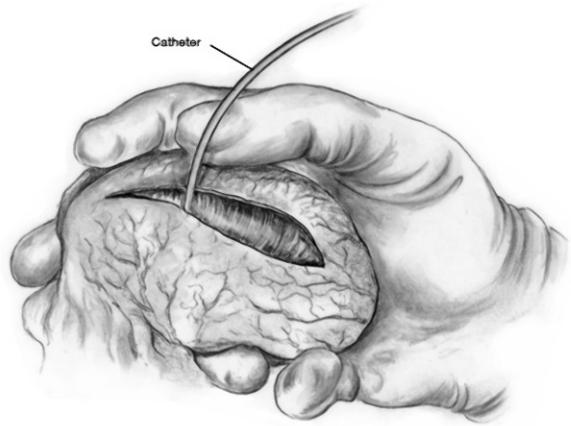

Figure 29-10. The renal pelvis and proximal ureter are catheterized and gently flushed to confirm patency and remove any remaining fragments.

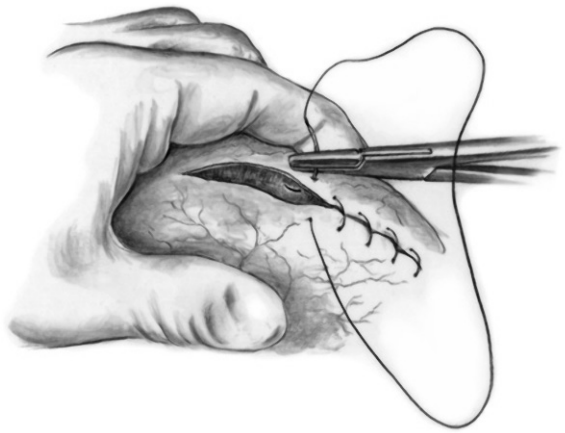

Figure 29-11. A simple continuous suture pattern is used to close the renal capsule incorporating a minimal portion of renal parenchyma if necessary.

or placement of a mattress suture(s) through cortical tissue at the level of hemorrhage. After hemostasis is obtained, the kidney is returned to its normal position and orientation within the abdomen; tacking sutures between each pole of the kidney and the sublumbar musculature may be necessary to prevent kidney rotation that could cause occlusion of the renal vasculature or ureter. Samples should be submitted for culture, histologic examination, and mineral analysis as indicated. The abdomen is lavaged with warm sterile saline and closure is routine. Sponge counts are recommended before abdominal closure to ensure nothing is inadvertently left in the abdomen. If bilateral nephrotomies are necessary, the procedures should be staged at 4 week intervals to lessen the risk of postoperative acute renal failure or decompensation.[12]

Pyelolithotomy

Pyelolithotomy is an alternative to nephrotomy and can be used to remove calculi from the renal pelvis if the proximal ureter is sufficiently dilated. Extracorporeal shock wave lithotripsy may also be considered to treat dogs with small nehroliths (< 1-2 cm).[16] Excretory urography, ultrasonography and scintigraphy can be used to confirm and estimate the severity of obstruction of the renal pelvis or ureter. In cases of ureteral obstruction, placement of a nephrostomy tube or ureteral stenting may be warranted prior to definitve treatment or as adjunctive treatment.[15]

The ureter exits the caudodorsal aspect of the renal hilus and may be obscured by overlying vessels and preihilar fat. Adequate exposure is generally obtained from the ventral surface of the hilus, but if necessary, the kidney can be elevated from the peritoneal attachments and rotated medially to expose the dorsal surface. Vascular occlusion of the kidney is not necessary during pyelolithotomy. The ureter is isolated by blunt dissection and a longitudinal incision is made over the renal pelvis extending along the proximal ureter. An 11-blade and iris scissors may facilitate pyelolithotomy; magnification is also extremely helpful, especially when operating cats or small dogs. The length of the ureteral incision should be adequate to allow the calculus to be gently removed without tearing tissues or fragmenting the calculus (Figure 29-12). After removing the calculus, a 3.5 Fr red rubber catheter should be passed proximally into the renal pelvis and distally into the ureter to gently flush any remaining calculi fragments (Figure 29-13). The catheter may be used to temporarily aid the surgeon to visualize ureteral tissue layers as the pyelolithotomy is closed. It is important to appose tissues accurately to avoid stricture or urine leakage at the surgical site. Absorbable monofilament 4-0 or 5-0 suture in a simple continuous pattern is recommended (Figure 29-14). If peritoneal attachments between the kidney and abdominal wall were disrupted during dissection, the kidney should be pexied to the abdominal wall as previously described. Samples should be submitted for histologic examination, calculus analysis, and culture as indicated. Closure of the abdomen is routine.

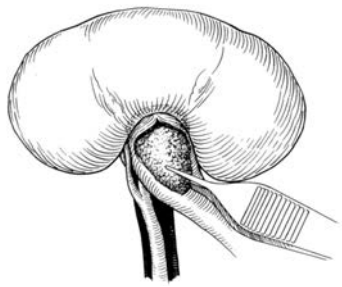

Figure 29-12. Incision in renal pelvis and ureter should be long enough to allow safe and gentle removal of calculi.

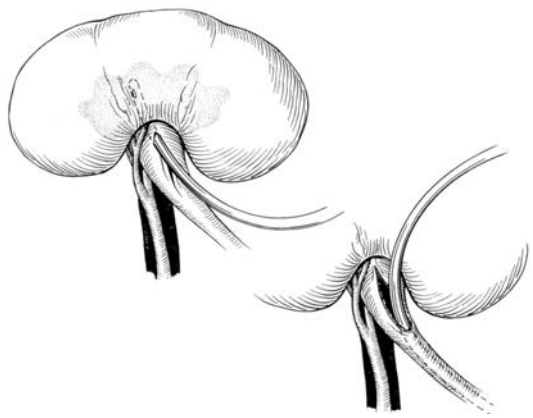

Figure 29-13. A catheter is placed to gently flush any remaining fragments from the renal pelvis and ureter.

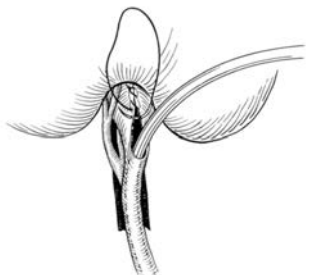

Figure 29-14. The catheter can be used to facilitate closure of the pyelolithotomy.

Nephroliths and Ureteroliths in Cats

S. Kathleen Salisbury

Introduction

The location and composition of uroliths in cats has changed dramatically over the past three decades. Between 1981 and 1999 there was a dramatic increase in the number of upper tract uroliths submitted to the Minnesota Urolith Center.[1] Approximately 75% of upper tract uroliths are composed of calcium oxalate.[1] During this 20-year period there was a 10-fold increase in the frequency of upper tract uroliths in cats at nine veterinary teaching hospitals.[1] A more recent case series of cats treated for ureterolithiasis found that approximately 98% of ureteroliths contain calcium oxalate.[2] Veterinary surgeons are increasingly faced with the challenge of surgical management of upper tract uroliths in cats.

Clinical Signs

Clinical signs of cats with ureteroliths or nephroliths tend to be nonspecific and include anorexia, vomiting, lethargy, and weight loss.[2] Polydipsia and polyuria, stranguria or pollakiuria, hematuria, and inappropriate urination may be seen. Pain may be evident if the ureter becomes acutely obstructed, however, pain appears to be much less common than in humans with ureteroliths. Affected cats may be asymptomatic and the calculi are detected during a work-up for other problems. Many cats with ureteroliths and nephroliths also have chronic kidney disease, therefore, unilateral ureteral obstruction may result in signs of renal failure. Physical examination findings are usually non-specific, but some cats will have small, irregularly shaped kidneys. Acute ureteral obstruction may result in the affected kidney being enlarged, firm, and painful.

Diagnosis and Preoperative Evaluation

Nephroliths and ureteroliths should be suspected in cats with chronic kidney disease, renomegaly, abdominal or lumbar pain, vomiting, or recurrent urinary tract infection. Cats that are presented with vague signs of illness or signs of renal disease should be evaluated for the presence of uroliths by survey abdominal radiographs and abdominal ultrasonography. Most uroliths of the upper urinary tract in cats are radiodense and can be seen on survey radiographs. However, calculi can be quite small and may be obscured by fecal material or other structures. It is common to find that one kidney is small and irregular in contour while the other kidney may be of normal size or enlarged. Ultrasonography is very helpful in confirming the presence of calculi and in assessing the degree of dilation of the renal pelvis and ureter. However, ultrasonography failed to identify ureteroliths in 23% of cats in one report.[2] The combination of abdominal radiographs and ultrasonography is reported to have a sensitivity of 90% for detection of ureteroliths in cats.[2] Excretory urography can be helpful in identifying ureteral obstruction, assessing the degree of dilation of the renal pelvis and ureter, and determining the tortuosity of the ureters

in preparation for surgery. However, many cats with ureteral obstruction do not concentrate the intravenously administered contrast medium adequately to delineate the ureters. In these cats, a percutaneous antegrade pyelogram can be performed. Contrast medium is injected directly into the renal pelvis using ultrasound guidance and radiographs are made of its passage down the ureter.[3,4] The technique also allows a urine sample to be obtained directly from the renal pelvis for bacterial culture.

A complete blood count (CBC), serum chemistry profile, and urinalysis should be performed to evaluate renal function and the cat's general health. A CBC may show a nonregenerative anemia if the cat has chronic renal failure; a leukocytosis and left shift may be present in cats with pyelonephritis. A serum chemistry profile may be normal or may show azotemia, hyperphosphatemia, and hyperkalemia. An idiopathic hypercalcemia is reported to occur in approximately 35% of cats with calcium oxalate uroliths.[5] A urinalysis and urine culture should be performed to determine if there is a urinary tract infection. If surgery is planned, a cross-match or blood typing should be performed in case administration of blood is needed during or after surgery. Compatible whole blood or packed red cells should be available.

Indications for Surgery

Indications for surgical removal of nephroliths and ureteroliths in cats are controversial. In general, nephroliths that are not associated with a urinary tract infection and that are not causing ureteral obstruction do not require surgical removal. However, if a cat with nephroliths has a urinary tract infection that cannot be cleared with appropriate antimicrobial therapy, then surgical removal of the nephroliths is recommended to allow clearance of the bacteria. If a nephrolith is causing complete or partial obstruction of urine flow, removal is indicated. Nephroliths that appear quiescent are generally not removed because the consequences of surgical removal are renal scarring and possible reduced renal function. In addition, it can be quite difficult to locate small nephroliths by nephrotomy or pyelolithotomy. If bilateral nephrotomies are required, the procedures should be staged with the nephrotomies separated by approximately 4 weeks. In general, the kidney that appears to have the most functional capacity should be operated first. Pyelolithotomies can be performed bilaterally at the same surgery.

There are no clear recommendations regarding surgical removal of ureteroliths in cats. Most ureteroliths cause some degree of obstruction of the ureter. Prolonged ureteral obstruction can lead to renal damage and loss of function. If a cat with a ureterolith is treated conservatively to allow the calculus to pass spontaneously, there is a chance of further loss of renal function during the weeks or months that it may take for passage, if passage of the calculus ever occurs. One study showed that resolution of ureteral obstruction occurred in very few cats treated with medical therapy alone.[10] It has not been determined if there is a "safe" waiting time for conservative management of ureteroliths in cats. The overall status of the cat's renal function should be considered in determining whether conservative or surgical therapy will be pursued. Many cats with nephroliths and/or ureteroliths are azotemic and have chronic kidney disease. Assessment of individual kidney function by nuclear scintigraphy is useful in cats with upper urinary calculi however this diagnostic aid is not widely available. If a cat has a ureterolith in one ureter and the other kidney has end-stage renal disease, surgical removal of the ureterolith is recommended to preserve the function of the obstructed kidney. If the cat is very ill due to ureteral obstruction by a ureterolith, it may not be appropriate to wait for the ureterolith to pass. As I have gained experience with ureteral surgery in cats, I have become more aggressive in pursuing surgery sooner rather than later. This is consistent with another report.[10] Aggressive fluid therapy is administered to stabilize the cat while monitoring the cat carefully for fluid overload. If the ureteral obstruction persists, surgical intervention is usually performed in 2-4 days. If bilateral ureterotomies are necessary, they can be performed in the same surgery.

Many cats with ureteroliths have concurrent nephroliths. Following ureterotomy, these cats are at risk for recurrent ureteral obstruction by nephroliths that may pass into the ureter. Because of this, ureterotomy is now generally reserved for cats with a single ureterolith and no nephroliths. Cats with multiple ureteroliths and nephroliths are generally being treated with ureteral stenting or subcutaneous ureteral bypass (SUB) placement.[6] Ureteral stenting results in dilation of the ureter so that urine can pass around and through the stent thus relieving the obstruction and preserving renal function. SUB placement allows urine to be diverted from the renal pelvis to the urinary bladder through a combination of a locking-loop nephrostomy catheter and a locking-loop cystostomy catheter.[6]

Surgical Treatment

Nephroliths

Nephroliths can be removed by either nephrotomy or pyelolithotomy. With either technique, however, it is not always possible to retrieve all the calculi. Nephrotomy should be avoided when possible because it can cause renal scarring and loss of function. Many cats with nephroliths already have reduced renal function and further loss of function should be avoided. Pyelolithotomy is the preferred technique for surgical removal of nephroliths because it does not require interruption of renal blood flow or incision into the renal parenchyma and the resulting loss of function. However, pyelolithotomy cannot be performed unless the renal pelvis is dilated beyond the renal parenchyma. If a kidney is severely hydronephrotic and non-functional, nephrectomy and ureterectomy are indicated.

All retrieved nephroliths and ureteroliths should be submitted for quantitative analysis so that appropriate preventative strategies can be implemented. Bacterial culture should also be performed on any calculi that are available.

Nephrotomy

After performing a complete abdominal exploratory, the kidney is packed off from the rest of the abdomen. The peritoneum is incised along the greater curvature of the kidney and the kidney is reflected medially. The renal artery is located on the dorsal

aspect of the renal hilus, the renal vein is ventral and the ureter is caudal. The renal artery is isolated by careful dissection and a bulldog vascular clamp is applied. It is not necessary to occlude the renal vein. The kidney should become soft and dark-colored if the entire arterial supply has been occluded. If the kidney does not become soft, the clamp should be removed and further dissection performed to identify additional branches of the renal artery. After occluding the renal arterial supply, a longitudinal incision is made through the renal capsule along the greater curvature for approximately two-thirds the length of the kidney. The renal parenchyma is separated by pushing the blunt handle of a scalpel through the tissue toward the renal pelvis. Once the renal pelvis is reached, the parenchyma is spread so that calculi in the pelvis can be visualized. Calculi are removed, the diverticula are explored for additional calculi, and the renal pelvis is flushed with saline. The ureter is catheterized and flushed to the bladder if possible to confirm its patency. The edges of the kidney are pressed together and the renal capsule is carefully closed with a simple continuous suture of 4-0 polydioxanone. The vascular clamp is removed from the renal artery and direct pressure is applied to the suture line to control hemorrhage as necessary. The warm ischemia time of the kidney should not exceed 20 minutes.[6] The kidney is tacked in place with a few capsular sutures to the surrounding psoas musculature to prevent the kidney from twisting on its blood supply and causing renal ischemia.

Pyelolithotomy

Magnification is helpful for performing pyelolithotomy in cats. I prefer to use an operating microscope unless the renal pelvis and proximal ureter are extremely dilated. The kidney is reflected medially and the dilated renal pelvis and proximal ureter are exposed by dissecting the perirenal fat away from the ureter at the caudal aspect of the renal hilus. A stay suture of 5-0 to 7-0 suture is placed in the dilated pelvis and a #11 blade is used to make a stab incision into the exposed pelvis. The incision is extended longitudinally with iris scissors. Calculi are retrieved from the renal pelvis and proximal ureter and the renal pelvis is flushed by passing a catheter through the ureteral/pelvic incision and up into the renal pelvis. If possible, the ureter should be flushed distally to the bladder to assure patency, however, this is not always possible due to the small diameter of the normal feline ureter. The pyelolithotomy is closed with full-thickness simple interrupted sutures of 5-0 to 7-0 polyglactin 910 or polydioxanone. The kidney is tacked in place to surrounding psoas musculature with a few capsular sutures.

Ureteroliths

Ureteral calculi can be removed by ureterotomy or partial ureterectomy and ureteroneocystostomy. Both procedures are technically demanding because of the small size of the feline ureter and should be performed using an operating microscope. Surgeons should have experience with microsurgical techniques and microsurgical instrumentation should be used to avoid unnecessary trauma to the ureter. Because of the difficulties associated with ureteral surgery in cats, some surgeons recommend that ureteroliths located in the middle or distal thirds of the ureter be treated by resection of the portion of the ureter from the calculus to the bladder to remove the calculus and reimplantation of the proximal ureter into the urinary bladder. I prefer to perform ureterotomies for all ureteroliths regardless of location. I reserve partial ureterectomy and ureteroneocystostomy for treatment of complications that could occur secondary to ureterotomy, such as ureteral stricture. Abdominal radiographs should be made immediately before surgery to confirm the current location of the calculi.

Ureterotomy

The ureter is examined visually using the preoperative radiographs to help locate the ureterolith. In many cases the calculus can be seen through the wall of the ureter. The ureter can be palpated gently to identify the ureterolith. If the calculus is located in the proximal ureter, care should be taken not to push the calculus back into the renal pelvis. To prevent the calculus from moving retrograde into the renal pelvis, a loop of moistened umbilical tape or a vascular tie can be placed around the most proximal aspect of the ureter immediately distal to the renal pelvis and the ureter can be gently occluded by applying pressure to the vascular tie. After the ureterolith is identified, the peritoneum is incised over the affected area of the ureter and the periureteral fat is dissected to expose the ventral aspect of the ureteral wall. The operating microscope is positioned over the ureter and a stay suture of 8-0 suture material is placed in the ureter at one end of the planned ureterotomy. A #11 blade is used to make a longitudinal incision into the ureter directly over the calculus and the incision is extended with microsurgical dissecting scissors. The calculus is removed and the ureter is flushed proximally and distally (if possible). If the ureter is very dilated, it can be flushed proximally with a 3.5 French tom cat catheter. If the ureter is not very dilated, a 27-gauge intravenous catheter can be used for flushing. It is often difficult to flush the distal segment of the ureter due to its small diameter. Some surgeons confirm patency of the ureter by passing a piece of suture material (size 2 polybutester[7]) down the ureter. I usually try to flush the distal ureter gently and palpate it carefully to be sure there is not another calculus more distally, but I do not usually pass anything down the ureter to avoid further trauma. A swab is taken from the ureter and/or calculus for aerobic bacterial culture and susceptibility testing. The ureterotomy is closed with full-thickness simple interrupted sutures of 8-0 polyglactin 910 with a BV130-4 taper needle (8-0 Coated VICRYL, Ethicon Inc, Somerville, NJ). In some cases the ureter is very thickened and fibrotic and it is difficult to pass the needle of the 8-0 polyglactin 910 through the wall. In those cases, 7-0 polydioxanone on a BV1 taper needle (PDS II, Ethicon Inc, Somerville, NJ) can be used. It is helpful to preplace the last two or three sutures to ensure proper suture placement. The final sutures are then tied. The suture line should be examined carefully under the operating microscope for urine leakage between sutures or through the needle holes. If urine leakage occurs between sutures, additional sutures should be placed. If urine leakage occurs through the needle holes, a small piece of absorbable gelatin sponge (Gelfoam®, Pharmacia and Upjohn Company, Kalamazoo, MI) soaked with the patient's blood can be placed over the suture line. After the ureterotomy is closed, the peritoneum can be closed over the site. However, if closure of the peritoneum compresses the distal ureter so that it causes a partial obstruction, the peritoneum can be left open. If calculi are present in more than one location in the ureter,

multiple ureterotomies can be performed at the same surgery. It is not usually possible to flush or milk calculi to a ureterotomy site that is more than a couple millimeters from the calculus unless the ureter is very dilated.

Partial Ureterectomy and Ureteroneocystostomy

Ureteroliths in the distal two-thirds of the ureter may be managed by resecting the ureter from the site of the calculus to the urinary bladder and then reimplanting the ureter into the bladder.[7] The ureter is ligated and transected proximal to the obstructing ureterolith and at its entry into the urinary bladder and the excised portion is removed with the calculus. The proximal portion of the ureter is implanted into the urinary bladder. Multiple techniques have been attempted for ureteroneocystostomy in cats but the best results occur with an extravesicular mucosal apposition technique (modified Lich Gregoir technique) using simple interrupted sutures.[8] This technique is performed by making a partial thickness incision through the serosa, muscularis, and submucosa of the ventral aspect of the apex of the urinary bladder to expose the mucosa. The distal end of the ureter is spatulated. An incision equal in length to the spatulated ureteral incision is made through the bladder mucosa at the caudal end of the muscularis incision. One suture is placed between the cranial end of the spatulation and the cranial end of the bladder mucosal incision. A second suture is placed between the distal end of the ureter and the caudal end of the mucosal incision. These sutures are placed full-thickness through the ureter and the bladder mucosa and tied. Then a stent of 4-0 polypropylene is placed in the ureteral lumen to aid in the placement of additional sutures. Two simple interrupted sutures are preplaced between the ureter and the bladder mucosa on one side of the stoma and then two similar sutures are preplaced on the other side of the stoma. If the ureter is very dilated, additional sutures may be needed on each side of the stoma. The sutures on one side of the stoma are tied and the polypropylene stent is removed. Then the remaining sutures are tied. The standard description of this technique recommends the use of 8-0 nylon swaged on a BV 130-5 taper needle (Ethicon Inc, Somerville, NJ) for the mucosal sutures. I prefer to use 8-0 polyglactin 910 swaged on a BV 130-4 taper needle (Ethicon Inc, Somerville, NJ) so that nonabsorbable suture material does not remain in the lumen of the urinary tract. After the mucosal sutures are completed, the bladder serosa and muscularis are apposed using simple interrupted sutures of 4-0 polydioxanone or polyglactin 910 to create a water-tight seal. The bladder is checked for leaks by injecting sterile saline into its lumen.

If there is tension on the anastomosis site between the ureter and the bladder, the kidney can be moved caudally (renal descensus) and the urinary bladder can be advanced cranially (psoas cystopexy).[7,9] The kidney is freed from its peritoneal and fascial attachments and moved to a more caudal and medial location taking care not to kink the renal vasculature. The renal capsule and a small amount of parenchyma is sutured to the body wall with 3 or 4 simple interrupted sutures of 4-0 nylon or polypropylene. To perform the cystopexy, the bladder is stretched cranially and the seromuscular layer of the dorsolateral bladder wall is sutured to the iliopsoas muscle with two or three simple interrupted nonabsorbable sutures.

Nephrostomy Tube Placement

Nephrostomy tube placement is indicated as an emergency procedure in cats with acute ureteral obstruction that are severely hyperkalemic and are poor candidates for a long surgical procedure. After instituting intravenous fluid therapy and attempting to lower the serum potassium concentration, the cat is anesthetized for nephrostomy tube placement. Although nephrostomy tubes can be placed percutaneously, it is recommended in cats they be placed via an open approach because feline kidneys are so mobile. A ventral midline celiotomy is performed to allow the kidney to be sutured to the body wall. Four sutures of 4-0 polydioxanone are placed from the greater curvature of the kidney to the dorsolateral body wall. The sutures are placed through the renal capsule and a small amount of renal parenchyma and through the transversus abdominus muscle and tied so that the kidney is secured to the body wall. The four sutures are placed to form a square (sutures are placed cranially, caudally, dorsally, and ventrally) so that the nephrostomy tube can be placed in the center of the square. A 5 French locking-loop pigtail nephrostomy catheter is preferred because it is less likely to become dislodged than a straight catheter.[12] A stab incision is made through the skin over the nephropexy site. Using ultrasound guidance, a 22-gauge intravenous catheter is inserted through the skin incision, body wall and greater curvature of the kidney into the renal pelvis at the site of the nephropexy. When urine backflows through the catheter, the stylette is removed. A urine sample is obtained from the renal pelvis for bacterial culture. At this point a pyelogram can be performed if desired. An angle-tipped hydrophilic 0.018-inch guidewire (Weasel Wire, Infiniti Medical LLC, Malibu, CA) is passed through the catheter and coiled in the renal pelvis. The catheter is removed over the wire. The pigtail nephrostomy catheter (5F Dawson-Meuller locking-loop pigtail catheter, Cook Medical, Bloomington, IN) is passed over the wire through the body wall and renal parenchyma and into the renal pelvis with the hollow cannula inside the pigtail catheter remaining secure to keep the catheter rigid during renal penetration. Once the tip of the pigtail catheter is confirmed to be in the renal pelvis, the cannula is immobilized as the catheter is advanced over the guidewire to form its loop. Once the loop of the pigtail is completely within the renal pelvis, the loop is locked in place by pulling on the string at the hub of the catheter. The string is secured and the cannula is removed from the catheter. The catheter is sutured securely to the skin and body wall with at least two friction sutures of 3-0 nylon. Each suture is tied tightly around the nephrostomy catheter being careful not to occlude the catheter lumen. The suture is then passed through the skin and body wall adjacent to the catheter. It is essential that the friction sutures are secured to the body wall and not just the skin because the mobility of the skin can cause dislodgment of the catheter. Alternatively, a Chinese finger trap suture may be used to secure the nephrostomy catheter. The nephrostomy catheter is attached to a sterile closed urine collection system. Following closure of the abdomen, a body bandage is applied to protect the nephrostomy tube.

If a locking-loop pigtail nephrostomy catheter is not available, a 16-gauge, 8-inch central venous catheter (Arrow International, Inc., Reading, PA) may be used for the nephrostomy tube. Additional side holes can be made near the tip of the catheter

before catheter placement. A nephropexy is performed as previously described.

A small stab incision is made with a #11 blade through the skin at the site of the nephropexy. The intravenous catheter is passed through the stab incision and body wall and then through the greater curvature of the kidney and into the renal pelvis. When urine backflows through the catheter, the catheter is advanced off the stylette into the renal pelvis and the stylette is withdrawn. A guide wire is threaded through the catheter into the renal pelvis and the catheter is withdrawn over the wire. A dilator is passed over the wire and into the renal pelvis. The dilator is withdrawn and the single lumen catheter is threaded onto the guide wire. The catheter is advanced up the guide wire until the distal two centimeters of the catheter (including any side holes) are in the renal pelvis. The guidewire is withdrawn while holding the catheter in place. The catheter is secured in place as previously described.

Once the cat is stable medically, the nephrostomy tube can be used to perform antegrade pyelography to document persistence of the ureteral obstruction. If the ureter remains obstructed, definitive ureteral surgery can be performed. One disadvantage of performing a ureterotomy after a nephrostomy tube has been placed is that the decompressed ureter is less dilated so performing the ureterotomy is more challenging than it would have been during the acute obstruction.

Nephrostomy tubes can be useful in some cats following ureterotomy when there is concern that the ureterotomy site may leak or develop an obstruction due to severe postoperative inflammation. Antegrade pyelography is performed four to six days postoperatively to evaluate the patency and integrity of the ureter. If the ureter is patent and there is no evidence of leakage at the ureterotomy site, the nephrostomy tube is removed. Nephrostomy tubes have also been used to treat ureteral urine leakage that may occur as a complication in the postoperative period. Nephrostomy tubes can become dislodged or obstructed. In addition, they can allow urine leakage from the kidney into the peritoneal cavity or the subcutaneous tissues.[10,12] Nephrostomy tubes that are maintained for several days or weeks can be associated with chronic, antibiotic-resistant urinary tract infections. Because of their potential complications and the increased nursing care required, I prefer not to place nephrostomy tubes unless there is a high likelihood of urine leakage or urethral obstruction postoperatively.

Postoperative Care

Many cats with ureteroliths and nephroliths are anorectic, so a gastrostomy or esophagostomy tube is usually placed at the time of surgery for postoperative nutritional support. Intravenous fluids are administered for three to five days after surgery to promote diuresis. Many affected cats are anemic at the time of surgery and the anemia may worsen postoperatively. If the anemia is moderate to severe, whole blood or packed red cells should be administered. Serum creatinine concentration is measured daily for the first few days after ureterotomy. Although the serum creatinine in some cats decreases immediately after surgery, it is common for it to remain high or even increase during the first couple of days after surgery. This is most likely due to partial ureteral obstruction from swelling at the ureterotomy site. Intravenous fluid therapy is continued and after three to four days the creatinine usually begins to decrease. Fluid therapy is discontinued when the creatinine is within the reference range or has remained stable for several days. Postoperative antibiotic therapy is indicated only if a urinary tract infection is present.

Outcomes and Postoperative Complications

Prevention

Dietary therapy should be based upon quantitative analysis of the calculus. Most nephroliths and ureteroliths in cats are composed of calcium oxalate. There are commercially available diets for prevention of calcium oxalate uroliths. Ideally, a canned diet should be fed so that the cat consumes more water. The urine pH can be monitored. If it remains acidic in spite of the use of a non-acidifying diet, potassium citrate can be administered to alkalinize the urine. The cat should be monitored every three to six months for recurrence of calculi by abdominal radiographs, ultrasonography, urinalysis and urine culture. If the cat has chronic kidney disease, a CBC and serum biochemistries should also be evaluated.

Complications

Postoperative complications are common following surgical removal of ureteral calculi in cats. In a series of 88 cats that survived surgical removal of ureteroliths, 31% developed major postoperative complications and 18% of these cats died.[10] Another report of 47 cats that underwent ureterotomy for urolith removal had a mortality rate of 21%.[13] The most common complications following removal of ureteral calculi are urine leakage and persistent ureteral obstruction. Urine leakage is usually apparent within two to four days. The blood urea nitrogen and serum creatinine concentrations will increase and the cat may show abdominal pain. If uroabdomen does not resolve spontaneously and requires a second surgical procedure, the prognosis is guarded. In the previously cited case series, the mortality rate of cats that underwent a second surgical procedure because of uroabdomen was 27% (3/11).[10] Three cats that developed uroabdomen were euthanized without additional surgery.[10] Partial or complete obstruction of the ureter following ureterotomy may be transient due to swelling at the surgery site. If the cat is becoming progressively more azotemic two to four days following surgery, an excretory urogram or percutaneous antegrade pyelography should be performed to determine if there is urine leakage or ureteral obstruction. Stricture at the ureterotomy site could occur as a long-term complication but this is not detected often.[14] Ureteral stricture can also be present at the time of initial surgery due to chronic ureterolithiasis and ureteral fibrosis. Approximately half of cats that recover from surgical removal of ureteroliths can be expected to have chronic kidney disease and maintain serum creatinine concentrations above the reference range.[10] Recurrence of ureterolithiasis has been reported in 40% of cats in which serial abdominal imaging was performed after medical or surgical management.[10] The second episode of ureterolithiasis occurred a median of 12.5 months (range 2 to 88 months) after the initial diagnosis.[10]

Editors Note: Minimally invasive therapy by interventional radiology has advantages when considering therapy for ureteral obstruction. Consultation with a specialist is recommended.

Extracorporeal Shock-Wave Lithotripsy

India F. Lane

Introduction

Extracorporeal shock-wave lithotripsy (ESWL), in which high amplitude sound waves are generated outside the body and focused on a hard surface to create fissure and fragmentation, has been applied primarily to nephroliths and ureteroliths in dogs and people. In human medicine, adaptation of shock-wave treatment revolutionized the treatment of urolithiasis in the 1980s,[1] and since that time, the addition of endosurgical and percutaneous techniques to ESWL have made open surgery of the urinary tract uncommon. As shock wave lithotripsy and laser lithotripsy have become more available in human medicine, a similar transformation is occurring in veterinary medicine; however, limited availability and cost of these procedures limits the number of patients who can be treated in this fashion. Additionally, variability in lithotriptors makes treatment protocols and responses difficult to compare; effectiveness will vary with machine type as well. Currently, the most common applications of ESWL include the treatment of nephroliths and ureteroliths in dogs, and treatment of ureteroliths in cats. In specific cases, ESWL can be applied to fragment urocystoliths as well.

Methods and Equipment Required

Application of shock-wave lithotripsy requires a source to generate shock waves, a method for focusing the shock waves (SW) to a solitary point, and a method for transmitting (or "coupling") the SW to the patient. Shock waves are generated by electrohydraulic, electromagnetic, or piezoelectrical energy sources. With extracorporeal methods, the shock waves are generated outside the body, then reflected to converge on a target (the urolith) in the patient (Figure 29-15A,B). Like ultrasound waves, shock waves readily travel through fluid or soft tissue until they reach the "hard" acoustic surface of the urolith. Energy reflection, creation of tensile stresses along the surface of the stone, generation of cavitation bubbles, and dynamic fatigue lead to fragmentation with repeated shock waves.[2,3] Early lithotripsy treatments using the Dornier HM3 (Dornier, Marietta,

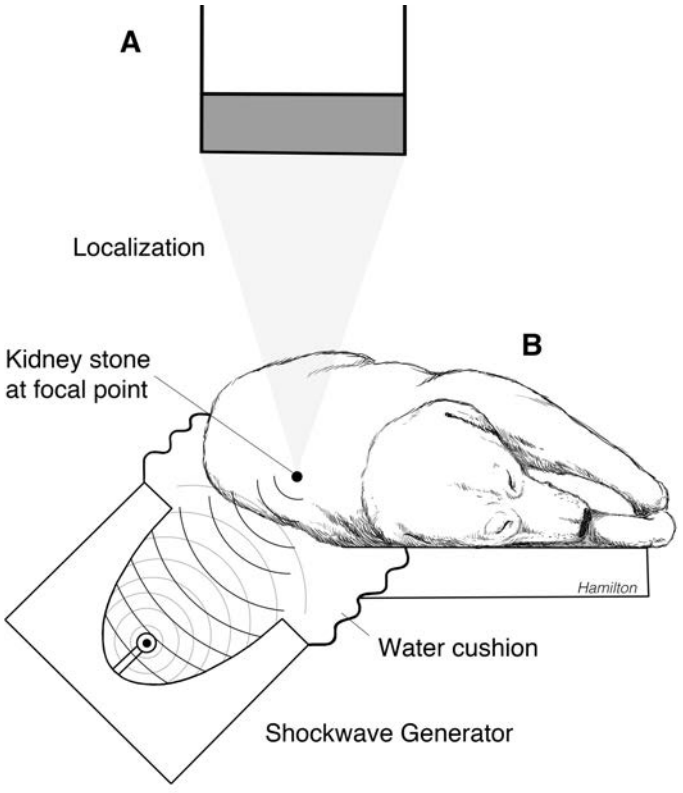

Figure 29-15. A. and **B.** Schematic depicting the extracorporeal shock-wave method. Shockwaves are generated outside the body, then reflected to converge on a target (urolith) in the patient.

GA), relied upon pulsatile sparks created by an electrohydraulic electrode and transmitted through a water bath medium ("wet" lithotripsy).[1,4,5] Newer lithotripters utilize other SW generators and "dry" methods, in which SW are coupled to the patient through a fluid filled cushion.[3,6-9] While these lithotriptors are easier to use and maintain, the efficacy of dry lithotriptors is lower than the "gold standard" water bath model, because of a smaller focal zone and in some cases, lower peak pressure. An advantage of this narrow focal zone is less damage to surrounding tissues; however, re-treatments are more common. The most recently produced lithotriptors are designed to increase portability and flexibility for various urologic procedures, as well as reduce cost of the equipment. Machines with mobile, handheld SW application sources may be useful for reaching uroliths in difficult locations and may allow for non-urologic applications (e.g. orthopedic) to be delivered by the same unit. However, these lithotriptors usually sacrifice efficiency and depth of penetration, which limits their effectiveness for nephroliths in larger human patients. While this would seem inconsequential in small animals, initial experience with the handheld units in dogs and cats suggests that efficiency is indeed sacrificed; a higher number of repetitive shocks and a higher retreatment rate are likely.[10] The cost of equipment varies widely; reconditioned dry ESWL lithotripters require at least a several-hundred-thousand dollar investment.

In general, ESWL treatment includes general anesthesia of the animal, localization of the urolith in the lithotriptor's focal zone, and application of sets of shock waves until sufficient fragmentation is observed on subsequent imaging. Shock-wave dose (power and number of shocks) and frequency varies depending on the patient and the machine settings. Usually, 1400-1500 SW are administered per kidney per treatment. Shock-waves are usually initiated at low power settings, then the power may be increased slowly to the effective level (usually 13 to 18 kV). Although this protocol was primarily created to improve patient comfort and procedure tolerance, it also affects urolith fragmentation by slowly creating small dust-like particles. Fluoroscopic or sonographic imaging is available for monitoring stone fragmentation. In-line sonographic visualization, such as that available with the Storz Modulith SL20 (Figure 29-16), can be very difficult in small animals and has not proven useful in our practice. Radiographic contrast media can be injected intravenously during treatment to enhance visualization of a ureterolith or radiolucent nephrolith; contrast nephropathy is possible, but rare.[11] Regardless of imaging capability, the degree of urolith fragmentation can be difficult to assess during treatment, since fragments may overly each other until they begin to move into the ureter.

Figure 29-16. The Storz Modulith SL 20 Lithotriptor.

Following lithotripsy treatment, a 2 to 4 day period of diuresis is continued to promote passage of stone fragments. Follow up radiographs and ultrasound are generally performed one or two days following treatment and every 3 to 4 weeks thereafter. Urolith passage may be rapid in some animals, or may take several months to completely clear from the urinary tract. Fragmentation has been considered complete in human beings when only clinically insignificant (< 2 mm) fragments remain visible.[13] Based on veterinary experience, even smaller fragments are desired in small animal patients in order to facilitate passage of all debris along the ureter. Small residual fragments also can serve as a nidus for urolith recurrence in stone-forming individuals.[12,13]

ESWL is contraindicated in animals with uncontrolled coagulopathy, hypertension, or other intra-abdominal disease such as chronic pancreatic or hepatic disease. Concurrent pyelonephritis or renal failure, while considered an indication for pursuing treatment of nephroliths, may increase the risk of SW induced renal injury in dogs and cats. I generally perform a more conservative lithotripsy regimen using less energy if measured glomerular filtration is subnormal, even if the animal is nonazotemic. Urinary tract infection should be managed and sterile urine obtained before performing ESWL. While small body size is not a contraindication, a greater percentage of the kidney is exposed to SW injury in patients or species with small kidneys.[14,15] The risk of damage to surrounding tissues, including lungs and bone, is also greater in very small animals.

Lithotripsy for Canine Nephroliths

If removal of nephroliths is indicated (progression in nephrolith growth, persistent urinary tract infection, presence of symptomatic or obstructive disease), lithotripsy is an option for treatment of the most common types of nephroliths in dogs (Table 29-1). Fragmentation of calcium oxalate nephroliths is reasonably effective in this species (Figure 29-17). In several reports, Adams has reported overall success in approximately 85% of dogs treated with the HM-3 lithotriptor.[4,11] We reported a similar overall response after our early experience with a Storz Modulith 20 dry lithotriptor,[16] and have since found fragmentation of canine nephroliths highly variable. Treatment of nephroliths up to 2 or 3 cm in their largest dimension can be treated using this technology; however, smaller nephroliths (< 1.5 cm) are generally more amenable to treatment in our experience.

Struvite nephroliths also can be fragmented by ESWL permitting more rapid elimination or to hasten medical dissolution; we have treated one dog in which all radiographic evidence of a large nephrolith was gone in less than one month. However, medical dissolution of struvite nephroliths is preferred when feasible, particularly for very large stones. Urate, xanthine and cystine

Table 29-1. Referral Considerations regarding ESWL for Canine Uroliths

- Do the uroliths require direct treatment or can they be monitored for progression or movement?
- Are uroliths clearly identifiable on survey radiographs so that they can be located readily during ESWL?
- Are nephroliths less than 1.5-2 cm in their largest diameter?
- Is the overall urolith burden reasonable for ESWL treatment?
- Does the risk posed by the urolith outweigh the risk of potential damage created by ESWL?
- Can the dog tolerate general anesthesia and fluid diuresis?
- Are concurrent problems such as chronic renal failure, hyperadrenocorticim, urinary tract infection and hypertension well controlled?
- Are the clients prepared for the costs and requirements for post-treatment monitoring?
- Is surgical intervention or repeat ESWL treatment readily available for an obstructive fragment?
- Is there a significant advantage of ESWL over surgical or laser lithotripy methods (urocystoliths)?

stones are more resistant to fragmentation. In 5 dogs with urate or xanthine stones, lithotripsy was effective in only 2.[11] For large or refractory uroliths, multiple treatments (separated by at least 4 weeks) may be considered. Ideally a ureteral stent is placed concurrently to facilitate fragment passage and prevent obstruction of the ureter. Transurethral, endoscopic ureteral stent placement may be feasible in some dogs using fluoroscopic guidance.[17] The reported re-treatment rate for nephroliths varies with machines, ranging from 30%[11] to 50%.[16]

Bilateral nephroliths may be treated at the same time or staged, depending on the size of the nephrolith and renal function. Bilateral uroliths can be treated during the same anesthetic episode unless concern about individual renal function dictates staged treatments. Treatment of large stones may also be staged, due to high shock wave dose and anesthetic time needed to create fragmentation. Additionally, large fragments may be expected, leading to the increased likelihood or ureteral obstruction by stone fragmentation post-ESWL.[11]

Potential Complications

Extracorporeal shock-wave lithotripsy, while considered safer than surgical approaches, is not without risk. Potential complications of lithotripsy for nephroliths include pain, the creation of obstructive ureteral fragments, damage to the kidney (parenchymal hemorrhage or subcapsular hematoma), or damage to other organs secondary to shock wave application. Adams (2013) estimates that 10% of ESWL treated dogs have transient ureteral obstruction. Stent placement or additional lithotripsy are indicated to alleviate persistent obstruction.[17a] Transient hematuria, transient or progressive decrease in renal function, retroperitoneal fluid accumulation, ureterectasia, pain, diarrhea and ureteral obstruction by urolith fragments have been observed in dogs.[7,18] I routinely treat with analgesics for 24 hours post treatment, and extend the treatment if fragments are actively moving along the ureter, or if clinical signs of pain are observed. Acute pancreatitis has been described as a consequence of right kidney ESWL treatment in two small (< 5 kg) dogs, with fatal complications in one dog.[19] Pancreatic injury may affect many ESWL treated dogs but clinical pancreatitis is seen in less than 2%.[17a] Fatal arrhythmia, possibly secondary to shock waves, was recently described in one dog treated with the HM-3.[11] We have observed a transient ventricular arrhythmia in one cat during ESWL application. Residual fragments are common, and may provide a nidus for harboring infection or for formation of recurrent uroliths. Complications can be minimized by ensuring the health and suitability of the patient for anesthesia and shock wave treatment, ensuring appropriate shock wave dosage and application, shielding other organs from shock waves during treatment, ensuring adequate diuresis and monitoring post treatment, and providing prompt treatment of obstructive fragments.

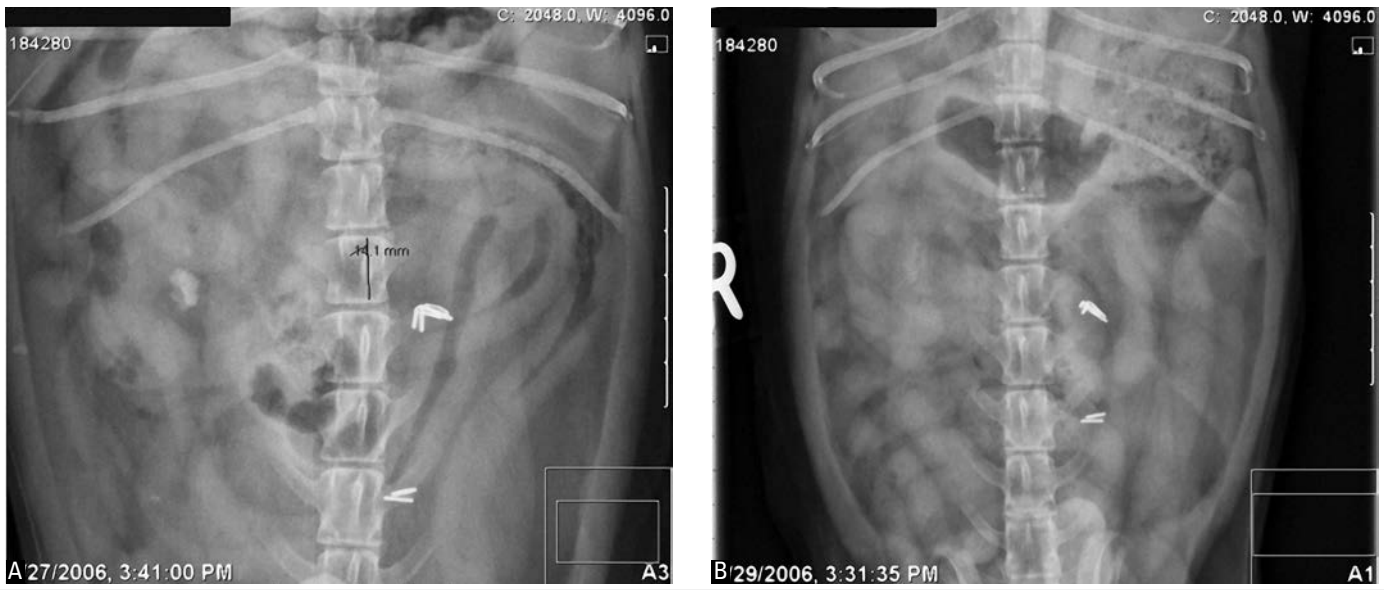

Figure 29-17. A. and **B.** Fragmentation of Calcium Oxalate Nephroliths in a canine patient using lithotripsy.

Lithotripsy (ESWL) for Canine Ureteroliths

Ureteroliths can also be fragmented using ESWL. The method is similar to that for nephroliths, although their treatment can be more difficult for several reasons. Ureteroliths are more difficult to image and focus, are not in contact with as much fluid as stones in the renal pelvis, have less room for fragments to fall away, and may be imbedded in the ureteral wall.[3] A higher shock wave dose may be required to sufficiently fragment ureteroliths. Using an aggressive treatment approach (mean 2600 SW at 14-19 kV) and a lithotripter with a small, high pressure focal zone, we have had very good success (> 90%) in fragmenting ureteroliths in dogs.[6,7] So far, only one ureterolith, lodged in the mid-ureter in a small dog (body weight < 3 kg), was insufficiently fragmented to pass after initial treatment. By comparison, retreatment rates for ureteroliths are approximately 50% using the HM3 lithotriptor.[11] Factors limiting successful fragmentation in human patients, that have led to an increase in ureteroscopic techniques, have included larger stone size (> 10 to 12 mm), distal (pelvic) location,[20,21] degree of obstruction and patient obesity.[20]

The primary complication of ureterolith fragmentation is further ureteral obstruction. Fragmentation or movement of a ureterolith can create a more lodged stone, even if the ureterolith was nonobstructive initially. In our experience, ESWL treatment of ureteroliths can be more painful postoperatively than treatment of nephroliths. Dogs appear to tolerate passage of ureteral fragments well, presumably due to the size and distensibility of the canine ureter. Breakthrough pain is an uncommon finding in ESWL treated dogs, whereas pain can be excruciating during stone passage in people.

Limitations of ESWL for Feline Uroliths

ESWL treatment of uroliths in cats has been limited by disappointing early results. Adams observed significant renal trauma (renal hemorrhage and functional impairment) in a small number of healthy cat kidneys treated with the HM-3, as well as insufficient fragmentation of upper tract uroliths in 5 clinically affected cats.[4] Using the HM-3 lithotriptor, Adams found that ureteroliths could be fragmented successfully in only 1 of 5 cats, and that fragmentation of nephroliths was incomplete. In addition, transient or permanent worsening of renal function occurred in several cats. Based on this experience, cat kidneys have been considered more sensitive to damage from ESWL.

Although promising results were obtained in a small group of healthy cats treated with a dry lithotriptor (no change in sonographic renal structure or function as assessed by renal scintigraphy)[22] fragmentation of nephroliths or ureteroliths to the size needed to pass through the extremely small ureteral lumen still poses a considerable challenge.[10,11] Feline uroliths also are more difficult to fragment *in vitro*,[23] a finding that correlates with clinical experience. Using a research electrohydraulic lithotriptor that simulates the function of the Dornier HM-3, breakage of intact calcium oxalate uroliths retrieved from dogs and cats was evaluated using digital image size.[23] In this study from the Minnesota Urolith Center, significantly less breakage was observed in feline stones than in canine uroliths following the same SW dosage (100 SW at 20 kV).[23] Increased shock-wave dosage (especially shock-wave number, while still limiting power and frequency) may help minimize the size of fragments, but can only be effectively applied to one or two small stones during a treatment session. The number and size of nephroliths (or the finding of multiple, concurrent nephroliths, ureteroliths and cystoliths) makes lithotripsy impractical for stone removal in many cats. Renoprotective agents may help minimize renal injury during aggressive shock wave treatment. Logical protective measures also might include pre-treatment with mannitol or calcium channel blockers.

Lithotripsy for Feline Ureteroliths

Lithotripsy of ureteroliths in cats poses similar, but magnified, challenges when compared to those encountered in dogs. Imaging of very small ureteroliths in cats can be extremely difficult using the available fluoroscopic monitors (Figure 29-18A-C). Distal ureteroliths, in particular, can be obscured by pelvic structures, whereas other small ureteroliths can be difficult to place precisely in the focal zone. Movement of the ureterolith during ESWL appears much more common in cats as well, either with respiration or due to mobility of the ureter or urolith. Frequent repositioning and coordination with ventilation is imperative for effective fragmentation. We have reported progressively improving results in several feline ureteroliths treated with ESWL[6] and have experienced an approximately 50% success rate (complete fragmentation and passage) after one or two treatments. Short term interim complications (retreatment, slow passage of fragments or debris) pose challenges; however most cats have had a favorable long term outcome. Unfortunately, further urinary tract compromise may occur in between treatments if the ureterolith remains obstructive. Surgical intervention is likely to alleviate obstruction more rapidly than lithotripsy in some cats, but is associated with significant morbidity.

Despite good fragmentation of a nephrolith, residual fragments still must be small enough to traverse the feline ureter (internal diameter < 0.4mm). Fluid and diuretic treatment to promote ureteral urine flow, or treatment with agents that may relax ureteral smooth muscle, are strategies that may improve the success of lithotripsy in cats. Based on experience with human beings, alpha antagonist and anti-inflammatory treatment may be the most promising adjunct treatments.[24] Amitriptyline also may relax urinary smooth muscle in cats.[25] Treated cats must be able to tolerate fluid diuresis, and should be screened for occult cardiac disease prior to treatment.

Although the primary risks of ESWL in cats have been viewed as damage to the kidney or worsening obstruction, other complications of ureteral treatments are possible. Ureteral rupture has been observed in one cat in our hospital. Pancreatic or bowel damage is also possible, given the size of the patient. Long-term effects on ureteral function or structure in small animals are currently unknown, but do not appear to be a major concern of ESWL in human patients.

Current Recommendations for Cats

At the current time, ESWL is most suited for treatment of a single (unilateral) obstructive ureterolith separated by some distance

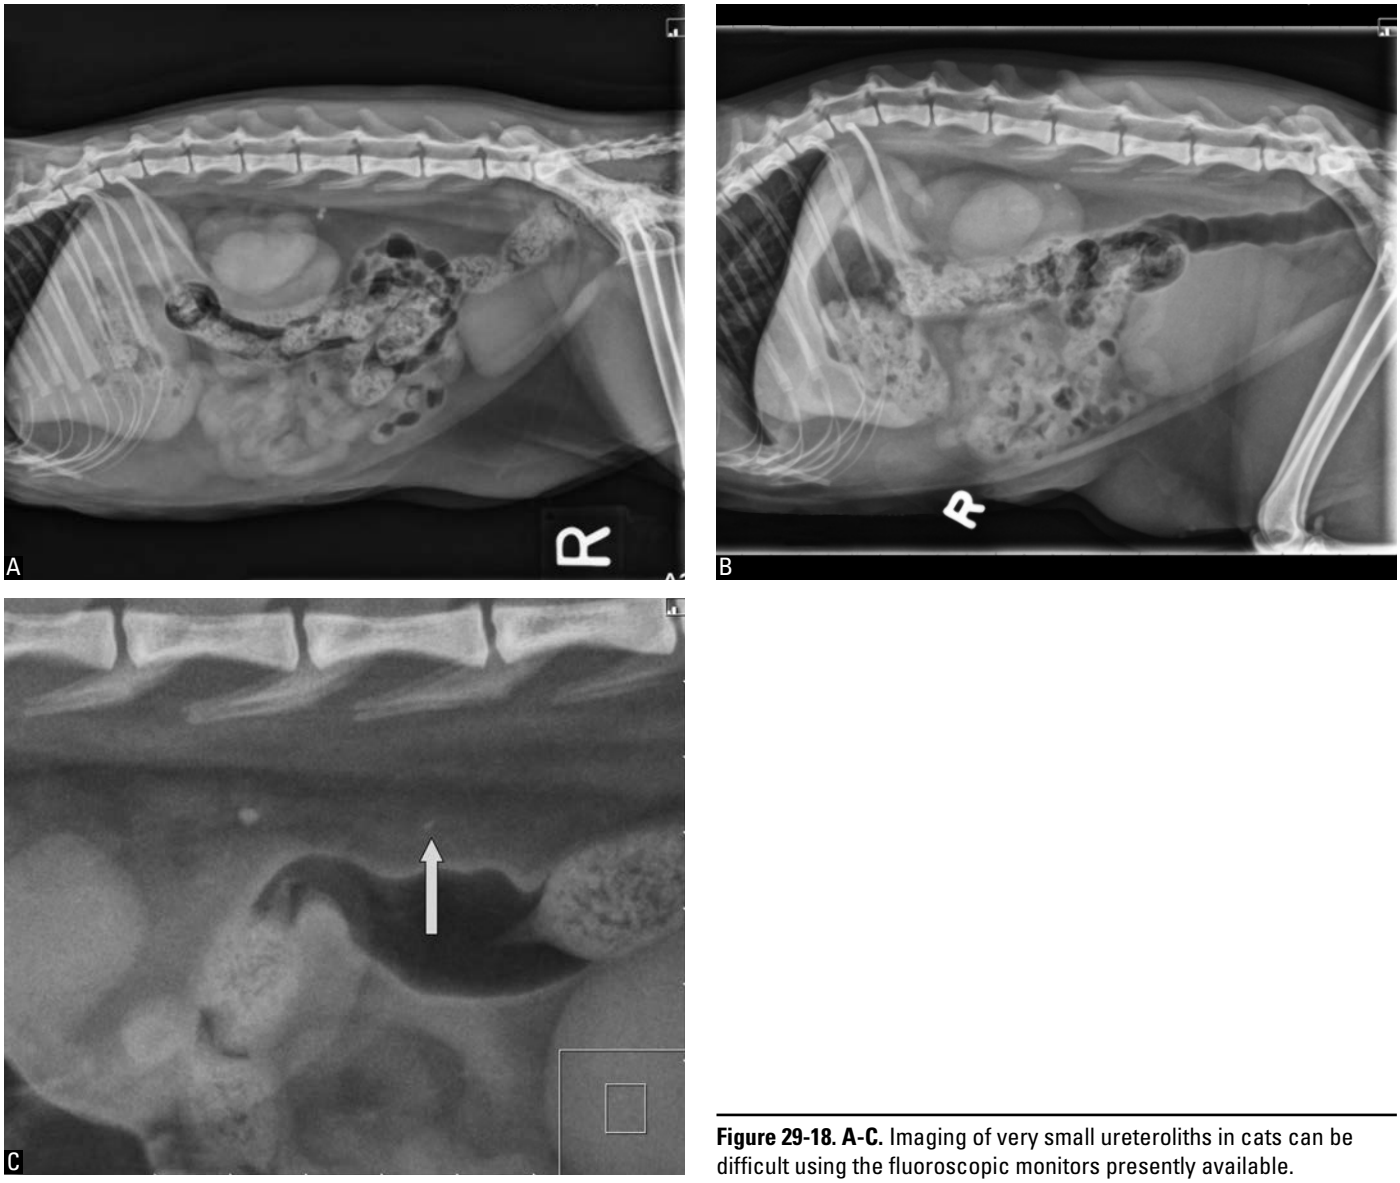

Figure 29-18. A-C. Imaging of very small ureteroliths in cats can be difficult using the fluoroscopic monitors presently available.

from the kidney. At this time, approximately one-half of cats with a single stone will have successful fragmentation of the stone (such that all fragments pass into the lower urinary tract) with one or two lithotripsy treatments. Obstructive nephroliths of small size (< 1 cm) also may be good candidates for ESWL, although the risk of renal injury increases with treatment of nephroliths. Owners of cats referred for lithotripsy should be prepared for multiple treatments, possible worsening of renal function, or progressive ureteral obstruction after ESWL (Table 29-2).[10] Surgical intervention or dialysis support may be necessary if these complications are severe. For these reasons, surgery or ureteral stenting[26] may be a preferred option for metabolically unstable, patients with completely obstructive ureteroliths, where the immediate relief of obstruction is of primary concern. Potential modifications of lithotripsy protocols, including slow rate of energy delivery, lower power regiments, newer lithotriptors, and use of ureteral stents may minimize renal damage in cats.

Lithotripsy for Urocystoliths in Dogs or Cats

Extracorporeal shock wave lithotripsy has not been widely recommended for treatment of bladder stones. Free movement of uroliths within the bladder limits the effect of the carefully targeted, repetitive shock waves, and may result in failure of fragmentation, or larger fragments than desired. In some cases, however, urocystoliths can be fragmented fairly easily. Most commonly, urocystoliths are treated concurrently when nephroliths are treated.[4] Extracorporeal lithotripsy can also be used to reduce the size of cystoliths for medical dissolution, removal by hydropropulsion, or prior to laser lithotripsy.[11] I have been pleased with the ability of the dry lithotriptor to fragment bladder stones for sufficient passage in several female dogs and one cat, but have avoided this treatment in male dogs due to the increased risk of urethral obstruction by small uroliths and stone fragments. Other clinicians have successfully applied the technique to small male dogs and removed the fragments by voiding urohydropropulsion.[11] A higher shock-wave dose may be required to create sufficiently small fragments; at this time it appears that urinary bladder tissue can tolerate this modification. For female dogs and cats, and male dogs large enough to undergo transurethral procedures, intracorporeal laser lithotripsy is preferred for optimal fragmentation of cystoliths.

Table 29-2. Referral Considerations Regarding ESWL for Feline Ureteroliths

- Do the uroliths require direct treatment or can they be monitored for progression or movement?
- Are ureteroliths clearly identifiable on survey radiographs so that they can be located readily during ESWL?
- Can a single stone be identified as the primary obstructive urolith?
- Is the obstructive ureterolith separated from the renal pelvis by 1 or more centimeters?
- Will an immediate benefit result from urolith removal in the patient (i.e., relief of obstruction, removal of infectious nidus, relief of pain)?
- Will a long-term benefit (e.g., protection of renal parenchyma, renal function, ureter) result from urolith removal?
- Does the risk posed by the urolith outweigh the risk of potential damage created by ESWL?
- Can the cat tolerate general anesthesia and fluid diuresis post treatment?
- Is the cat's metabolic condition stable enough to undergo lithotripsy and assess reponse to treatment over days to weeks?
- Are concurrent problems such as chronic renal failure and hypertension well controlled?
- Is surgical intervention or repeat ESWL treatment readily available for an obstructive fragment?

Referral Considerations

The many new options for nonsurgical management of uroliths provide exciting opportunities for case management. Appropriate case selection, however, is critical to the success of the procedure and to client satisfaction. In addition to reviewing guidelines and information available regarding lithotripsy, clinicians should review the many summaries now available in textbooks and journals regarding general management of nephroliths and ureteroliths. Most referral centers providing lithotripsy treatment have prepared handouts or websites summarizing the indications, protocols and costs of therapy. Both referring clinicians and clients should be aware that access to a lithotriptor and availability of trained personnel may limit appointments and create delays in treatment. Facilities with in-house equipment are more likely to be able to accommodate emergency case referrals (ESWL for obstructive ureteroliths, laser lithotripsy for urethroliths). Clients should be prepared for 4 to 7 days of hospitalization for their animal and the possibility of multiple procedures and follow-up examinations over several months. Adequate local follow-up examinations, including high quality sonographic evaluation of the urinary tract, must be available. Repeat treatments, when indicated, are usually performed at 4 to 8 week intervals. Due to the intensity of pre-treatment and post-treatment patient handling, ESWL is not well suited for aggressive animals.

Laser Lithotripsy for Treatment of Canine Urolithiasis

Ellen B. Davidson Domnick

Introduction

Uroliths are a common cause of hematuria, stranguria, and dysuria in dogs.[1,2] Obstructive uroliths, if left untreated, may cause azotemia, recurrent urinary tract infections, loss of kidney function, or death.[1-3] Surgical removal is the traditional treatment for removal of recurrent stones or obstructive stones in veterinary medicine.[2,4-6] Surgery in the carefully selected patient is relatively quick, relieves obstruction, and decreases or reverses loss of glomerular function. However, surgery is invasive and complications, including damage to healthy functioning tissue, perioperative hemorrhage, urethral or ureteral stricture, intra-abdominal adhesions, and urolith recurrence are common.

Nephrotomy may cause a temporary decrease in renal function and nephron loss in those animals with preexisting renal disease. Recurrence of calculi formation, adhesions, and urine leakage may occur after cystotomy.[5,6] Leakage of urine from the kidney, ureter or bladder causes uroperitoneum and metabolic, fluid, electrolyte, and acid-base abnormalities. Incomplete removal of calculi especially from the bladder is not uncommon. Because of the small size and irregular contour of some uroliths, complete removal of all stones can be difficult.[7,8] Flushing the bladder and urethra is not a reliable method to ensure complete removal of all calculi; in one study, uroliths were incompletely removed in 1 of 7 dogs and 1 of 5 cats following cystotomy.[9]

Complications following urethrotomy include hemorrhage, urine leakage, and possible urethral stricture; and is indicated only if obstructive uroliths cannot be hydropropulsed retrograde into the bladder for dissolution or removal.[5,7,10] The urethrotomy site may be closed or left to heal by 2nd intention, in which case hemorrhage occurs for 7 to 10 days. Chronic stricture formation following urethrotomy increases the risk of blockage during voiding of calculi. Other potential complications include scarring of the incision site, tissue irritation, urethrocutaneous fistulae, and diverticula formation. Permanent urethrostomy may be necessary if stricture occurs. Complications of urethrostomy include hemorrhage, recurrent urinary tract infections, and inguinal and scrotal scalding.[5]

Lithotripsy

In human urology, surgical removal of uroliths has been largely replaced by lithotripsy.[1,11] Lithotripsy, the act of breaking or fragmenting stones, uses the generation of shock waves or laser energy to fragment uroliths. There are two forms of lithotripsy that use shock waves to fragment the stone; electrohydraulic shock-wave lithotripsy (EHL) and extracorporeal shock wave lithotripsy (ESWL). All shock waves, when focused, fragment urinary stones by erosion and shattering.[12,13]

EHL uses the generation of sparks in a fluid medium to develop shock waves. The shock wave is generated at the tip of an insulated wire that is placed immediately adjacent to uroliths within the urinary tract. The shock wave passes through the body of a urolith and reflects back from its edge to pass back through the body of the stone. Many 1° and 2° shock waves are created, causing shearing forces that destroy the lattice of the urolith.[11,13] EHL has been used successfully in horses; successful ureteroscopic EHL was performed by perineal urethrostomy in a 3 yr. thoroughbred colt.[14] In an 18-year old thoroughbred gelding, a ballistic shock wave lithotriptor was used to break up an 8 cm. bladder calculus and by flushing out the sand-like residue under epidural anesthesia.[15]

In ESWL, shock waves are generated outside the body and directed or focused toward the urolith. The stone is localized during lithotripsy with ultrasonographic or fluoroscopic guidance. ESWL is standard therapy for renal and upper urinary tract calculi in humans, with over 75 to 90% of stones resolved

with lithotripsy.[12,13] Because of the relative immobility of the renal pelvis, ESWL is most applicable to renoliths that are relatively fixed as shock waves move through them. The relative mobility of the bladder and bladder stones makes ESWL less ideal for treatment of stones in the lower urinary tract.[16] Nephroliths and ureteroliths have been successfully treated in dogs with 1st and 2nd generation lithotriptors.[1,17] Expense, purchase, upkeep, and availability of ESWL have limited its use in small animals.[13,17] (See ESWL by Dr. I. Lane).

Laser lithotripsy, an alternative to other forms of shock wave lithotripsy, effectively eliminates uroliths in humans, horses, ruminants, pigs, and dogs.[18-32] Laser-induced shock wave lithotripsy transforms light energy into acoustic energy (photoacoustic) or thermal (photothermal) energy, depending on pulse duration.[21] The shock wave generated is large enough to fragment uroliths by photoacoustic or photothermal ablation.[21] During lithotripsy, laser energy is transmitted and directed to the urolith surface through a small diameter flexible optical fiber that allows the operator to directly visualize the urolith under endoscopic guidance. The development of fiberoptic cables has greatly increased therapeutic applications of the laser, as fiberoptics allow the laser delivery beam to be brought in contact with the stone.[26] The small fiber size of a laser generally between 300 to 600 microns in diameter (0.3 to 0.6 mm), allows it to be passed through instrument channels in newer generation flexible and rigid endoscopes, and limits retropulsion. Fiberoptics allow the operator to safely, effectively, and accurately deliver laser energy and fragment a stone with little damage to surrounding tissue damage.[31-33] In humans, laser lithotripsy is the 2nd most preferred method for urinary calculi removal after shock wave lithotripsy.[18,34-35]

A pulsed laser that can be delivered through fiberoptic cables is required. Pulsed laser energy is absorbed by water in the urolith, the resulting photothermal effect fragments the urolith, and fragments are actively flushed out with a flushing system attached to the endoscope's biopsy port. Any remaining stone fragments are left to be passed normograde during urination.[31] Because stones can be visualized endoscopically and the fiber is placed directly on the surface of the stone, the stone is consistently fragmented.[18,31] Laser lithotripsy is useful for patients at risk for hypertension or renal dysfunction, is non-invasive, protects renal function, and rapidly resolves clinical signs of obstruction.[26,36]

Lasers used in Lithotripsy

Both the Holmium: Yttrium Aluminum Garnet (Ho:YAG) and pulsed dye lasers can effectively fragment biliary and urinary stones.[22,26,37] but the dye laser energy required for urolith fragmentation may damage the optical fibers and fragmentation efficiency is dependent on urolith composition and color.[19] The pulsed dye laser has a wavelength of 504 nm, which is selectively absorbed by black or brown, the color of many uroliths. This is a disadvantage when treating "pale" uroliths such as cystine, because fragmentation may be ineffective for relatively colorless stones.[38] Pulsed dye laser lithotripsy is effective in fragmenting the most common uroliths of horses, calcium carbonate, and may be performed in standing horses with less surgical invasiveness and trauma to the urinary tract.[27] In male horses urethroliths are accessible at the distal urethra via a perineal urethrotomy or via a transurethroscopic approach. Transendoscopic pulsed dye laser lithotripsy was effective in the treatment of calcium carbonate urolithiasis in 2 adult geldings.[27] The principle disadvantages included cost of the procedure and the time delay required for use of the pulsed dye laser lithotriptor.

Success in fragmenting calcium carbonate uroliths in horses with Ho:YAG has been mixed; successful removal of calculi was reported in 5 horses with a combination of laser lithotripsy, lavage, basket snare removal, and digital manipulation.[39] In another report, the Ho:YAG failed to adequately fragment calculi, and pulsed dye lithotripsy or digital manipulation was necessary to remove the uroliths.[40]

Initial experience in human urology with the Ho:YAG laser has demonstrated its safety and that no excess hemorrhage, renal deterioration or trauma occurs.[25] Reported stone-free rates are 67 to 84% for renal calculi, with complications rates of < 1%.[25] Ho:YAG lithotripsy is effective for ureteral and renal calculi in morbidly obese patients.[26] Additionally, the photothermal effects of the Ho:YAG laser use are minimal; lesions are consistently < 1 mm.[25,26]

Advantages of the Ho:YAG laser for lithotripsy. The Ho:YAG laser is portable and rugged. The Ho:YAG laser precisely cuts with minimal damage to adjacent mucosal tissue. It offers fiber optic delivery, which is ideal for endoscopic use, and can treat tissue in a liquid environment such as the urinary tract. Protective eyewear is available for its infrared wavelength (2100 nm). Its laser wavelength is poorly absorbed in tissue, resulting in minimal damage to the adjacent urethral mucosa.[30-32] Its effect is independent of stone color.[38] Of all lasers, Ho:YAG produces the smallest fragments in all stone types. The reported efficacy of the Ho:YAG laser in fragmenting uroliths is 100% vs. 78 to 89%, for the pulsed dye laser.[38]

Laser Lithotripsy in Veterinary Medicine

The Ho:YAG laser effectively fragments urinary stones independent of composition, water content, or size.[32,41] Pulsed Ho:YAG laser energy fragments canine uroliths *in-vitro* without optical fiber damage. In an initial in vitro study all stones were successfully fragmented in less than 30 seconds.[30] This and other studies have shown that that higher pulse frequencies (10 to 40 Hertz [Hz]) and lower pulse energies ($\leq$ 1 joule[J]) were safer and more efficient for urolith fragmentation using Ho:YAG laser energy.[30,32,42]

In a subsequent in vivo experimental study, laser lithotripsy with the Ho:YAG laser successfully fragmented obstructive uroliths in the urethra of male dogs.[31] Mean time for adequate fragmentation was rapid, 166.7 seconds (range, 47 to 494.5 seconds). Minimal (< 30 mg) or no urolith material was evident within the urethra after lithotripsy. Urinary clinical signs related to lithotripsy resolved without further treatment in all dogs by day 5. Endoscopic evaluation of the urinary tract on day 10 revealed no mucosal lesions, stricture or narrowing of the urethra, or urolith remnants. No dog became obstructed during 30 days of observation.

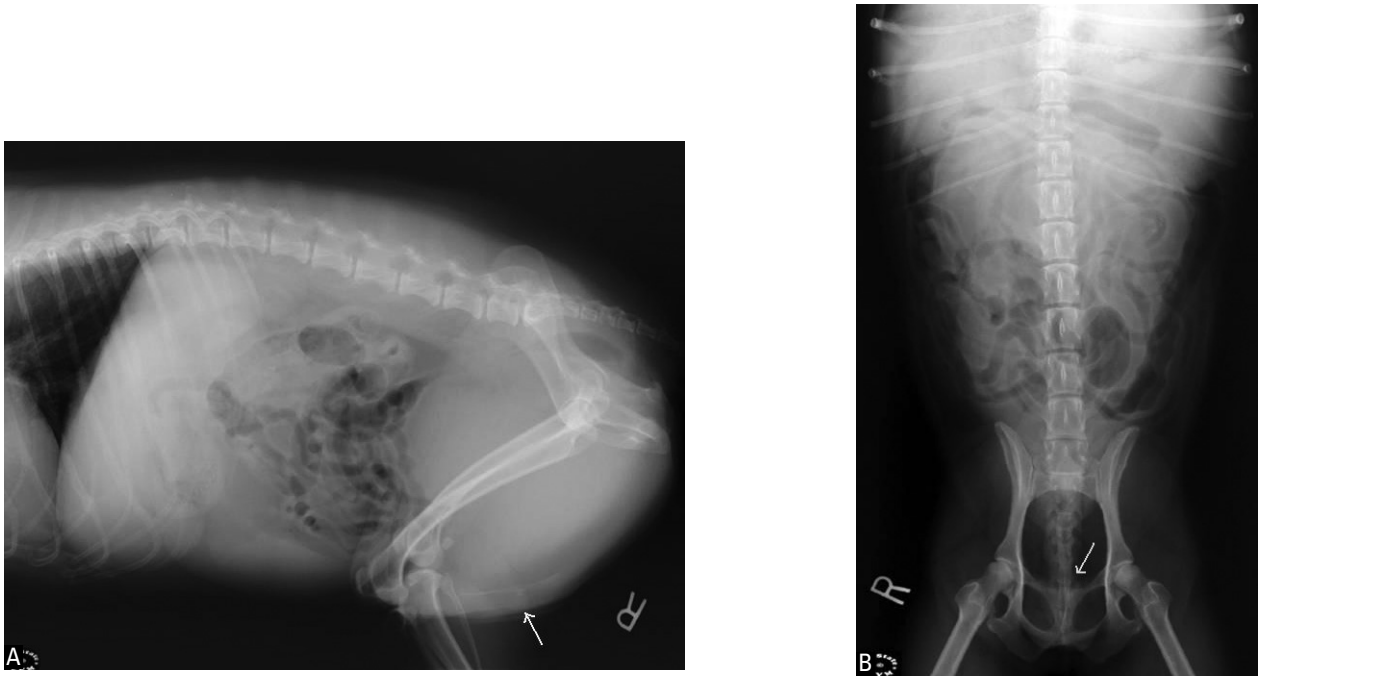

Figure 29-19. A. (lateral) and **B.** (Ventro Dorsal) radiogrpahic views of a dog with obstructive urethrolith formation (arrows).

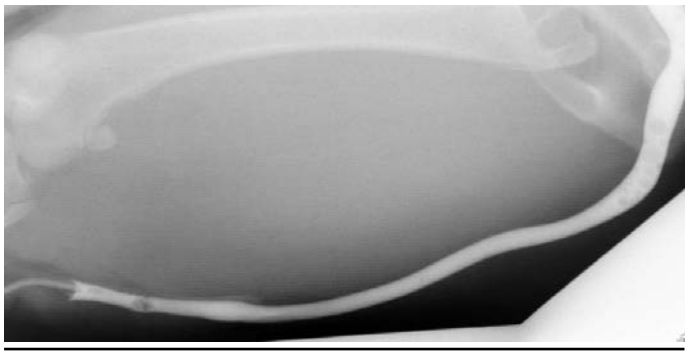

Figure 29-20. Pre-lithotripsy positive contrast cystourethrogram of the dog in Figure 29-19. Filling defect at the region of the os penis is evident. More proximal radiolucent apparent filling defects are air bubbles.

Laser lithotripsy has been performed in male dogs with spontaneously occurring urolithiasis that could not be relieved with catheterization or urohydropropulsion (Figures 29-19 to 29-21). Stone burden ranged from one to seven per dog, and stone types were calcium oxalate or magnesium ammonium phosphate. Both urolith types in this group of dogs were successfully fragmented in less than 130 seconds in all dogs, and no complications from the procedure have been reported to date (Table 29-3). Differences in stone density or composition does not appear to affect the efficiency of laser fragmentation. No recurrence of clinical signs of obstructive urolithiasis or stricture formation has occurred in four dogs; one dog developed recurrent calcium oxalate cystoliths 25 months after lithotripsy which was treated via cystotomy.

Lithotripsy Technique for Urethral Calculi

All dogs with urinary calculi should have complete imaging (radiography and ultrasound) of the entire urinary tract, laboratory analyses including urinalysis and urine culture, and urine function and clotting studies if necessary prior to lithotripsy.

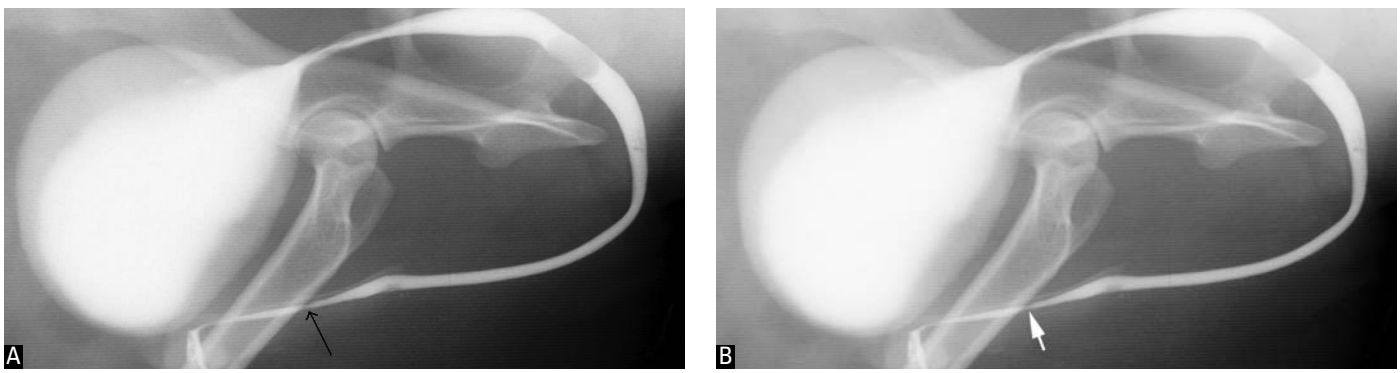

Figure 29-21. A. Post-lithrotripsy positive contrast cystourethrogram of the same dog. No filling defects are evident. There is mild narrowing of the distal urethra at the site where the stone was treated. This is likely due to mild spasming of the urethra from the lithotripsy procedure. **B.** Post. lithrotripsy positive contrast cystourethrogram of the same dog. No filling defects are evident. There is mild narrowing of the distal urethra at the site where the stone was treated (arrow) which is likely due to mild spasming of the urethra from the lithotripsy procedure.

Table 29-3. Results of Dogs undergoing Laser Lithotripsy

Dog	Signalment	Stone analysis	Laser time (seconds)	Laser settings (total energy)	Outcome
1	8.5 kg 9-year old male intact miniature Schnauzer	Stone content of 100% COM; shell of 100% COD	Multiple stones in bladder and at os penis 127.4 sec	637 J	Euthanized 26 months post-lithotripsy for unrelated illness; no recurrences of uroliths
2	3.9 kg, 3-year old male castrated Maltese	Could not collect fragments due to small size	1 stone lodged at os penis 44 sec	220 J	No episodes of dysuria, no urolith recurrence at 25 months
3	12.9 kg, 10 year-old male beagle	90% MAP hexahydrate (struvite) and 10% CPC stone forms	1 stone at os penis 77 sec	385 J	19 months following lithotripsy, the dog is urinating normally, no further evidence of obstructive urolithiasis.
4	11.9 kg, 10-year old male castrated Lhasa Apso	100% COM with a shell content of 20% COM and 80% COD	1 calculus at os penis, several small cystoliths 130.7 sec	653 J	No evidence of urinary tract disease or obstructive uroliths 28 months post-lithotripsy.
5	12 kg, 8 year-old male castrated Schnauzer	15% COM and 85% COD	1 calculus at os penis 9.8 sec	49 J	15 months post-lithotripsy, the RDVM performed cystotomy to remove 2 COM cystic calculi. The dog had been maintained on a diet designed for management of CO urolithiasis.

Key:
COM = calcium oxalate monohydrate
COD = calcium oxalate dihydrate
MAP = magnesium ammonium phosphate
RDVM = referring veterinarian
CPC = calcium phosphate carbonate

A 2.5 mm (7.5 French) (Karl Storz, Inc., Goleta, CA) or 2.8 mm (8.4 French) (Mitsubishi Endoscopy, Irvine, CA) flexible endoscope with an intraluminal channel is passed retrograde through the urethra to the level of the most distal urolith. A 320 um low-OH optical laser fiber (Sunrise Technologies, Fremont, CA) is passed through the operating channel until the aiming beam is visible extending from the tip of the endoscope. The fiber is directed onto the urolith surface and laser energy (sLase210 Ho:YAG laser, New Star Lasers, Auburn, CA) is applied in contact mode to the urolith surface until complete fragmentation occurs. Power settings are 5 Watt (W) power at 15 Hertz (Hz). Experience has shown that the total laser energy applied should be less than 1 J/pulse.[31] Continuous flushing with normal saline (0.9% NaCl) solution delivered through the biopsy/irrigation port of the endoscope is performed during lithotripsy. This provides excellent visualization and allows normograde and retrograde flushing of the stones.

Fragmentation of the stone is considered complete when the fragments are easily flushed out through the urethra and the fragments are visually smaller than the urethral lumen at the level of the obstruction. Urethral obstruction occurs consistently at the level of the proximal or mid-os penis. The urethral mucosa is examined endoscopically before scope removal to determine that there is no immediately discernable gross damage to the mucosa.

In my clinical experience, all canine urolith types fragment consistently independent of composition, but continual readjustment and attention to the aiming beam position on the stone as it fragments is critical. Experience with use of the Ho:YAG laser is important to minimize potential complications including collateral tissue damage from reflected photoacoustic energy and risk of retropulsing a large fragment into the urinary bladder. Continual readjustment and attention to the aiming beam position on the stone as it fragments is critical. Continual flushing of the urethra or bladder to clear debris and fragments, and dilate the urethra during laser lithotripsy is helpful. Even when flushing is performed gently and overfill of the bladder is not permitted, iatrogenic bladder rupture can occur.[43]

Lithotripsy Technique for Cystic Calculi

Despite advances in nutrition and antibiotic treatment, cystic calculi remain a common problem in dogs and cats.[7,8] Approximately 79 to 93% of all urinary calculi in dogs occur in the bladder.[44] Cystic calculi may cause recurrent urinary tract infections and obstruction. Traditionally, stones are removed by cystotomy, but surgical morbidity and cost of surgical removal are concerns especially when stones recur.[5] There is not a widespread useful alternative to surgical removal of calculi in dogs.[4,5] Minimally invasive alternatives, such as laparoscopic

cystotomy have been described, but are available on a limited basis.[45] ESWL has a high rate of residual stone fragments and is used primarily for ablation of ureteroliths or nephroliths because the relative mobility of the urinary bladder decreases its efficiency in fragmenting cystic calculi.[13]

Several recent studies have documented the efficacy of laser lithotripsy for the treatment of urethral and cystic calculi in dogs.[46,47,48] Lithotripsy using this technique is a minimally invasive procedure that appears to be a safe procedure with minimal complications. Depending upon the operator, anesthesia time can be longer than traditional surgical techniques such as cystotomy. Results of all three studies suggest that the use of laser lithotripsy is a safe and effective alternative to surgical removal of cystoliths and urethroliths in dogs (Table 29-3). At this time, laser lithotripsy is most available in academic or referral practices.

A brief description of cystic lithotripsy follows. A contrast urethrocystogram is performed prior to lithotripsy. In males, the dog is placed in dorsal recumbency and the prepuce and ventral abdomen are prepared aseptically. A 2.5 mm (7.5 Fr.) (Karl Storz, Inc., Goleta, CA) or 2.8 mm (8.4 Fr.) (Mitsubishi Endoscopy, Irvine, CA) flexible ureteroscope with an intraluminal channel is passed retrograde through the urethra to the bladder. In females, the dog is placed in dorsal recumbency with the hindquarters placed slightly beyond the edge of the table and elevated slightly. This allows the tail and hind limbs to remain out of the way and puts the dogs at a comfortable angle for the examiner.[49] A rigid 1.9 mm, 2.7 mm, or 4.0 mm cystoscope (Karl Storz Veterinary Endoscopy, Inc, Galeta, CA) is used for dogs < 10 kg, 10 to 20 kg, and 15 to 20 kg and above, respectively. The calculi are visualized and immobilized with an endoscopic basket (Securos endoscopic basket, Boston Scientific Inc., Boston MA) to grasp and immobilize each stone in preparation for fragmentation. Some stones do not need to be mobilized inside the basket; instead, lithotripsy is performed by immobilizing stones between the laser fiber and the bladder wall.

The remainder of the procedure is performed as for urethral lithotripsy. The entire bladder, with particular attention to the mucosa, should be examined endoscopically before scope removal to determine that there is no immediately discernable gross damage or large stone remnants. Random bladder biopsies may be performed after lithotripsy using a 3.5 mm endoscopic biopsy cup (apposing cup biopsy forceps, Karl Storz Veterinary Endoscopy, Goleta, CA).

Post Lithotripsy Recovery

Vital signs (temperature, pulse, respiration, and pain) are monitored routinely and patients generally are permitted water and food within 12 hours of the procedure. Dogs are monitored daily for gross hematuria, stranguria, and poilakiuria. Dogs frequently are poilakiuric initially. Mild to moderate hematuria and poilakiuria, if they occur, generally are self-limiting and resolve within 24 to 48 hours in affected dogs.[31] Similar clinical signs routinely occur in humans after laser or extracorporeal shock wave lithotripsy.[12,13,36,50] Concurrent cystotomies to retrieve bladder uroliths that are not accessible with the laser result in clinical signs of hematuria and stranguria for several days postoperatively.[5] Temporary urethral catheters in dogs are placed if moderate stranguria persists following lithotripsy. Catheterization is unnecessary in most cases, unless urethritis develops. In my experience, stranguria secondary to post-lithotripsy edema is more likely in dogs with chronic, multiple urethroliths.

Pronounced, prolonged stranguria or hematuria may indicate the presence of residual stones or more severe urethral mucosal damage. In those cases, additional imaging such as urethrography/cystography, endoscopic examination and retreatment may be necessary if the dog has evidence of obstructive urolithiasis (acute dysuria).

Remaining urolith fragments that are too small for further fragmentation or that retropulse proximally generally are voided normally within 24 hours.[31] Small (< 30 mg) fragments should pass easily during urination after lithotripsy. Large (> 100 mg) fragments may result in reobstruction from incomplete fragmentation. A fragment that retropulses into the bladder during urethral lithotripsy or is not located during bladder lithotripsy may later move distally and lodge in the urethra at the level of the os penis. In human lithotripsy procedures, intraoperative contrast fluoroscopy is routinely performed to confirm that no large fragments remain.[12] Retropulsion increases as fiber diameter and pulse energy increases therefore small fibers should be used.[50] Alternatively, stones that are fragmented and photomechanically retropulsed into the urinary bladder may be removed laparoscopically.[45] This would avoid laparotomy, but requires an additional procedure.

In dogs with large fragments, repeat lithotripsy to treat recurrent obstruction is an option, but waiting for reobstruction to occur may not be satisfactory and could result in complications from obstructive urolithiasis. Regardless, dogs with clinical signs of reobstruction may have urethral endoscopy and repeat lithotripsy if necessary. The effect of multiple lithotripsy sessions on the lower urinary tract of dogs is unknown. Repeat lithotripsy has not been reported in the veterinary literature. Confirmation of complete fragmentation with post-lithotripsy contrast studies and observation of normal urination is advised.

Histologic mucosal changes following lithotripsy in humans and dogs include temporary erythema, erosion, hemorrhage, or ulceration.[30,31,38,51] Depending upon the location and microscopic character of the lesions, causes include damage from the urolith as it was placed or lodged into the urethra, mechanical damage from the endoscope or grasper as it is directed into the urethra, or damage associated with the fragmentation and flushing of stone fragments.[38] Long-term deleterious effects on the urethral mucosa from repeated laser lithotripsy are unlikely.[52]

Lithotripsy for Treatment of Nephroliths

Surgical morbidity, effect on glomerular filtration rate, and cost of surgical removal of renoliths are important concerns in veterinary surgery.[4,5] To date, there is not a widespread alternative to nephrotomy or pyelolithotomy for removal of nephroliths in dogs. In human urology, surgical removal for renoliths and uteroliths has been superseded by minimally invasive procedures. Options for removal of stones in the renal pelvis include ESWL, percuta-

neous nephrolithotripsy (PCNL), intracorporeal or transureteral endoscopic retrieval, or laser lithotripsy.[12,22,25,26,51]

ESWL is the most common technique for removal of kidney stones in humans, but has a higher rate of resistant residual stone fragments.[25,50] In addition, some stones located in the lower pole of the pelvis are not amenable to ESWL.[47] ESWL has been reported on a limited basis in veterinary medicine and is available at some referral practices.[1,13,17] Future advancements in ESWL therapy in veterinary medicine may occur as lithotriptors become more available.

PCNL In humans, allows a minimally invasive approach to the renal pelvis and renolith fragmentation with fluoroscopic or ultrasound guidance.[54] Renoliths larger than 3 cm in diameter, staghorn-shaped stones, calcium oxalate monohydrate stones, and cystine stones that are relatively resistant to ESWL are indications for PCNL.[26,38] Prior to lithotripsy, a percutaneous pyelogram may be performed to locate the exact stone position and size. The intrarenal collecting system is accessed through a percutaneous nephrostomy tract. In this procedure, a hollow needle is passed into the renal pelvis under fluoroscopic or ultrasonographic visualization. A flexible guide wire is then passed through the hollow needle and manipulated through the ureter. The nephrostomy tract is formed by dilating the skin abdominal wall muscles, and renal tissues using progressively larger plastic dilators or a balloon catheter. After the tract has been adequately dilated, a hollow plastic sheath is placed into the tract into the renal pelvis. A rigid or flexible endoscope is passed into the pelvis and/or proximal ureter. Stones are retrieved with an endoscopic basket if very small. If they are larger, a Ho:YAG laser fiber is placed into the central operating channel of the endoscope and lithotripsy is performed. Laser energy delivered to the surface of the stone creates photothermal energy that reduces the stone to tiny fragments, the majority of which are washed out with the irrigant.[21,51] The cutaneous tract is left to heal by second intention.

Initial experience in humans with the Ho:YAG laser has demonstrated its safety. There is no evidence of decreased renal function after Ho:YAG lithotripsy.[25] In a study of 25 pediatric patients, only one had significant decrease in glomerular filtration rate (GFR) following Ho:YAG PCNL.[22] Additionally, only one of 18 patients in a retrospective study had decreased GFR > 20% (the threshold for significant decrease). There was no correlation between GFR and stone size, stone location, or energy.[47]

Reported stone free rates are 67 to 84% for renal calculi, with complications rates of < 1%.25 Ho:YAG lithotripsy is effective for ureteral and renal calculi in morbidly obese patients who are not candidates for ESWL. Additionally, the photothermal effects of the Ho: YAG laser are minimal; lesions were consistently less than one mm.[25] In the future, laser lithotripsy with PCNL may offer a non-invasive, cost-effective, rapid treatment option for dogs with nephroliths. Studies to evaluate and modify the technique for use in small animals are being performed.

Conclusion

Laser lithotripsy is a non-invasive, cost-effective, rapid treatment option for dogs with urinary calculi in the bladder and/or urethra. This is especially important for breeds (or individual dogs) that are predisposed to recurrent urolith formation. Techniques for laser fragmentation of obstructive uroliths in the urethra and bladder have been established. Further advancements in lithotripsy in veterinary patients may obviate the need for traditional surgery.

Until the complex and multifactorial causes of stone formation in dogs are elucidated and stone formation is preventable, the further development of minimally invasive treatment protocols that prevent the need for multiple surgical procedures has many advantages. Laser lithotripsy appears to have applications for treatment of urolithiasis, a common and potentially dangerous health problem in dogs. In particular, successful laser lithotripsy may reduce or prevent associated problems that affect animal urinary health such as urinary tract infections, acute dysuric obstruction, and hydroureter/hydronephrosis. Potential disadvantages of laser lithotripsy include patient and operator safety issues, cost,laser maintenance, and the training and experience required for successful stone fragmentation.

Renal Transplantation in Companion Animals

Lillian R. Aronson

Introduction

Clinical renal transplantation in cats was performed successfully in 1984 by Dr. Clare Gregory and Dr. Ira Gourley at the University of California-Davis, School of Veterinary Medicine. The ability to successfully perform renal transplantation as treatment for renal failure in companion animals was due to a number of factors including the development of microsurgical techniques and the availability of microsurgical equipment in veterinary practice, the ability to use an allograft from an unrelated donor and the

administration of cyclosporine for immunosuppressive therapy in the dog and cat.[1-3]

Results published in 1992 evaluating the first 23 cases of feline renal transplantation, supported transplantation as a treatment option for cats in end stage renal failure. In that study, 70% of the cats were discharged from the transplant facility and the mean survival period was 12 months for all cats with the longest surviving for 31 months.[4] In 1996, a retrospective study evaluating 66 cases of feline renal transplantation (including the 23 cases that had been previously described) was published.[5] In that study, although the percentage of cats surviving to discharge was similar to the first report during the 9 year study period, there was an improvement in perioperative survival. Perioperative survival rate improved from 64% in the first 33 cats to 79% for the last 33 cats.[5] It is estimated that over 400 feline renal transplants have been performed since the procedure was first introduced in 1984. Although a retrospective study describing all cases that have been performed to date is not available, recent information from veterinary surgical centers active in tranplantation suggests that survival times are continuing to improve (Table 29-4). Improved survival may be related to more stringent case selection, as well as the clinician's ability to better recognize and treat complications both in the immediate postoperative period and long term. Cats are the predominant species to undergo transplantation and will be the focus of this chapter, however information will also be presented on canine transplantation since it is becoming more common at selected university hospitals.

Client Education

It is important for clients to realize that renal transplantation is a treatment option for animals in chronic renal failure, but is not a cure. Medical therapy including subcutaneous fluid therapy, low protein diets, phosphate binders, hormonal therapy including Erythropoietin and Darbopoietin, gastrointestinal protectants, and antihypertensive medication can often be discontinued following surgery however the pet will still need immunosuppressive therapy for life. Selection criteria for transplantation are rigorous and the owner needs to understand the risks of the procedure and that their cat may be turned down as a potential candidate if the cat fails any aspect of the medical screening process or if the cat has a fractious temperament. The cost of renal transplantation is high and additional veterinary visits postoperatively for monitoring of renal function and determining serum levels of cyclosporine are required. It is necessary for the owner to identify a veterinary hospital that can provide 24 hour care and a veterinarian who is willing to care for a renal transplant recipient. Finally, a critical aspect of any transplant program is donor adoption. The client must be willing to provide a lifelong home for the donor animal regardless of the outcome of the transplant procedure.

Evaluation of a Potential Recipient

Thorough screening, which is often performed by the referring veterinarian working with the transplant surgeon, is essential for a potential feline renal transplant recipient to decrease the incidence of morbidity and mortality that can occur following the surgical procedure. Although the ideal time to perform transplantation is not known, experienced clinicians suggest that the best candidate for renal transplantation is a cat in early decompensated renal failure.[6,7] Indications of decompensation include continued weight loss and worsening of anemia and azotemia in the face of medical management. Although attempts to alter the physical deterioration of animals with chronic renal failure have been reported to be unsuccessful, the placement of either an esophagostomy tube or percutaneous endoscopic gastrostomy (PEG) tube has been used successfully for up to 2 years for the medical management of some potential renal transplant candidates[6,7] (Personal communication, Mathews, KG). It is noted that the degree of azotemia, anemia, urine specific gravity and age, do not determine a suitable patient for transplantation. In one report, cats greater than 10 yrs of age had an increase in mortality, particularly during the first 6 months following surgery.[8] To date, the oldest cat that has had successful transplantation at our hospital was 18 years of age.

Both physical and biochemical parameters should be carefully evaluated to determine if a cat is suitable for transplantation. Current evaluation in our hospital includes laboratory testing (complete blood count/chemistry/blood type and crossmatch/thyroid evaluation), evaluation of the urinary tract (urinalysis, urine culture, urine protein:Cr ratio, abdominal radiographs, abdominal ultrasound), evaluation for cardiovascular disease (thoracic radiography, blood pressure electrocardiography, echocardiography, and infectious disease screening (FeLV/FIV, Toxoplasma titer, IgG and IgM) (Table 29-5).

Table 29-5. Pre-operative screening for a Potential Feline Renal Transplant Recipient

- Abdominal ultrasonography
- Thoracic radiography
- Electrocardiography, echocardiography, blood pressure
- Feline leukemia virus, Feline immunodeficiency virus
- Toxoplasmosis titer, IgG and IgM

Evaluation of the Urinary Tract

Evaluation of the urinary tract to rule out underlying infection or neoplastic disease is essential prior to transplantation. Based on biopsy reports from cats that have been transplanted, the most common diagnosis of renal disease is chronic tubulointerstitial nephritis. Other diseases successfully treated by transplantation include polycystic kidney disease, membranous glomerulonephropathy, calcium oxalate urolithiasis and ethylene glycol toxicity.[6] If on abdominal ultrasound, renomegaly is identified and the cause is not polycystic kidneys or perinephric pseudocysts, then a fine needle aspirate or a biopsy is recommended to rule out Feline Infectious Peritonitis (FIP) or neoplasia. Animals diagnosed with a urinary tract infection should be treated with the appropriate antibiotic therapy based on culture and sensitivity prior to presentation. In patients with recurrent urinary tract infections or those that have recently been treated, but at the time of presentation have a negative urine culture, a Cyclosporine (CsA; Neoral, Sandoz Pharmaceuticals) challenge is indicated. The patient is administered Cyclosporine for approximately two weeks at the recommended dose for transplantation immunosupression. The urine is evaluated for the presence of an infection on at least 2 occasions; after therapeutic CsA blood levels have been obtained and at the end of the 2 week period. Although negative urine culture results will not guarantee that a patient will remain infection free after transplantation and chronic immunosupression, it can eliminate some cats with occult infections. Alternatively, all potential transplant candidates can be treated with CsA for 2 weeks prior to surgery to attempt to identify occult infection prior to transplantation.[7]

The incidence of cats with calcium oxalate (CaOx) urolithiasis and concurrent renal failure and subsequent presentation of the cat for renal transplantation, has been increasing. In a recent retrospective study, renal transplantation was a successful treatment option for cats whose underlying cause of renal failure was associated with CaOx urolithiasis.[9] No difference in long term outcome was found between a group of 13 stone formers and a control group of 49 cats whose underlying cause of renal failure was not related to stone disease. If hydronephrosis is present on abdominal ultrasound during the recipient screening process, a pyelocentesis and urine culture is recommended prior to transplantation to identify patients that may be harboring an infection. The author has identified five cats with obstructive CaOx urolithiasis that have had a negative urine culture from urine collected from the urinary bladder and a positive urine culture from urine collected by pyelocentesis (L.R. Aronson unpublished data 2005). Allograft rejection as well as an increase in morbidity and mortality can occur in an immunosupressed patient harboring an infection.

Cardiovascular Disease

Many cats presented for transplantation have systolic murmurs identified on physical examination. These murmurs may be secondary to the anemia of chronic renal failure and not represent significant heart disease.[6] Historically, because of complications associated with transplanting cats with hypertrophic cardiomyopathy, cats with underlying cardiac disease were not accepted into the program. In a recent study performed at the University of California-Davis evaluating cardiac abnormalities in 84 potential transplant recipients, only 22% were found to have a normal heart on echocardiographic examination. The most common abnormalities identified included both papillary muscle and septal muscle hypertrophy and it was suggested that these changes may be related to chronic uremia, hypertension, age or early changes of hypertrophic cardiomyopathy.[10] We have identified patients with similar changes on echocardiography that were unable to tolerate fluid therapy prior to transplantation. Four patients developed varying degrees of pulmonary edema and pleural and pericardial effusion. Following transplantation, fluid therapy was reinitiated without complication. In 2 cats, echocardiographic evaluation performed within 3 months following surgery revealed resolution of echocardiographic abnormalities. Potential candidates with diffuse hypertrophic cardiomyopathy or those with congestive heart failure are declined as candidates for renal transplantation in our hospital. In cats with less severe cardiac disease, a decision is made on a case to case basis.

Infectious Disease

If a cat has an active FIV infection or is FeLV positive, they are declined as candidates for transplantation. All potential transplant donors and recipients currently undergo serologic testing (IgG and IgM) for Toxoplasmosis. *Toxoplasma gondii* can cause significant morbidity and mortality in both human and veterinary immunocompromised patients. Most human transplant patients will display clinical signs within the first 3 months following surgery since this is the period of maximum immunosupression.[11] In a report describing 3 cats and 1 dog, disseminated toxoplasmosis occurred within 3 weeks to 6 months following transplantation.[12] As a matter of policy at our facility, we do not use seropositive donors for seronegative recipients, but we have successfully used a seropositive donor for a seropositive recipient. Seropositive recipients are placed on lifelong prophylactic Clindamycin (25 mg PO q12h) which is started in conjunction with immunosupression. Tribrissen has also been used in cats that did not tolerate Clindamycin. To date, 10 recipients with a positive IgG and/ or a positive IgM titer have been placed on prophylactic Clindamycin therapy. Two cats are currently alive 105 and 545 days following transplantation. Eight cats have died a median of 379 days following transplantation. Cause of death included, lymphosarcoma (3 cats), presumed antibiotic toxicity (1 cat), cardiomyopathy (1 cat), accidental avulsion of the allograft (1 cat), chronic pyelonephritis (1 cat) and allograft failure (1 cat). None of the cats died from an active *Toxoplasma gondii* infection (L.R. Aronson unpublished data 2005).

Although we have become more selective in case selection in recent years, with the availability of hemodialysis and the increasing experience of clinicians who manage these cases we have "pushed the envelope" by performing transplants on cases that may be considered questionable recipients. Definitive findings that preclude renal transplantation include cats with neoplastic disease, severe cardiac disease, FeLV positive status, active FIV infection, recurrent or existing urinary tract infection that fails medical therapy and/or a CsA challenge, uncontrolled hyperthyroidism and a fractious temperament. (Table 29-6). Although objective information associated with survival has been identified with regard to some aspects of the screening

Table 29-6. Tests results or conditions that rule out Tranplantation in the Cat

- Primary or metastatic neoplasia
- Severe cardiac disease
- FeLV positive status
- Active FIV infection
- Recurrent or existing urinary tract infection that fails medical therapy and/or a CsA challenge
- Uncontrolled hyperthyroidism
- Fractious temperament

Test results or conditions that May rule out Tranplantation in the Cat

- Inflammatory bowel disease
- Diabetic patients
- Patients with echocardiographic abnormalities that suggest they are unable to receive fluid therapy

process in recipients, some clinical uncertainties continue to pose challenges including animals with inflammatory bowel disease, diabetes mellitus, and those cats with echocardiographic abnormalities that are not able to receive fluid therapy without causing fluid overload (See Table 29-6).

Evaluation of a Potential Donor

Cats selected as kidney donors are in excellent health and are typically between 1 to 3 years of age. Standard evaluation includes a serum chemistry profile, complete blood count, urinalysis and culture, FeLV and FIV testing and a Toxoplasmosis titer (IgG and IgM). The feline kidney donor must also be blood-cross match compatible to the recipient and of a similar size. Additionally, CT angiography is performed on all of the potential donors to evaluate the renal vasculature as well as evaluate the renal parenchyma for any abnormalities (Table 29-6).[13] This screening technique has allowed us to identify potential donors unsuitable for donation including those with renal infarcts as well as the presence of multiple arteries. A suitable home is found for any donor that fails the screening process. In a study evaluating the long term effects of performing a unilateral nephrectomy in a healthy cat, 16 donors were followed between 24 and 67 months postoperatively.[14] Fifteen of the 16 cats were clinically normal and serum creatinine concentrations for these cats remained within the reference range. One cat was diagnosed with chronic renal insufficiency 52 months following surgery. Although renal donation does not appear to affect normal life expectancy, long term monitoring is recommended in these animals.

Preoperative Recipient Treatment

Preoperative care for the recipient varies depending on the stability of the animal. At some centers, hemodialysis is performed prior to surgery in cats with severe azotemia (BUN > 100 mg/dL, Cr > 8mg/dL).[8] In cases that do not require hemodialysis, the recipient is typically placed on intravenous fluid therapy of a balanced electrolyte solution at 1.5 to 2 times the daily maintenance requirements. In some cases, underlying cardiac disease may preclude this rate of fluid administration because of the risk of development of pulmonary edema and pleural effusion. Additionally, the calcium channel blocker amlodipine (Norvasc, Pfizer labs, 0.625 mg/cat PO q24h) may be indicated prior to surgery if the cat is hypertensive. Anemia is typically corrected with either whole blood transfusions or packed red cells with the goal of obtaining an endpoint packed cell volume of 30% prior to surgery. If the cat is stable on admission with respect to anemia, blood transfusions are administered at the time of surgery. The first unit that is administered is a unit previously collected from the cross-match compatible donor cat. It is important to note that some cats in chronic renal failure are not transfusable because of incompatabilities despite the fact that the cats are of the same blood type and have had no known exposure to blood products. If the patient is traveling a great distance to the transplant hospital, blood crossmatching should be performed prior to admission. A blood sample can be sent to the transplant hospital for cross-matching in order to identify a compatible kidney donor as well as identify 2 to 3 potential blood donors. Hormonal therapy including Erythropoietin or Darbopoietin can be administered if a delay is expected and can greatly reduce the need for blood products at the time of surgery. Although uncommon, the owner should be cautioned regarding the possibility of the development of antibodies to these drugs which can result in significant morbidity and potentially mortality in the postoperative period. If deemed necessary, phosphate binders and gastrointestinal protectants can be given and if the cat is anorectic, a nasogastric, esophagostomy or PEG tube may be placed prior to surgery to administer nutritional support.

Feline Immunosupression

Two protocols are currently being used for the feline renal transplant recipient. In the first protocol, a combination of the Calcineurin inhibitor, CsA and the glucocorticoid, prednisolone are used together for their synergistic effects. Because the dose of cyclosporine that cats often require for immunosupression is small, an oral liquid formulation is used so that the dose can be titrated accordingly for each individual cat. Currently, the oral liquid formulation, Neoral (100 mg/ml), is recommended. Neoral is a microemulsified formulation and is preferred over the other oral liquid formulation, Sandimmune (Novartis Pharmaceuticals), because of better gastrointestinal absorption allowing for more predictable and sustained blood concentrations of the drug.[6] Additionally, the dose of Neoral necessary to maintain therapeutic blood concentrations compared to Sandimmune is less, making the drug more economical for clients.

Depending on the transplant facility performing the procedure, CsA is typically begun 24 to 96h prior to transplantation. Depending on the cat's appetite, Neoral is administered at a dose of 1 to 4 mg/kg PO q12h. In the author's experience, cats that are anorexic or that are eating a minimal amount prior to surgery have a much lower drug requirement to obtain appropriate drug levels prior to surgery. A 12-hour whole-blood trough concentration is obtained one day prior to surgery to adjust the oral dose for the surgical procedure. A target 12-hour whole-blood trough concentration of 300 to 500 ng/ml prior to surgery

using the technique of high-pressure liquid chromatography (HPLC) is recommended.[15] This level is maintained for approximately 1 to 3 months following surgery and is then tapered to approximately 250 ng/ml for long term maintenance therapy. Prednisolone is administered beginning the morning of surgery. At our facility, prednisolone is started at a dose range of 0.5-1 mg/kg q12h orally for the first 3 months and then tapered over several weeks to q24h. Protocols for both CsA and prednisolone vary between transplantation facilities. Doses have ranged from 0.25 to 2.5 mg/kg PO q12h orally starting the morning of surgery and then tapering to 0.25 mg/kg PO q24h by 1 month following surgery.[2,3,15] Prednisolone is preferred over prednisone for immunosupression in the these patients. In an abstract evaluating the bioavailability and activity of these two drugs in cats, serum prednisolone levels were significantly greater for oral prednisolone than oral prednisone.[16] It was suggested that these differences may be related to a decreased hepatic conversion of prednisone to prednisolone in some cats or decreased gastrointestinal absorption of prednisone.

A second protocol allows for once daily administration of medication. With this protocol, ketoconazole (10 mg/kg PO q24h) is administered in addition to the CsA and prednisolone.[17,18] Following the addition of ketoconazole, to the immunosuppressive protocol, CsA and prednisolone are administered once a day and CsA doses are adjusted into the therapeutic range by measuring 24 hour whole blood trough levels. Ketoconazole is an antifugal agent that can affect the metabolism of CsA by inhibiting both intestinal and hepatic cytochrome P450 oxidase activity resulting in increased blood CsA concentrations.[18] This protocol may reduce the cost of immunosuppression following surgery as well as be more appealing for owners whose work schedule does not permit twice a day dosing of medication. If twice daily dosing is necessary, the ketoconazole dose can also be split and then added to twice daily regimens to reduce costs. Ketoconazole administration is discontinued if signs of hepatotoxicity are identified.

At our facility, high performance liquid chromatography (HPLC) is the method of choice for measurement of whole blood CsA concentrations. This technique measures only the parent compound and not the metabolites of CsA which can vary depending on the patients' metabolism.[19] Flurescent immunoassay methods using either monoclonal or polyclonal antibodies have also been used. Antibodies can cross-react with the metabolites of CsA resulting in higher and more variable CsA concentrations than results obtained using the HPLC method. Although the HPLC method is the preferred method for both human and veterinary patients, immunoassay methods can still be used. Using one immunoassay method (TDxFLx assay, Abbott Laboratories) in cats, an accurate estimation of the HPLC can be determined since the correlation between these 2 methods is very high in an individual cat.[19] Whole blood CsA levels will be 1.5 to 4.2 times higher than levels measured with the HPLC method.[17,19] In a study evaluating CsA disposition following intravenous and multi-dose oral administration in cats, substantial individual variation of oral absorption was identified and results suggest that evaluation of 2-hour CsA blood concentration may be a better measure for estimating drug exposure than the 12-hour whole-blood trough concentration.[20] More work in this area is necessary prior to changing current drug monitoring protocols. Since CsA has a bitter taste, the medication is placed into a gelatin capsule prior to administration. If the owner is unable to medicate the cat, they should be given empty gelatin capsules to practice with until they feel comfortable with the technique. The capsule sizes that we most commonly use range from #1 to #3 depending on the dosage. The prednisolone, as well as other medication that the cat is taking, can be added to the gelatin capsule.

Both in vitro and in vivo studies have been performed evaluating the effects of various novel immunosuppressants such as tacrolimus, sirolimus, mycophenolate mofetil and leflunomide in cats, they have not been evaluated in the clinical patient.[21,22] Although these drugs may be effective for renal transplantation in cats, they are not without complication in the human transplant patient. Currently no other alternative immunosuppressive protocols exist for cats that cannot take CsA and prednisolone.

Canine Immunosupression

Canine transplantation remains a challenge with regard to determining the best immunosuppressive therapy, particularly in unrelated donor and recipient pairs. The selection of a major histocompatibility complex (MHC) identical littermate as a donor has been shown to improve long term graft survival in the recipient.[6] Various immunosuppressive protocols are currently being used in both unrelated and related donor and recipient pairs with varying results. The combination of Neoral, prednisolone and azathioprine (Imuran, Glaxo Wellcome) has been found to successfully maintain renal allografts in both MHC match and mismatched donor and recipient pairs. In one study using 4 healthy, unrelated mongrel dogs, immunosupression using Neoral (20 mg/kg/day) combined with azathioprine (5 mg/kg PO q48h) and prednisolone (1 mg/kg/day) resulted in 2 dogs surviving the 100 day study period, 1 dog being euthanized for an intestinal intussusception and 1 dog being euthanized for a severe upper respiratory infection.[23] The current dosage of Neoral recommended for dogs is 2.5-5 mg/kg PO q12h to attain a 12 hour whole-blood trough concentration of 500 ng/ml and 3 to 5 mg/kg PO q48h for azathioprine.[6] Transplantation has also been successful in unrelated dogs with the addition of rabbit antidog antithymocyte serum to the CsA, azathioprine and prednisone regimen.[24] Finally, leflunomide has shown promise experimentally when combined with CsA. In a recent study evaluating MNA 715 (an immunomodulatory drug derived from leflunomide) and CsA in a mismatched dog transplant model, the combination of these 2 drugs significantly prolonged renal allograft survival and reduced the severity in histologic rejection.[25] MNA715 was administered at an initial loading dose of 4 mg/kg PO q24hr followed by a dose of 2 mg/kg PO q24hr.

Anesthetic Protocols for Recipient and Donor

The specific anesthetic protocol for these patients is not unique to this surgical procedure, however there are important concepts to be emphasized. An example of a donor and recipient anesthetic protocol that have been successfully used at our hospital is presented (Table 29-7). The reader is also referred to a recent publication on anesthetic management in feline renal

- Hydralazine if needed for hypertension: 2.5 mg/4 kg cat SQ

transplantation.[26] At the time of anesthetic induction, both the donor and recipient cats are given cephalexin (22 mg/kg IV q2h). Additionally, an epidural injection is performed on both cats (Bupivicaine [0.1 mg/kg] and Morphine [0.15 mg/kg]) for analgesia. Both cats may be under anesthesia for as long as 4 to 6 hours and hypothermia is of serious concern and can be detrimental to these patients. A circulating warm air blanket is used throughout the procedure and continuous monitoring of esophageal temperatures is performed. In addition to cephalic catheters, an indwelling double lumen jugular catheter is placed into the recipient right jugular vein so that venous blood gases, the PCV and TP as well as the electrolytes can be monitored throughout surgery. The left side of the neck is preserved in animals where an esophagostomy tube may be placed. Additionally, at the time of anesthetic induction, the recipient is given a unit of cross-match compatible whole blood from the kidney donor followed by other cross-match compatible blood products as needed. The donor cat is administered mannitol on 2 occasions during the surgical procedure; 0.25 g/kg IV at the time of the abdominal incision and 1 g/kg 20 minutes prior to nephrectomy. Mannitol (0.5-0.1 g/kg IV) is occasionally administered to the recipient if there is concern regarding allograft perfusion following vascular anastomosis. Systemic arterial blood pressure is monitored regularly in both cats non-invasively via a Doppler technique and hypotension corrected by decreasing the concentration of inhalant anesthetic, or by the administration of fluid boluses, blood products or a continuous infusion of dopamine (5 ug/kg/min). Intraoperative hypertension can be treated successfully with the SQ administration of hydralazine (2.5 mg SQ for a 4 kg cat).

Renal Transplantation Surgery

Successful renal transplantation in the cat requires an operating microscope and surgical experience with microsurgical vascular and ureteral surgical procedures.

Feline Surgical Technique

In our hospital, 3 surgeons are required for each transplant procedure; 2 surgeons to operate on the donor and recipient and a third surgeon to close the donor following the nephrectomy. The donor cat is brought into the surgical suite approximately 45 minutes prior to the recipient and the donor kidney prepared for nephrectomy. At the time of initial incision, the donor is given a dose of mannitol (0.25 g/kg IV over 15 minutes). The alpha adrenergic agonist acepromazine (0.1 mg/kg IV) has also been recommended by some surgeons.[17] These drugs are used to minimize renal arterial spasms, improve renal blood flow and protect against renal tissue injury that can occur during the warm ischemia period. It is essential to harvest a donor kidney with a single renal artery. Many renal arteries bifurcate close to the kidney. A minimal length of 0.5 cm of a single renal artery is necessary for the arterial anastomosis.[6] The CT angiography that was performed on the donor prior to anesthesia not only provides important information regarding the renal vasculature, but also prevents delays between the donor nephrectomy and recipient anesthesia induction. The left kidney is preferred as a donor because it provides a longer renal vein than the right kidney. In most situations, if two renal veins are present, the smaller vein can be sacrificed. Prior to sacrificing a small vein, however, it is important for the surgeon to identify the ureteral vein and determine that it is not draining into the renal vein that is being sacrificed. The renal artery and vein are cleared of as much fat and adventitia as possible and the ureter is dissected free to the point where it enters the bladder serosa. Using sterile paper, templates are made of both the donor renal artery and vein to determine the size of the venotomy and aortotomy to be performed in the recipient. Harvesting the donor kidney is performed when the recipient is fully prepared to receive the kidney. Fifteen minutes prior to nephrectomy, a 2nd dose of mannitol (1.0 g/kg IV) is given to the donor cat.

An operating microscope is used for the majority of the recipient surgery. Following a full abdominal exploratory, the colon and ileum are tacked to the body wall using 3-0 chromic gut to aid in surgical exposure. Two surgical methods of renal trans-

plantation have been described. The first technique described transfers the transplanted kidney to the recipient's iliac vessels. In this technique, an end-to-end arterial anastomosis of the external iliac and renal artery and an end-to-side anastomosis of the external iliac vein and renal vein are performed.[2] Approximately 12% of cats having this procedure developed pelvic limb complications including pain, hypothermia, edema, paresis and paralysis.[5] These complications have been successfully prevented by changing the vascular surgical technique. In the revised procedure, the renal artery is anastomosed end-to-side to the caudal aorta (proximal to the caudal mesenteric artery), and the renal vein is anastomosed end-to-side to the caudal vena cava (Figure 29-22A and B).[27] Partial occlusion vascular clamps are used to obstruct blood flow in both the aorta and the caudal vena cava. Using the previously made templates from the donor vessels, windows are created in both the aorta and vena cava that match the size of the renal artery and vein, respectively. An aortotomy clamp is used to create the stoma in the aorta and adventitial scissors are used to create an oval defect in the vena cava. The aorta and vena cava are flushed with a heparinized saline solution. Two sutures of 8-0 nylon are placed at the cranial and caudal aspect of the aortotomy site. Sutures are not pre-placed in the venotomy.

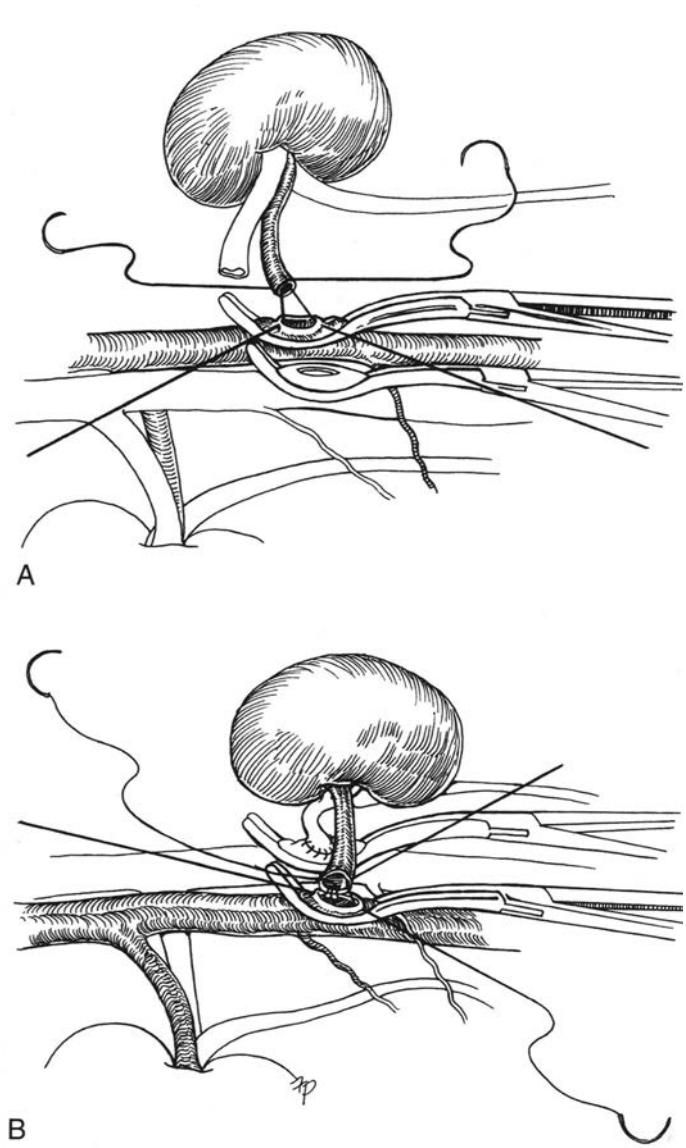

Figure 29-22. A and **B.** Transplantation of the renal allograft onto the recipients abdominal aorta and vena cava. The renal artery is anastomosed end to side to the aorta using 8-0 nylon and the renal vein is anastomosed end to side to the vena cava using 7-0 silk.

Following the second mannitol infusion in the donor, the graft is harvested and flushed with a phosphate-buffered sucrose preservation solution. Excess adventitia on the end of the renal artery is excised and the artery dilated. The renal artery is anastomosed to the aorta using 8-0 nylon in 2 rows of simple continuous sutures; one on the medial aspect and one on the lateral aspect of the artery. The renal vein is anastomosed to the vena cava using 7-0 silk. A back wall technique is used first to suture the portion of the renal vein closest to the renal artery. The anastomosis is completed once the second side of the vein is sutured using a continuous pattern. The venous clamp is removed first and then the arterial clamp. Some hemorrhage may occur but typically can be controlled with direct pressure. Significant leaks are repaired with the placement of additional single interrupted sutures. Occasionally, renal arterial spasm can occur following release of the vascular clamps. The application of topical lidocaine or acepromazine has been effective in some cases in eliminating this problem. Others recommend the systemic use of chlorpromazine or acepromazine for treating the vascular spasms that can occur and have found these drugs to be more effective than lidocaine.[17] In a comparison of the two surgical techniques, although not statistically significant, the graft warm ischemia and total surgical times were shorter using the arterial end-to-side technique compared to the iliac vessel technique. Additionally, pelvic limb complications were not identified using the revised technique.[27]

An alternative to performing the donor and recipient surgeries simultaneously is the use of hypothermic storage to preserve the donor kidney until the recipient surgery is performed. Following preparation of the donor kidney within the donor, a nephrectomy is performed and the graft flushed with a phosphate-buffered sucrose organ preservation solution.[17] To perform this technique, the renal artery is cannulated with an 18-gauge catheter, perfused with 25 to 50 ml of preservation solution at 100 cm water pressure and then placed in a stainless steel bowl which contains approximately 200 ml of preservation solution. The bowl is floated in an ice slush, the kidney agitated until cold to the touch and the bowl is covered with a sterile drape.[17,28] This technique is preferred by some surgeons because it reduces personnel and resources needed for the transplantation procedure and the cold preservation technique has been found to minimize ischemic injury that can occur to the kidney.

Once the vascular anastomosis is complete, a ureteroneocystotomy is performed. Three techniques have been described and are currently being performed at different surgical centers. I prefer the intravesicular mucosal apposition technique.[3] With this technique, a ventral midline cystotomy is performed. A mosquito hemostat is used to make a hole at the apex of the bladder and then the end of the ureter is grasped and brought directly into the bladder lumen. Tunneling of the ureter through the bladder wall is not performed (Figure 29-23). The bladder is

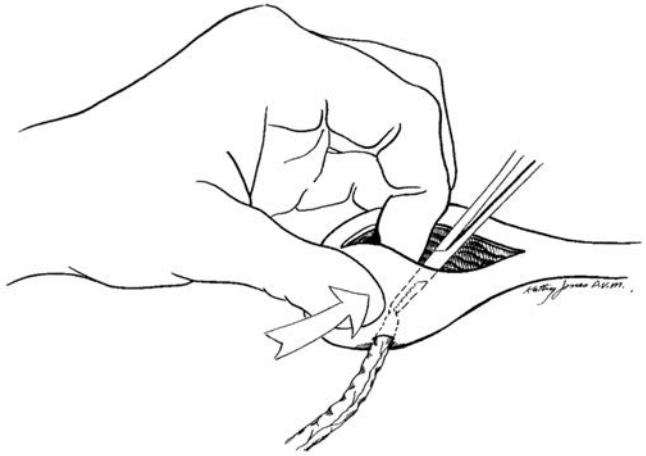

Figure 29-23. A ventral cystotomy is performed and the allograft ureter tunneled directly through the apex of the bladder using a mosquito forcep.

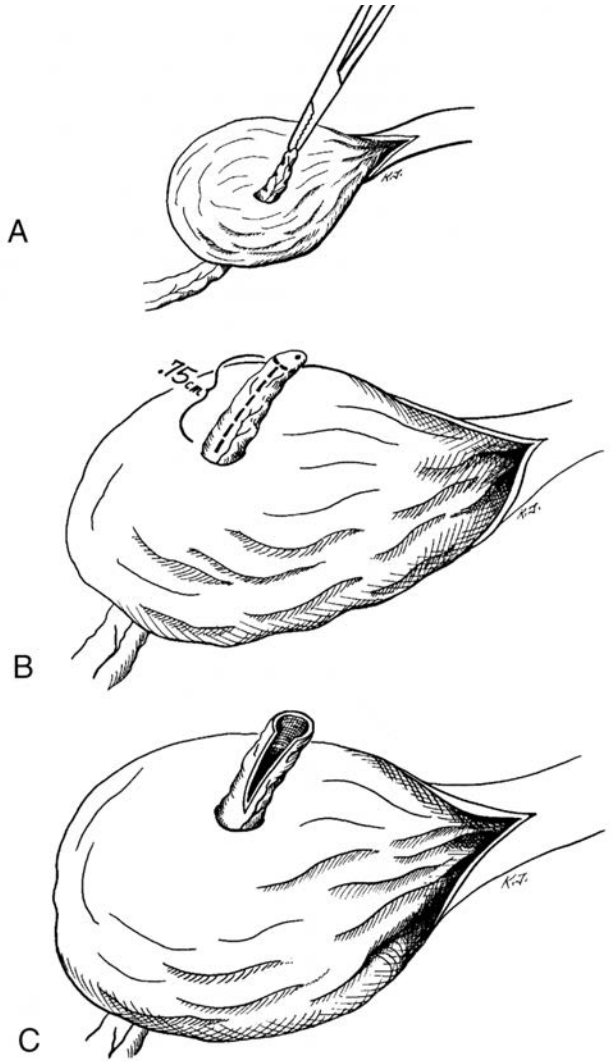

Figure 29-24. The bladder is everted for better exposure. The crushed end of the ureter is excised and the end of the ureter spatulated using straight microvascular scissors.

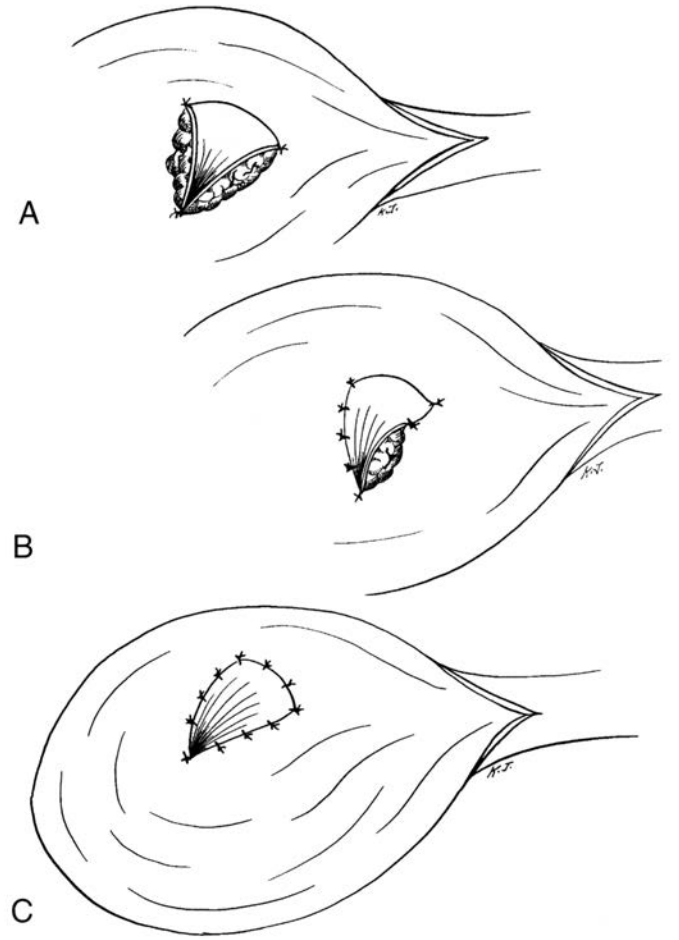

Figure 29-25. The ureteral mucosa is sutured in an interrupted pattern to the bladder mucosa using simple interrupted sutures of either 8-0 nylon or 8-0 vicryl. The first and most important suture is placed at the proximal end of the ureteral incision (point of the "V"). It is important that no periureteral fat is exposed once suturing is complete as this can lead to adhesions and granuloma formation potentially resulting in a ureteral obstruction. Once completed, the bladder is then closed routinely.

everted, the distal end of the ureter is excised, periureteral fat removed and then the end of the ureter is spatulated a distance of 0.5-0.75 cm (Figure 29-24). The ureteral mucosa is sutured to the bladder mucosa using either 8-0 vicryl or 8-0 nylon in a simple interrupted pattern. The first and most critical suture is placed at the proximal end of the ureteral incision (point of the "V") (Figure 29-25) It is important that no periureteral fat is exposed once suturing is complete as this can lead to adhesions and granuloma formation potentially resulting in a ureteral obstruction. A 5-0 polypropylene suture can be used to check for ureteral patency. Following completion of the anastomosis, the bladder is closed with absorbable suture in a single layer appositional pattern.

Two newer techniques for ureteral implantation, both extravesicular, have recently been described. In the first technique (Figure 29-26), a 1 cm incision is made through the seromuscular layer on the ventral surface of the bladder allowing the mucosa to bulge through the incision.[6,29] A smaller incision (3 to 4 mm) is made through the mucosal layer of the bladder at the caudal

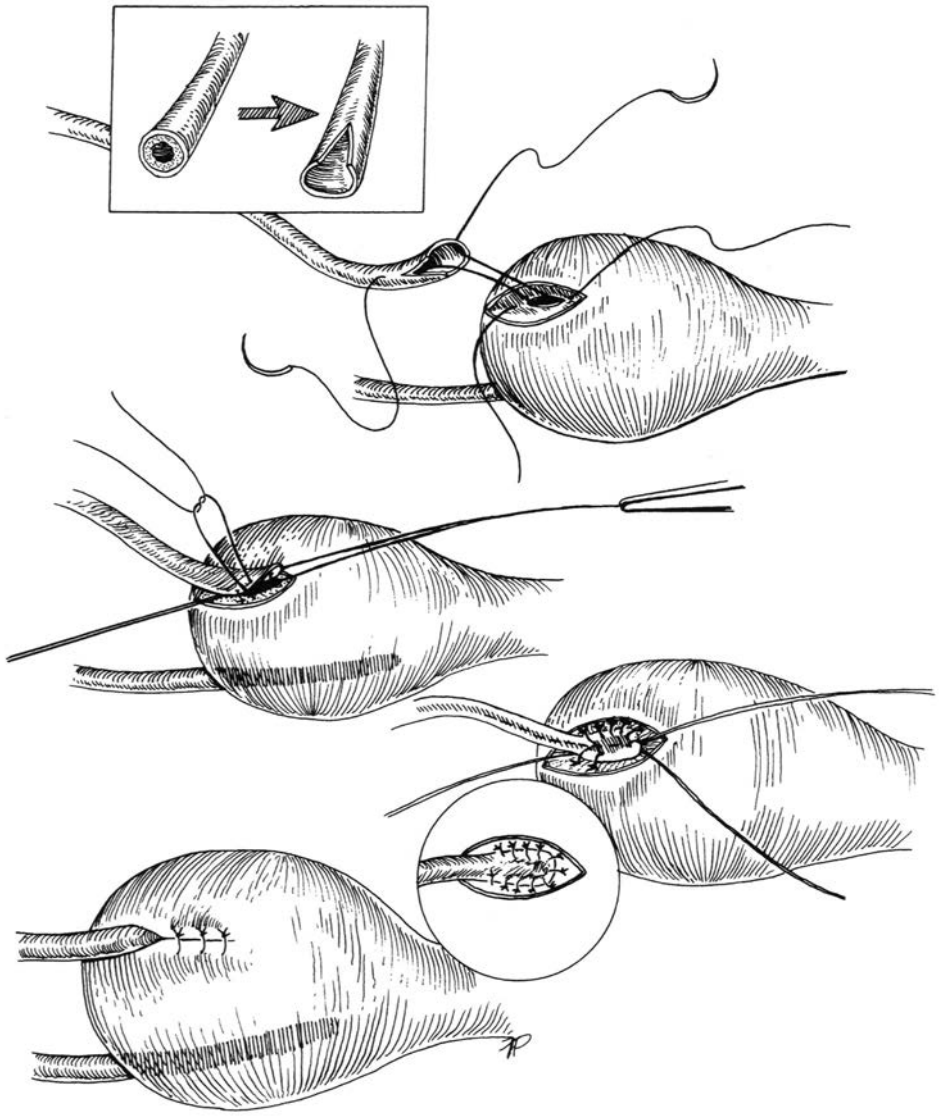

Figure 29-26. Extravesicular technique for ureteroneocystostomy. A 1 cm incision is made on the ventral surface of the bladder through the seromuscular layer allowing the mucosa to bulge through the incision. A smaller incision (3 to 4 mm) is made through the mucosal layer of the bladder at the caudal aspect of the seromuscular incision. The distal end of the ureter is spatulated and the ureteral mucosa is sutured to bladder mucosa using 8-0 nylon. The proximal and distal sutures are placed first. The seromuscular layer is closed over the ureter in a simple interrupted suture pattern.

aspect of the seromuscular incision. The distal end of the ureter is prepared as previously described. Ureteral mucosa is sutured to bladder mucosa using 8-0 vicryl or nylon. The proximal and distal sutures are placed first. Similar to the previous technique, 5-0 polypropylene suture can be used to check for ureteral patency. Once the ureteral anastomosis is complete, the seromuscular layer is apposed in a simple interrupted pattern over the ureter using 4-0 absorbable suture such as PDS. In the second technique, the entire ureter and ureteral papilla are harvested and sutured using an extravesicular technique.[30] A 2 mm cuff of bladder wall is isolated along with the distal end of the ureter. A 4 mm defect is made at the apex of the bladder and the ureteral papilla sutured in place using 8-0 Vicryl in a 2 layer pattern; mucosa to mucosa and seromuscular layer to seromuscular layer.

Prior to abdominal closure of the recipient, a biopsy of one of the native kidneys is taken (if not previously performed) and an esophagostomy tube placed if nutritional support is deemed necessary. Finally, the allograft is pexied to the abdominal wall. If the kidney is transplanted onto the aorta and vena cava, the adjacent body wall is incised and the incised edge sutured to the renal capsule using 6 interrupted sutures of 4-0 polypropylene. Another procedure involves the creation of a musculoperitoneal flap (based ventrally) which is elevated from the adjacent body wall and sutured to the renal capsule using 4-6 interrupted sutures of 5-0 polypropylene.[6] The pexy is critical to prevent allograft torsion on its vascular pedicle causing ischemia and subsequent graft loss. The native kidneys are usually left in situ to act as a reserve if graft function is delayed. If warranted, the kidneys can be removed at a later time. In cases of polycystic kidney disease, often one of the native kidneys needs to be removed at the time of the transplantation procedure in order to make room in the abdomen for the allograft.

Canine Surgical Technique

The surgical techniques described for renal transplantation in the dog are similar to those described for the cat with minor differences. Both the iliac vessel technique as well as anastomosing the renal vasculature to the caudal aorta and vena cava have been performed successfully in the dog and unlike the cat, magnification may not be necessary depending on the size of the patient.[6] Unlike cats, the iliac vessel technique is still being used both experimentally and clinically in the dog. The selected iliac artery is prepared for an end-to-end anastomosis to the renal artery and the external iliac vein is prepared for an end-to-side anastomosis to the renal vein. A bulldog vascular clamp is placed near the aortic bifurcation to occlude the iliac artery. The artery is subsequently ligated distally, severed and then flushed with heparinized saline solution. The end of the artery is dilated slightly and cleaned of any excess adventitia. The external iliac vein is isolated in the same region, tributary veins ligated and then 2 bulldog vascular clamps placed as far apart as possible (first distally and then proximally). A partial occlusion clamp can also be used. A venotomy in the external iliac vein is performed and then 2 rows of simple continuous sutures are used on the medial and lateral aspect of the renal vein and iliac vein as previously described for the cat. The renal artery and iliac artery are anastomosed using a simple interrupted pattern. Suture material used for the vascular anastomoses is 4-0 to 6-0 silk for the venous anastomosis and 5-0 to 8-0 nylon or polypropylene for the arterial anastomosis. Both intravesicular and extravesicular techniques for ureteroneocystostomy have been used successfully in canine transplantation. The renal capsule of the allograft is sutured to the abdominal body wall with simple interrupted sutures of 3-0 polypropylene, with a musculoperitoneal flap (based ventrally) using 3-0 polypropylene or by suturing the allograft capsule to the adjacent mesocolon with simple interrupted sutures of 3-0 polypropylene.[6,24]

Postoperative Care and Perioperative Complications

Important points of postoperative care in the transplant patient include minimizing stress and handling of the patient and treatment of hypothermia. The recipient is administered a balanced electrolyte solution with the volume adjusted depending on the cat's hydration status and oral intake of water. Blood transfusions should be given as needed. The cat is maintained on IV antibiotic therapy (cefazolin, 22 mg/kg IV q8h) until the intravenous catheter is removed and then the cat is maintained on oral amoxicillin combined with clavulenic acid (Clavamox, 62.5 mg PO q12h) until the feeding tube is removed. If the cat is Toxoplasma positive, Clindamycin (25 mg PO q12hr) is administered and continued for the lifetime of the cat. Postoperative pain has been controlled successfully using either hydromorphone (0.1-0.2 mg/kg IM or SQ q4-6h), buprenorphine (0.005-0.02 mg/kg IV q4-6h) or a constant rate infusion of butorphanol (0.1-0.5 mg/kg/h). An extended data base evaluating the packed cell volume, total protein, electrolytes, blood glucose and acid base status is initially evaluated 2 to 3 times daily and then tapered accordingly depending on the patient's stability. A renal chemistry panel is checked every 24 to 48 hours and a blood CsA level is checked every 3 to 4 days. The oral CsA dose is adjusted accordingly depending on postoperative blood levels. It has been the author's experience that CsA requirements typically decrease in the early postoperative period, likely associated with preoperative fasting of the patient and postoperative anorexia. The prednisolone dose is continued as previously described (0.5 to 1 mg/kg PO q12h). Voided urine is collected daily to assess urine specific gravity. Typically with appropriate pain control and improvement in azotemia, most cats start eating within 24 to 48 hours following the surgical procedure. In some cases in which continued anorexia is thought to be associated with altered gastric motility following surgery, metoclopramide administration (0.2 mg/kg SQ q6-8h) has been successful in improving a cat's appetite. If the cat remains anorexic, feeding is begun using the esophagostomy tube. Feeding is continued until the cat is eating and drinking and then tapered accordingly.

Patients are monitored for postoperative seizure activity every 1 to 2 hours for the first 3 days. During the 1990's, the most common complication reported in cats during the perioperative period was central nervous system (CNS) disorders including disorientation and seizures which occasionally progressed to a comatose state as well as respiratory and cardiac arrest.[31] In one report, the median time until onset of seizure activity was 24 hours following surgery.[5] Many variables were evaluated and showed no difference between affected and unaffected cats with respect to the degree of azotemia, magnesium and cholesterol levels, intraoperative blood pressure, osmolality, serum electrolyte and blood glucose concentration, erythropoietin and CsA administration.[7,31] In one study, postoperative hypertension was identified as a major contributing factor to postoperative seizure activity in the feline renal transplant recipient.[32] Additionally, the administration of antihypertensive therapy significantly reduced the seizure frequency and the morbidity and mortality associated with neurologic complications. Because of these findings, during the first 48 to 72 hours, indirect blood pressure is monitored every 1 to 2 hours for the development of hypertension. If the systolic blood pressure is equal to or exceeds 170 mmHg, hydralazine (Sidmack Laboratories, 2.5 mg SQ) is administered. The hydralazine dose can be repeated if the systolic pressure hasn't decreased within 15 minutes. If the cat is refractory to hydralazine, acepromazine (0.005-0.01 mg/kg IV) has been used successfully. It is important to note that the cause of CNS disorders in human transplant patients is thought to be multifactorial, and since there appears to be a difference between transplant centers in the incidence of hypertension and CNS disorders, the occurrence of CNS disorders in cats following renal transplantation remains a challenge.[17] Postoperative hypotension may also produce complications. Systolic blood pressure should be maintained at equal to or greater than 100 mmHg. Sustained hypotension can be a serious problem leading to poor graft perfusion. These patients need to be treated aggressively to prevent acute tubular necrosis and delayed graft function.

If transplant surgery is technically successful, azotemia typically resolves and the cat improves clinically within the first few days following surgery. If improvement is not identified during this time or if improvement in renal function as well as the clinical status of the patient is initially identified, but then worsens, an

ultrasonographic examination of the allograft is warranted. The allograft should be evaluated for any signs of hydronephrosis and hydroureter as well as renal blood flow. If ureteral obstruction is suspected, the cat is anesthetized and the allograft ureter evaluated. In some cases, the ureter may need to be re-implanted into the urinary bladder. If graft perfusion is adequate and no hydronephrosis/hydroureter exists, delayed graft function may be occurring. Typically, if perfusion remains adequate, improvement in graft function often occurs within the first few weeks following surgery. The author suspected delayed graft function in one cat and significant improvement didn't occur for approximately 6 to 8 weeks postoperatively. This cat experienced prolonged episodes of hypotension during surgery as well as in the immediate postoperative period.

Normally, without major complication, the recipient is transferred from the intensive care unit to the renal transplantation ward within a few days following surgery. Patients are discharged when graft function appears adequate and CsA blood levels are stable. If otherwise stable, cats with a delay in function of their graft can also be discharged. Medical management can be continued in this subset of patients until graft function returns to normal. If the transplanted kidney fails to function, the kidney should be biopsied prior to attempting retransplantation of the patient.

Long-Term Management and Complications

Following discharge, both cats should be evaluated by the primary care veterinarian once a week for the first 4 to 6 weeks initially and then extended to monthly intervals if the cat is clinically stable. During each exam, a renal panel, packed cell volume, total protein, a cyclosporine level and a urinalysis of a free-catch urine sample is performed. Body weight should be monitored regularly. It is recommended that a complete blood count and serum chemistry panel be performed every 3 to 4 months and an echocardiography performed every 6 to 12 months if the cat had been diagnosed with underlying cardiac disease prior to transplantation. The feeding tube can be removed at suture removal if oral intake of food and water is appropriate.

There is seemingly little correlation between the oral dose of cyclosporine and the blood level that will be achieved in an individual animal. Cats of similar weight on identical doses of CsA may vary markedly in blood levels achieved. Because of individual patient variability in the absorption of oral cyclosporine and its metabolism, it is essential that blood levels are monitored regularly to maintain therapeutic concentrations and minimize side effects from toxicity. As previously described, CsA trough levels are maintained for approximately 1 to 3 months following surgery at 300 to 500 ng/ml and then tapered to approximately 250 ng/ml for maintenance therapy. Although rare, a fatal side effect of CsA therapy, hemolytic uremic syndrome (HUS), has been identified in the cat.[33] Patients develop hemolytic anemia, thrombocytopenia with rapid deterioration of renal function secondary to glomerular and renal arteriolar platelet and fibrin thrombi. Unfortunately, the disease typically has not manifested itself until after the transplant procedure and the mortality rate has been 100%.

If renal function remains normal following transplantation, the anemia associated with renal failure should resolve within 3-4 weeks after surgery.[34] If graft function remains adequate, but the anemia persists, iron supplementation should be considered.

Renal complications following transplantation have included renal rejection, hemolytic uremic syndrome, oxalate nephrosis and renal failure. Both acute and chronic rejection have been described in the cat. Acute rejection with loss of function of the affected organ can occur at any time, but is most common within the first 1 to 2 months following surgery. Acute rejection is often associated with poor owner compliance in administration of required medication. Some cats that are experiencing a rejection episode may be lethargic, depressed, anorexic and PU/PD and thus prompt a visit to a veterinarian while in other cats, clinical signs may be minimal. For this reason, weekly blood sampling is critical during this time period to detect any changes in serum creatinine concentration. Histopathologic, sonographic, and scintigraphic examination of allograft rejection in cats has recently been described.[35,36] In one study, allograft histopathology revealed significant interstitial inflammation and tubulitis with varying degrees of intimal arteritis.[35] A significant increase in cross sectional area of the kidney on ultrasound examination has been identified in cats during a rejection episode.[36] Although normal allograft enlargement is expected during the first week postoperatively, a gradual decline in size should then occur. Allograft rejection should be suspected if renal enlargement persists or progresses beyond 7 days. Additionally, a subjective increase in echogenicity and a decrease in corticomedullary demarcation may be identified in allografts undergoing rejection.[36] Neither resistive index nor glomerular filtration rate were sensitive indicators in normal grafts and those undergoing allograft rejection.[36-38] Prior to initiating treatment for rejection, a urine sediment should be evaluated to rule out obvious infection and an abdominal ultrasound performed of the allograft to rule out ureteral obstruction.

Treatment for a possible rejection episode should not be delayed and these tests should only be performed prior to initiating therapy if in house capabilities are available. Acute rejection episodes are treated with intravenous administration of cyclosporine (6.6 mg/kg q24h given over 4 to 6h) and prednisolone sodium succinate (Solu Delta Cortef, Upjohn, 10 mg/kg IV q12h). Each milliliter of the IV cyclosporine is diluted with 20 to 100 ml of either 0.9% NaCl or 5% Dextrose (not Lactated Ringer's solution). Because CsA is light sensitive, the IV fluid lines should be covered. Following the completion of the CsA infusion, the cat is continued on IV fluid therapy. The infusion of CsA can be repeated, however if the creatinine concentration does not improve within 24 to 48 hours, other causes for the azotemia should be investigated. Chronic rejection is characterized by a gradual loss of organ function over months to years, often without a known episode of rejection. Kidneys undergoing chronic rejection show severe narrowing of numerous arteries and thickening of the glomerular capillary basement membrane. Unfortunately, the cause of chronic rejection is undetermined. As described previously, HUS is a rare, but fatal complication in the feline renal transplant recipient. Three feline transplant recipients were dignosed with HUS secondary to cyclosporine therapy.[33]

Results of a recent study suggest that transplantation is a treatment option for cats with calcium oxalate (CaOx) urolithiasis. No difference in long term outcome was found between a group of 13 cats with CaOx calculi and a control group of 49 cats whose underlying cause of renal failure was not related to calculi formation.[9] Although formation of calculi in the allograft did not significantly reduce survival, the power of the study was low and there was a trend towards lower survival rates in cats that formed calculi. Four of the 5 cats that formed calculi following surgery had calculi attached to the nylon suture used to perform the ureteroneocystostomy and two cats that formed calculi after surgery were diagnosed with a urinary tract infection. We speculate and recommend that the use of absorbable suture material for performing the ureteroneocystostomy and a more thorough screening for urinary tract infection be performed in these cats.

Another potential cause for the recurrence of azotemia in the first few months postoperatively in the feline renal transplant recipient is the development of retroperitoneal fibrosis.[39] The cause is unknown but may be associated with operative trauma, infection, the presence of foreign material, inadequate immunosupression, hemorrhage or urine leakage during the transplant procedure. Ultrasound examination of the kidney reveals hydronephrosis with or without hydroureter and occasionally, a capsule can be identified surrounding the allograft. Surgery has been successful in relieving the obstruction and restoring normal renal function.

Finally, similar to humans following transplantation, complications occur secondary to chronic immunosuppressive therapy. Cats and dogs are more susceptible to bacterial and fungal infections as well as opportunistic infections such as the reactivation of latent *Toxoplasma gondii* infection.[12] Bacterial urinary tract infections in the transplant patient cause direct morbidity and mortality due to the infection itself, and may also activate the rejection process. Two cats have developed fatal Mycobacterium infections following chronic immunosuppressive therapy; one cat had systemic disease and the other cat had septic arthritis.[40,(personal communication, Aronson 2005)] Transplant recipients are also more susceptible to various forms of neoplasia and diabetes. Decreased immune surveillance, activation of latent oncogenic viruses such as the Epstein Barr virus and chronic antigenic stimulation are thought to put human patients at increased risk for various forms of neoplasia.[7] The prevalence of neoplasia in cats following renal transplantation has been reported from 9.5 to 14% with lymphoma being the most common type reported.[41]

Conclusion

Renal transplantation offers a unique method of treatment for renal failure in cats. Currently, approximately 90 to 95% of cats recover from surgery sufficiently to be discharged to the owner and approximately 70% of these cases are alive and clinically doing well 1 year after transplant. Transplant success in the canine is considerably less than the feline unless matched donors and recipients are used. Survival times have steadily improved as more animals have been treated and careful screening of recipients is performed, and early recognition of problems and complications has improved. Clients interested in renal transplantation for their pet need to understand the risks of surgery and recovery and that substantial ongoing care is necessary for the life of the animal.

Management of Ureteral Ectopia

Mary A. McLoughlin

Introduction

Ureteral ectopia is a complex congenital abnormality of the urinary system frequently resulting in urinary incontinence. Distal displacement of one or both ureteral orifice(s) to sites within the bladder neck, urethra, vagina or vestibule has been described in small animal patients. *Intermittent, continual or positional urinary incontinence* is the most common clinical symptom reported in both juvenile and adult patients diagnosed with ureteral ectopia. Ureteral ectopia is diagnosed with significantly greater frequency in females compared to males in all affected species. Ureteral ectopia is reported in both purebred and mix-breed dogs. It has been documented with greater frequency in specific breeds including Labrador retriever, Golden retriever, Siberian husky, Newfoundland, Skye terrier, West Highland white terrier, Wire-haired fox terrier, Soft-Coated Wheaten terrier as well as Standard and Miniature poodles. The specific etiology of this developmental anomaly remains unclear and a genetic basis has not yet been established.

Two types of ectopic ureters are recognized in veterinary patients based on the anatomic structure and pathway of the distal ureter. Extramural ureters exit the kidney and completely bypass the bladder opening directly into the proximal, middle or distal urethra, uterus, vagina or vestibule. The incidence of extramural ectopic ureters is rare. Intramural ectopic ureters attach to the serosal surface of the bladder in the expected dorsolateral anatomical position, yet fail to open into the bladder lumen at the tip of the trigone. Intramural ectopic ureters tunnel submucosally through the trigonal region to open at sites within or distal to the bladder neck. Intramural ectopic ureters are the most common type of ectopic ureters identified in both male and female dogs. Additional anatomic variations of the distal ureteral segment include multiple fenestrations, ureteral troughs, dilation, branched ureters and associated ureteroceles. Urinary incontinence since birth or following ovariohysterectomy is the most frequently reported clinical symptom in patients diagnosed with ureteral ectopia. Normal voiding patterns may also be observed in these patients. The cause of urinary incontinence is considered multifactorial. It can result from urine outflow distal to the bladder neck and urethral sphincter mechanism,or functional and/or structural abnormalities of the vesicourethral junction and urethra resulting in primary sphincter mechanism incompetence. The degree of urinary incontinence and patterns of urination cannot be used to confirm the diagnosis of ureteral ectopia nor determine if unilateral or bilateral disease exists.

Diagnosis

Ureteral ectopia is the most common cause of urinary incontinence in young female dogs. However, it should also be considered as a rule-out for patients with history of incontinence after ovariohysterectomy. Physical examination is often normal with the exception of moist or urine stained hair in the perivulvar or prepucial region.

Perivulvar or prepucial dermatitis secondary to urine scalding may be observed. Careful abdominal palpation is performed to discern marked abnormalities in kidney size that can result from hydronephrosis or dysplasia. Results of hematological and serum biochemical evaluations are often normal unless associated abnormalities of the upper urinary tract that diminish renal function exist. Urinary tract infections are frequently identified resulting from ascending bacterial pathogens.

The specific diagnosis of ureteral ectopia is based on identification of one or both ureteral orifice(s) in a distally displaced position. Uroendoscopy or direct visualization at surgery is considered to be the "gold standard" for the diagnosis of ureteral ectopia in female dogs. Direct visualization of the lumenal surface of the lower urinary and reproductive tracts using a rigid or flexible endoscope has dramatically improved our ability to accurately diagnose and classify ectopic ureters and identify associated abnormalities in a minimally invasive manner. Radiographic imaging techniques including intravenous urography (IVU) with or without fluoroscopy, vaginocystography, contrast enhanced computed tomography (CT) and ultrasonography may also provide a valuable method of diagnosis as well as providing valuable information regarding structure and function of the urinary tract. Specific identification of the ureteral orifice with imaging techniques can be difficult or obscured by contrast accumulation in the urinary bladder resulting in a potential false positive or false negative diagnosis.

Surgical Techniques

The goal of surgical treatment of ureteral ectopia is resolution of urinary incontinence and re-establishment of anatomical integrity of the lower urinary system. The specific surgical correction of ureteral ectopia is based upon location and morphology of the ectopic ureter(s), and associated abnormalities of the urogenital tract. A variety of urologic abnormalities have been reported associated with ureteral ectopia including renal dysplasia, renal agenesis, hydronephrosis, hydroureter, tortuous ureter and presence of a septal remnant at the opening of the cranial vaginal vault. Evaluation of renal structure and function is an essential part of the surgical planning. Ultrasonographic evaluation of the upper urinary structures combined with either contrast radiography (IVU) or differential renal nuclear scintigraphy is performed to characterize renal function. Nephroureterectomy is performed when a kidney is determined to be nonfunctional. Renal biopsy and culture are recommended if structural abnormalities of a functional kidney are noted.

Ureteral Reimplantation

Extramural ectopic ureters may result in persistent incontinence because the ureteral orifice is positioned distal to the bladder neck and urethral sphincter mechanism (Figure 29-27A). Repositioning the ureteral orifice directly into the bladder may restore urinary continence provided additional functional or structural abnormalities of the urethral sphincter mechanism do not exist.

The urinary bladder and proximal urethra are exposed and isolated. The distal aspect of the extramural ectopic ureter is isolated at the site of attachment to the dorsolateral surface of the vesicourethral junction, urethra, uterus or vagina. The extramural ureter is ligated at its distal point of attachment with 3/0 absorbable suture material and the ureter transected cranial to the ligature (Figure 29-27B). The surgeon should gently isolate the distal 1/3 of the ureter from the ureteral fascia and retroperitoneal space avoiding disruption of the ureteral arterial blood supply located longitudinally within the fascial attachment. The site of ureteral reimplantation is determined by examining bladder size and position without traction and relative to ureteral length. Ureteral reimplantation can be performed at any site within the bladder between the apex and the tip of the trigone however it is critical to avoid tension at the vesicoureteral anastomosis. A ventral midline cystotomy is performed and a small mucosal incision or defect created at the proposed site of ureteral reimplantation. A mosquito hemostat is passed through the mucosal incision at an oblique angle to exit the serosal surface of the bladder. The surgeon then gently guides the ureter through the bladder wall defect (Figure 29-27C). Once positioned within the bladder lumen, the terminal .25 cm of the ureter is excised and discarded. If the ureteral orifice is extremely small, magnification should be used to accurately place the ureterovesicular anastomotic sutures. Alternatively, the terminal end (4

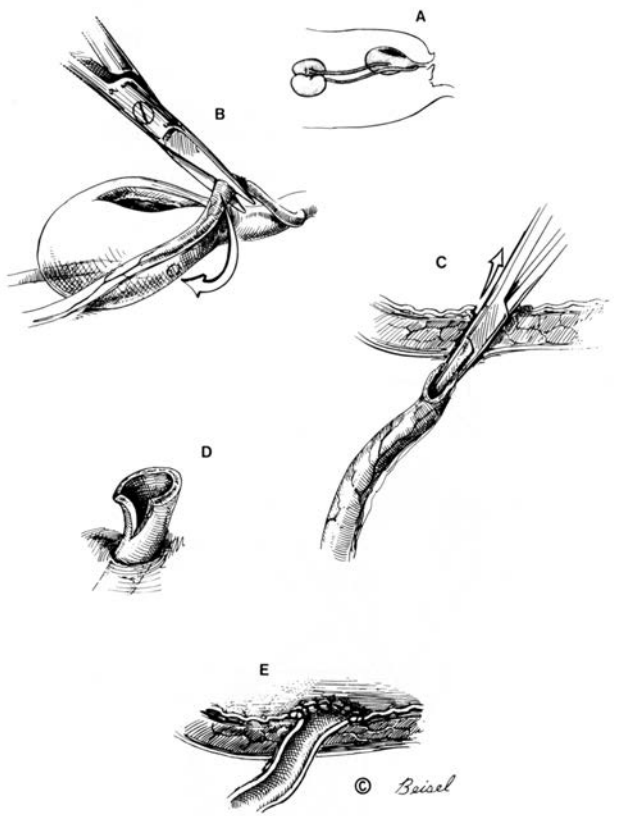

Figure 29-27. A. Reimplantation of an extramural ectopic ureter. **B.** A caudal ventral midline celiotomy to expose the bladder and ureters. The extramural ureter is isolated at its distal point of attachement, ligated and transected. A ventral midline cystotomy is performed. **C.** A mosquito hemostat is passed thru a small mucosal incision within the bladder and passed thru the bladder wall. The transected ureter is gently guided through the bladder wall. **D.** The terminal .25 cm. of the ureter are excised and discarded. If necessary, a 4-6 mm longitudinal incision can be made with small metzenbaum scissors to widen the orifice facilitating vesicoureteral anastomosis. **E.** Vesicoureteral anastomosis is performed placing simple interrupted sutures in the ureteral mucosa and bladder mucosa.

to 6 mm) of the ureter can be incised longitudinally with small metzenbaum scissors to spatulate or widen the orifice to facilitate the intravesicular anastomosis (Figure 29-27D). Intravesicular ureteral anastomosis is accomplished by suturing the ureteral mucosa to the incised edges of the bladder mucosa using 4 to 6 interrupted 5-0 absorbable, monofilament sutures (Figure 29-27E). The bladder is closed in a routine manner with a 4-0 absorbable monofilament suture material in a one or two layer closure.

Neoureterostomy and Urethral/Trigonal Reconstruction

Urinary incontinence caused by an intramural ectopic ureter is attributed to both the ectopic position of the ureteral orifice and/or malformation or dysfunction of the proximal urethral sphincter mechanism by the submucosal ureter. Historically, surgical repair of intramural ectopic ureters has focused on the creation of a new ureteral opening within the bladder lumen and ligation of the distal submucosal ureteral remnant. Persistent or recurrent urinary incontinence after surgery has been frequently reported after this surgery. To restore the functional anatomy of the internal urethral sphincter mechanism in an effort to improve continence after surgery, the terminal segment of the intramural ureter is resected from the surrounding tissues of the bladder neck and urethra. Surgical apposition of the urethral mucosa and smooth muscle layers of the remaining defect are performed to realign the smooth muscle layer of the internal urethral sphincter mechanism.

A ventral midline cystotomy and urethrotomy is performed to expose the trigone and intramural ureter(s). Most displaced ureteral orifices are visualized distally within the bladder neck or urethra (Figure 29-28A). However, if a displaced ureteral orifice is located distally beyond the extent of this approach, a small incision can be made through the urethral mucosa into the lumen of the submucosal ureter to create an orifice avoiding the surgical morbidity of pelvic osteotomy. An appropriate sized (5,8 or 10 French) soft urethral catheter is passed retrograde through each displaced ureteral orifice (Figure 29-28B). With the catheter in place, the ureter is sharply dissected from the surrounding urethral tissues including the mucosa, submucosa and muscularis using small metzenbaum scissors. Surgical dissection through the seromuscular layer on the dorsal aspect of the urethra should be avoided. Primary closure of the mucosal/submucosal defect created by dissection in the bladder neck and urethra is performed using 4 or 5-0 synthetic absorbable, monofilament suture material in a continuous pattern. Closure of the urethral mucosa including a deep bite of the underlying smooth muscle layer is performed. Hemorrhage is controlled by placement of the suture pattern to close the defect. It may be necessary to dissect a portion of the submucosal ureter followed immediately by closure of the defect to control hemorrhage before continuing with the complete dissection (Figure 29-28C). The ectopic ureter is completely dissected from its submucosal position distally to the site where the ureter passes through the bladder wall. The ureteral remnant is transected approximately .5 cm from the site where the ureter passes through the bladder wall. To create a new permanent ureteral opening within the bladder, the ureteral mucosa is sutured to the bladder mucosa using 5-0 absorbable suture in an interrupted pattern (Figure 29-28D). An appropriate size soft urethral catheter can be passed from the bladder lumen distally to exit the vulva. The tip of an appropriate size balloon tipped urinary catheter is carefully sutured to the tip of the red rubber catheter protruding from the vulva with a silk suture. The urethral catheter is withdrawn into the bladder lumen to facilitate the passage of the balloon tipped catheter through the urethra during surgery. The urethral catheter is detached and discarded and the catheter balloon inflated with saline. The cystotomy and urethrotomy are closed

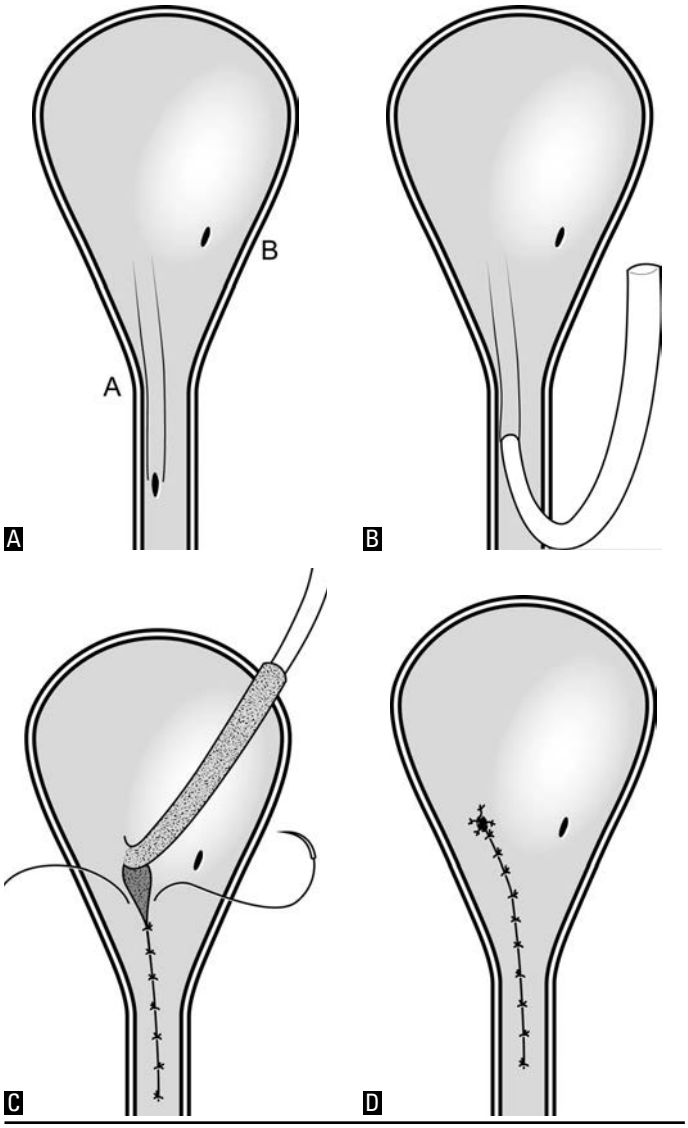

Figure 29-28. A. Neoureterostomy and trigonal and urethral reconstruction. A ventral midline cystotomy and urethrotomy expose the displaced ureteral orifice. **B.** The ectopic ureteral orifice is catheterized with an appropriate sized urethral catheter. **C.** The ureter is sharply dissected from the surrounding urethral tissues. Closure of the remaining defect in the bladder neck and proximal urethra is performed using a continuous or interrupted suture pattern. **D.** The ectopic ureteral remnant is completely dissected from its submucosal position distally to the site where the ureter passes through the bladder wall. The ureteral remnant is transected approximately .5 cm from the site where the ureter passes through the bladder wall. To create a new permanent ureteral opening within the bladder, the ureteral mucosa is sutured to the bladder mucosa.

using 4-0 absorbable monofilament suture in a single or double layer continuous or interrupted pattern.

The urinary catheter and a closed urine collection system should be maintained for 24 to 48 hours after surgery. Following removal of the urethral catheter, stranguria may be noted. Administration of NSAID therapy can be considered if renal function is normal.

Nephroureterectomy

Removal of a nonfunctional, dysplastic or hydronephrotic kidney with a severely dilated ectopic ureter is indicated as a salvage procedure provided renal function in the contralateral kidney is normal. Aerobic bacteriologic cultures from the renal pelvis should be obtained if a urinary tract infection is diagnosed prior to surgery or pyelonephritis is suspected. Perform a ventral midline celiotomy from xyphoid to pubis. Gently free the kidney from its retroperitoneal attachments and reflect it medially to expose the vascular pedicle and ureter at the dorsal aspect of the renal hilus. Bluntly dissect the perirenal fat from the renal hilus to expose the vascular pedicle. Isolate and doubly ligate the renal artery and vein individually with an appropriate sized silk suture. An additional transfixation suture is placed through the renal artery and the renal artery and vein transected. Sharply dissect the ureter from the ureteral fascia and retroperitoneal space to its termination. The ureter is ligated at its most distal point of attachment with a 3-0 absorbable suture and transected cranial to the ligature. *Nephroureterectomy without the removal of the associated intramural ureteral remnant will likely result in continued incontinence after surgery.* A ventral midline cystotomy and urethrotomy is performed to identify and remove the submucosal remnant of the ectopic ureter as previously described.

Post-Surgical Considerations

Mild to moderate ureteral dilation occurs following surgical manipulation of the ureter and generally resolves within 4 to 6 weeks after surgery. However, moderate to severe hydroureter, present prior to surgery, is most likely a developmental response of the ureter to increased lower urinary tract outflow pressure. Successful surgical correction of ureteral ectopia may improve but will not completely resolve the hydroureter in this situation.

Persistent urinary incontinence is the most common complication after surgical repair of unilateral or bilateral ureteral ectopia. Urinary incontinence has been reported to occur in 44 to 67% of patients undergoing either ureteral reimplantation, neoureterostomy or ureteronephrectomy alone. Patients with continuous or recurrent symptoms of urinary incontinence should be completely evaluated for additional causes of incontinence including urinary tract infection,other congenital abnormalities of the urogenital tract and primary sphincter mechanism incompetence. Aerobic bacteriologic cultures of urine samples obtained via cystocentesis should be performed and appropriate antibiotic therapy administered based on results of antibiotic sensitivity testing. Alpha-adrenergic drugs such as phenylpropanolamine, ephedrine sulfate and oxybutinin have been used successfully to manage some patients with mild urinary incontinence after surgery. An additional consideration for patients with unrelenting urinary incontinence after appropriate surgical correction of the ureteral ectopia, is the use of endoscopically placed urethral submucosal bulking agents such as bovine collagen to treat the sphincter mechanism incompetence.

Editor's Note: Until recently, surgical correction has been the primary treatment for ectopic ureter. Surgical correction is challenging and a high degree of technical skill is required. Surgical time, patient pain, and required hospitalization are potential disadvantages. Cystoscopic laser ablation performed by minimally invasive techniques has shown promising results. Cystoscopic capability and laser access are required. Consultation with an internist at a referral center is recommended.

Chapter 30

Urinary Bladder

Cystotomy and Partial Cystectomy

Elizabeth Arnold Stone and Andrew F. Kyles

Introduction

Cystotomy is indicated to remove cystic and urethral calculi, to approach ectopic ureters, to examine the interior surface of the bladder for tumors, polyps, and ulcers, to remove blood clots, sloughed urothelium, or foreign bodies, and to repair some types of bladder rupture. Partial cystectomy is indicated to excise bladder neoplasms, polyps, ulcers, patent urachus, urachal diverticula, and infected urachal remnants. Total cystectomy has been used as a treatment for malignant tumors that are extensive or that involve the trigone and ureters. Various surgical techniques for urine diversion after partial cystectomy with or without the creation of a urine reservoir have been described, but all are associated with significant postoperative morbidity. Alternatives to total cystectomy include palliative treatment by placement of a permanent cystostomy catheter, chemotherapy,and radiation therapy.

Depending on the indication, preoperative assessment before cystotomy or cystectomy should include evaluation of renal function, urinalysis, and quantitative bacteriologic culture and diagnostic imaging of the bladder using survey radiography, contrast cystography, or ultrasonography.

Surgical Technique

Cystotomy

A caudal midline incision is made in female dogs and cats. In the male dog, a paraprepucial incision is used; the skin incision curves lateral to the prepuce, the prepuce is retracted laterally, and a midline abdominal incision is made through the linea alba.

A ventral cystotomy incision is recommended because it provides better access to the trigone, ureteral openings, and proximal urethra than a dorsal incision, and the risk of adhesions or leakage is similar with either location of the incision.[1] The bladder is isolated from the abdomen with moistened laparotomy sponges or towels. A retention suture is placed at the cranial end of the bladder, and a second suture is placed at the caudal end of the planned incision. The length of the incision is determined by the size of the calculi or by the extent of the planned exploration of the bladder interior. The bladder is emptied by cystocentesis using a 22-gauge needle and syringe (Figure 30-1). A stab incision is made into the bladder with a scalpel. The incision is extended cranially and caudally with scissors (Figure 30-2). Retention sutures can be placed lateral to the incision to help open the bladder and to allow inspection of the interior (Figure 30-3).

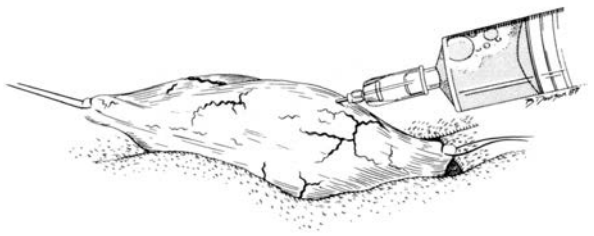

Figure 30-1. Retention sutures are placed cranial and caudal to the ends of the proposed cystotomy incision. Urine is removed by cystocentesis.

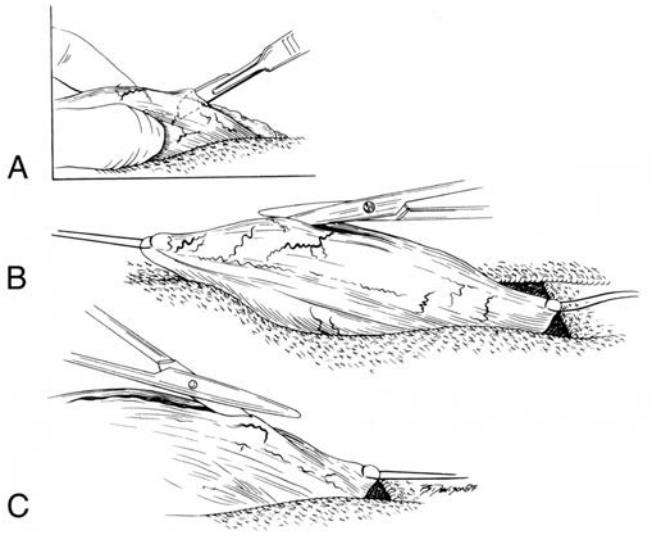

Figure 30-2. *A.* A stab incision is made into the bladder. *B.* and *C.* The incision is extended cranially and caudally with scissors.

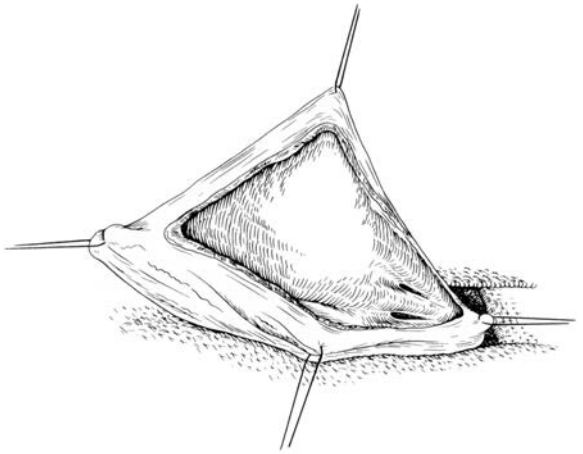

Figure 30-3. Retention sutures are placed on each side of the incision and the interior of the bladder is inspected.

Calculi are removed with a bladder spoon or forceps. Passing a urethral catheter and flushing the urethra from the bladder and from the urethral opening alternately can often dislodge urethral calculi. The bladder lining is inspected, and abnormal appearing areas are sampled for biopsy. The ureteral openings can be identified in the trigone and catheterized if necessary. The bladder is flushed with warm saline before closure.

The bladder is closed in one layer with absorbable suture material. An inverting pattern (e.g., Cushing) or simple continuous is used in a bladder of normal thickness, and a simple interrupted pattern is used in a thickened bladder wall (Figure 30-4). The suture material should not enter the lumen of the bladder, but should incorporate the submucosal layer. The bladder closure can be tested by injecting saline to distend the bladder and evaluating the incision for leakage. The abdomen is lavaged with warm saline and is closed routinely.

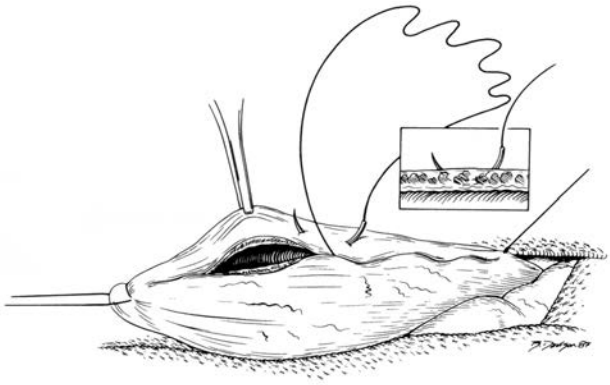

Figure 30-4. The bladder is closed in a single layer inverting pattern. In a thickened bladder wall, a simple interrupted appositional pattern is preferred.

Partial Cystectomy

Up to 75% of the urinary bladder can be excised and the remaining tissue closed around a 5 mL Foley catheter bulb. A return to normal bladder volume and function within 3 months is anticipated.

If bladder neoplasia is suspected, the bladder wall is gently palpated and a cystotomy incision is made at least 2 cm away from the bladder mass. The mucosal surface of the bladder is inspected for additional tumors. The mass should not be manipulated during the cystectomy. The bladder wall with the mass is excised with a 1 to 2 cm margin of grossly normal tissue. Care is taken to preserve as much of the blood supply to the bladder as possible. It is preferable to preserve the trigone with the ureters intact, but if necessary, the ureters can be reimplanted into another location in the residual bladder. After tumor excision, gloves and drapes should be changed and new instruments used to close the bladder and abdomen, to prevent tumor seeding.[2] Closure of the bladder incision is similar to the cystotomy closure described previously. Placement of simple interrupted sutures may facilitate apposition of the bladder remnant.

Postoperative Management

The patient should be allowed to urinate frequently. If this is not possible, the bladder should be kept empty for 2 to 3 days by intermittent catheterization or with an indwelling urethral catheter connected to a closed urine collection system. Following cystotomy, retrieved calculi are submitted for quantitative mineral analysis, and appropriate medical management is initiated to help prevent urolith recurrence. Following partial cystectomy, an indwelling urinary catheter should be placed if more than 50% of the urinary bladder is excised. Excised tissue should be submitted for pathologic examination. With suspected bladder neoplasms, evaluation of the tissue margin is facilitated by pinning the specimen flat to a corkboard and marking the edges of the excised tissue with India ink before fixing in formalin.

Cystostomy Tube Placement

Julie D. Smith

Introduction

Cystostomy tube placement is a method of diverting urine from its normal bladder and urethral flow. Clinical indications for cystostomy tube placement include temporary and permanent urine bypass of the urethra. Temporary bypass is indicated in patients with urethral obstruction due to urethral calculi, inflammation, or neoplasia. Temporary bypass may also be indicated in patients with bladder atonia while awaiting response to medication and for temporary urinary diversion after urethral surgery. Permanent cystostomy tubes can be used as palliative treatment for bladder neck or urethral neoplasia.

Latex or mushroom tipped or Foley urinary catheters have been used most commonly as cystostomy tubes. Low profile cystostomy tubes are more expensive but are less cumbersome and less prone to accidental removal. They are also more suitable for long term use.

Preoperative Management

In a patient with suspected urethral obstruction, placement of a transurethral catheter should be attempted. If a transurethral catheter cannot be passed, urethral obstruction can be temporarily bypassed by placement of a cystostomy tube. The tube can be placed quickly and with minimal anesthetic compromise to the patient. This placement allows for drainage of urine while awaiting more definitive diagnostic procedures or for stabilization of a critically ill animal before instituting more definitive therapy.

If urethral or prostatic neoplasia is causing significant urethral obstruction, a cystostomy tube can be placed through a

minilaparotomy or during a staging laparotomy. The cystostomy tube can be used as permanent palliative therapy, or it can be placed while awaiting response to more definitive therapy, such as chemotherapy or radiation.

Surgical Technique

A minilaparotomy (1 to 2 cm skin incision) is made in the caudal third of the abdomen. Usually, the bladder is easily palpable, and the incision is made over the bladder (Figure 30-5A). The incision can be made on the midline through the linea alba, or paramedian through the abdominal body wall. In male dogs, it is often easier to make a paramedian incision lateral to the prepuce, or alternatively, the prepuce can be retracted laterally to make a midline incision. The bladder is exteriorized, and two retention sutures are placed to allow for retraction (Figure 30-5B).

A pursestring suture using synthetic absorbable suture is placed through the serosa and muscular layers of the bladder wall in the ventral portion of the exteriorized bladder. When a ventral midline approach is used, the tube is placed through a separate paramedian incision in the body wall; when a minilaparotomy is performed, the tube can be placed through the primary body wall incision. A stab incision is made into the bladder within the pursestring (Figure 30-5C), and the cystostomy tube is introduced

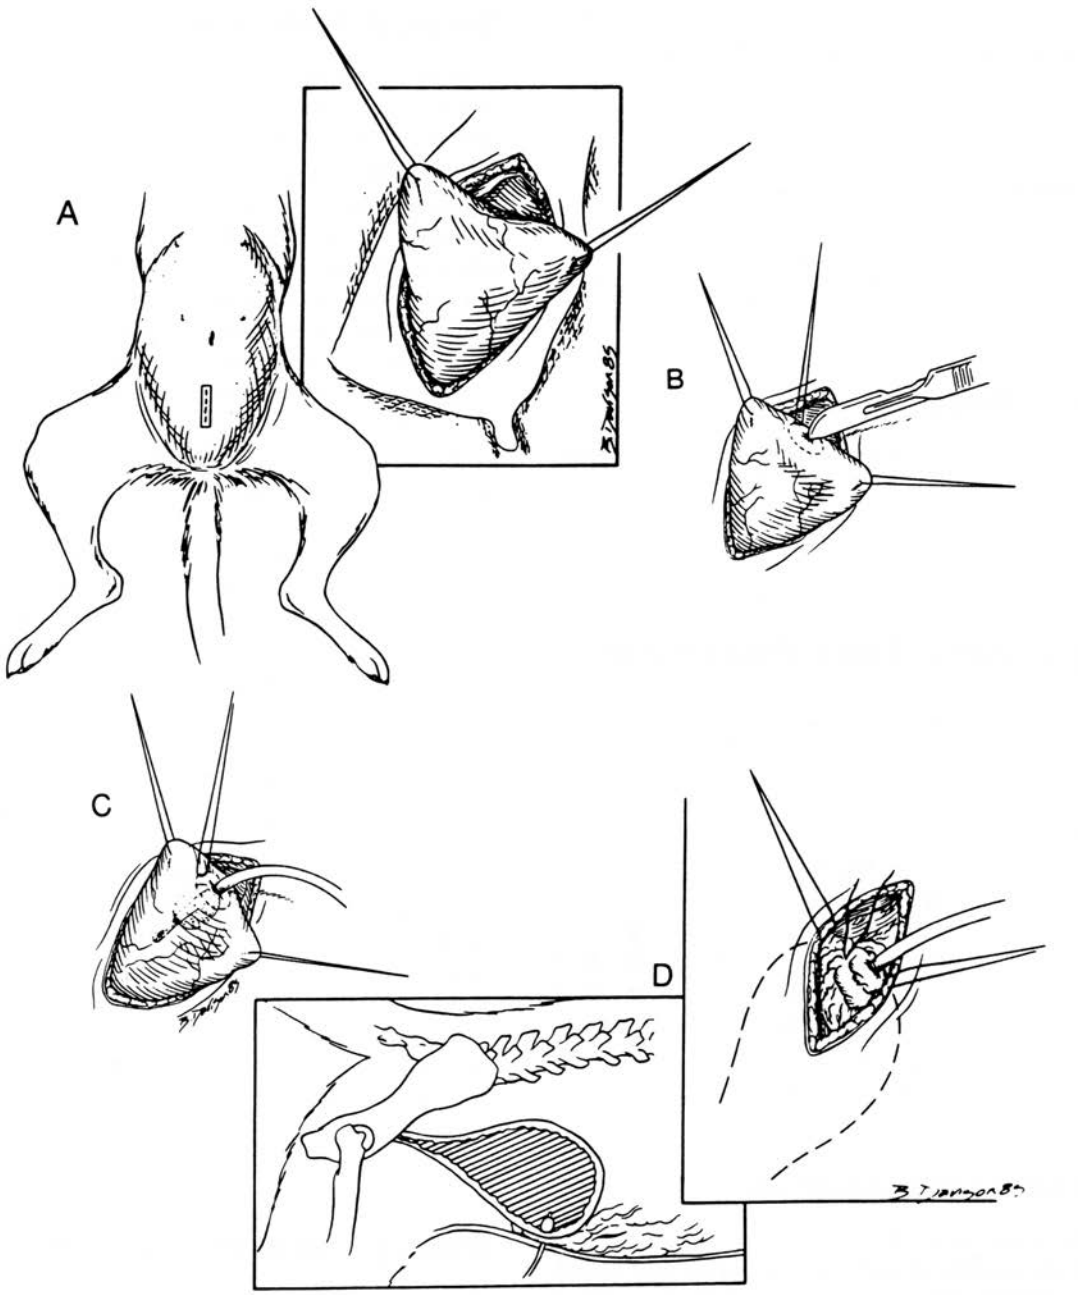

Figure 30-5. Cystostomy tube placement. **A.** Site of the skin incision. **B.** Exteriorized bladder held by retention sutures. **C.** Placement of the pursestring suture and stab incision into the bladder wall. **D.** Insertion of a Foley catheter into the bladder after passage through body wall. **E.** Omentum incorporated around the catheter to help secure the pexy of the bladder. **F.** Sagittal section with catheter in placed, with optional omentum wrapped around the cystostomy tube.

into the bladder (Figure 30-5D). A Foley catheter (8 or 12-French) is recommended for temporary bypass, and the catheter balloon is inflated with sterile saline. If the catheter is to remain in place for weeks to months, a mushroom-tip (Pezzar) urinary catheter or a low-profile cystostomy tube is recommended. The omentum can be incorporated around the catheter (Figure 30-5E), or the retention sutures can be placed between the bladder and the body wall to help secure the "pexy" of the bladder. The incisions in the body wall and skin are closed around the catheter, and the catheter is secured to the skin (Figure 30-5F). The catheter is connected to a closed drainage system, or alternatively, the bladder can be intermittently drained. The catheter can be safely removed after 7 to 14 days, allowing for a strong adhesion to form between the bladder and body wall. After tube removal, urine leaks from the stoma for 1 to 3 days: the stoma is allowed to heal by second intention.

Postoperative Management

After urine flow is restored by temporary bypass of the obstructed urethra, fluid therapy is continued to correct dehydration, azotemia, and electrolyte and acid-base disturbances. Urine output is carefully monitored by continuous, closed-system drainage in the critically ill patient.

If the cystostomy tube was placed to remain for a longer period (i.e., urethral neoplasia, bladder atonia), the clients can be taught to drain the patient's bladder intermittently with a syringe. The cystostomy tube should be protected from self-mutilation by the patient with an Elizabethan collar or side brace if necessary. Low-profile tubes offer an advantage over Pezzar or Foley catheters since they are less likely to become dislodged due to inadvertent snagging of the tube on various objects.

Over time, the presence of the cystostomy tube will cause a urinary tract infection. Prophylactic antibiotics are not recommended, because of the potential development of a resistant bacterial urinary tract infection or fungal infection. After removal of the tube, the urine should be cultured, and appropriate antibiotics should be administered. If the catheter is to remain in place permanently, the administration of antibiotics should be carefully considered only if the animal is showing systemic signs or discomfort from the urinary infection.

Colposuspension for Urinary Incontinence

Elizabeth Arnold Stone

Introduction

Urethral sphincter mechanism incompetence is a common cause of urinary incontinence in the bitch. It can occur as a congenital or an acquired condition and has multifactorial origin. Among factors contributing to the pathophysiology of the condition is a caudally located bladder neck and proximal urethra ("pelvic bladder"), a common finding in bitches with urethral sphincter mechanism incompetence. The caudally located bladder neck may predispose to incontinence during increases in intra-abdominal pressure when this pressure acts on the intra-abdominal bladder but is transmitted less efficiently to the extra-abdominal intra-pelvic proximal urethra. A competent urethra maintains urinary continence under these conditions, but in a bitch with urethral sphincter mechanism incompetence, such disparity in pressure transmission can result in urinary incontinence. Thus, bitches, with this combination of disorders, leak urine at times of abdominal pressure increases, particularly when they are recumbent.

Indication

In a bitch with a "pelvic bladder", colposuspension may alleviate urinary incontinence associated with urethral sphincter mechanism incompetence by moving the lower urogenital tract cranially, thereby positioning the bladder neck and urethra within the abdomen. After the procedure, increased intra-abdominal pressure is transmitted simultaneously to the bladder and to the bladder neck and proximal urethra. In this way, increases in intravesical pressure resulting from raised intra-abdominal pressure may be counteracted by simultaneous increases in urethral resistance.

Urethral sphincter mechanism incompetence is a multifactorial condition and colposuspension corrects only one of the factors. Thus, colposuspension is not expected to cure all animals. In a study of 150 bitches, approximately 50% were completely continent, with the degree and frequency of incontinence significantly reduced in a further 40%. The severity of the incontinence remained unaltered in 10% of bitches.[1] In another study, 55% of "spay-related" urinary incontinent bitches were completely dry, requiring no medical treatment, two months after surgery. However, less than 14% remained continent at 1 year with no treatment. With the addition of medication (usually phenylpropanolamine), 36% had complete control and another 41% were greatly improved 1 year after surgery.[3]

Our approach is to perform surgery in affected younger bitches (less than 8 years of age) as the first form of treatment in the hope that long term medical therapy and their potential side effects can be avoided. Colposuspension is delayed in juvenile bitches with congenital urethral sphincter mechanism incompetence until after the first estrus because more than half of such animals become continent after their first heat. Animals with severe

congenital urethral hypoplasia may be unsuitable for colposuspension. In such animals, the bladder neck cannot be returned to abdominal position by colposuspension. Fortunately, such severe urethral hypoplasia is rare, and its treatment is described elsewhere.[2] In older bitches, colposuspension is reserved for animals that have failed to respond to medical therapy.

Surgical Technique

After general anesthesia is induced, the bitch is placed in dorsal recumbency with the hind limbs flexed. The ventral abdominal skin and vagina are prepared for aseptic surgery, the vagina by douching with dilute aqueous povidone iodine solution. An 8 French (smaller bitches less than 35 kg) or a 10 French (larger bitches more than 35 kg). Foley catheter is inserted through the urethra into the bladder, and the cuff is inflated. The catheter is then gently withdrawn until the cuff rests in the bladder neck. The presence of the catheter facilitates identification of the urethra and bladder neck during surgery.

A midline, caudal abdominal approach is made. The prepubic fat and fascia are separated by careful blunt and sharp dissection on both sides of the midline at the level of the pubic brim, and the prepubic tendons and external pudendal vessels are identified (Figure 30-6A). These vessels must be avoided during subsequent placement of sutures around the prepubic tendon.

The midline incision is continued through the linea alba of the abdominal muscle wall and extends caudally to the pubic brim. Self retaining (Gosset or Balfour) retractors are used to hold the rectus abdominis muscle edges apart, and the bladder is identified. Cranial traction on the bladder allows the intrapelvic bladder neck to be pulled into the abdomen and identified by the presence of the inflated Foley catheter cuff. Seeing the bladder neck and proximal urethra is often difficult because of the presence of local retroperitoneal fat.

The vagina is displaced cranially and is cleared of fat and fascia on both sides of the urethra. This is most easily accomplished by inserting a finger into the vagina (Figure 30-6B and C). The urethra is palpated through the ventral vaginal wall and is displaced to the bitch's left. Using the finger in the vagina, the vaginal wall on the right side of the urethra is pushed cranially and ventrally toward the caudal end of the abdominal incision. The vaginal wall is exposed by using a dry swab to clean off the overlying fat and fascia in a caudolateral direction (Figure 30-6C). The bladder neck can be seen as a swelling because of the Foley catheter cuff in the bladder. The vaginal wall is grasped with Allis tissue forceps. The technique is repeated on the other side of the vagina (Figure 30-6D). The surgeon then changes gloves, and the vulva is covered with a large sterile swab or surgical drape throughout the remainder of the procedure.

When the surgeon's finger and the patient's vagina are of incompatible sizes (very large or very small bitches or those with gross vaginal strictures or septa), the vagina has to be located by blunt and sharp dissection of the overlying fat and fascia on either side of the urethra, grasped with tissue forceps, and then pulled cranially. This is more difficult than the use of a finger in the vagina, and, fortunately, most bitches with urethral sphincter mechanism incompetence are of a size compatible with one's finger. It is sometimes helpful in extremely large or small bitches to identify the vagina by inserting a Poole suction tip or a closed Carmalt clamp.

The vagina must now be anchored cranially to maintain the bladder neck in an intra-abdominal position. The vagina is sutured to the prepubic tendon on each side of and approximately 1 to 1.5 cm away from the midline. The sutures (monofilament nylon) are passed through the abdominal wall caudal to the tendon, in and out of the vaginal wall (as far laterally as possible), and back out of the abdominal wall cranial to the tendon, avoiding any abnormal twisting of the vaginal wall (Figure 30-6E). The sutures may enter the vaginal lumen during this procedure, hence the need to prepare the vagina for aseptic surgery.

One or two sutures are placed around the prepubic tendon, depending on the size of the bitch and the position of the external pudendal vessels laterally. Most affected bitches are medium to large breeds, and the optimum number of sutures is two around each tendon (Figure 30-6F). Number 0 nylon is suitable for most bitches, but No. 1 nylon should be used in very large breeds. On the rare occasions when colposuspension is performed in small or toy breeds, it may only be possible to place one suture through each side of the vagina and around each prepubic tendon.

Before the sutures are tied, they are pulled tight to ensure that, after they are tied, the urethra will not be compressed against the pubis by an arch of vagina (See Figure 30-6F). Compression on the urethra may result in postoperative dysuria. The surgeon should be able to insert the tip of a blunt instrument such as Mayo scissors or Carmalt forceps easily between the urethra and the vaginal arch and pubis. If the urethra is compressed, the sutures should be repositioned. This is rarely a problem when the sutures have been placed as far laterally on the vagina as possible. After the sutures are properly placed, they are tied, the Foley catheter is removed, and the abdomen is closed routinely.

Postoperative Care

Preoperative, perioperative, and postoperative analgesics are used routinely. These are not usually required after the first 24 hours. Antibiotic therapy (e.g., amoxicillin) is used for 10 days postoperatively as a precaution to minimize the risk of peritonitis in case colposuspension sutures have entered the vaginal lumen. We have never encountered this complication. The use of a rectal thermometer to take the animal's temperature postoperatively is avoided because some bitches are sensitive in this area for a few days after surgery. In some bitches, local subcutaneous tissue swelling occurs, presumably because of the small dead spaces left after dissection to expose the prepubic tendons. Such swelling is not a problem and resolves spontaneously within 5 to 7 days. The animal is closely observed for signs of dysuria and to determine whether the incontinence has resolved. In most successful cases, the response is immediate, although some bitches remain incontinent for weeks before becoming continent. Skin sutures are removed routinely 7 to 10 days after the surgical procedure.

Possible Complications

Because the surgical procedure involves trauma to intrapelvic structures, some animals are stimulated to strain, usually immediately after recovery from general anesthesia. This can be controlled by the administration of appropriate analgesics. Rarely, some bitches find the first postoperative defecation uncomfortable if the feces are firm and bulky. This problem can be controlled with stool softeners.

Dysuria may occur immediately postoperatively. This complication is rare (approximately 5% of dogs in our experience) and may be caused by vaginal stimulation by the surgical procedure leading to suppression of the micturition reflex or reflex dyssynergia. Clinical observations and the response to diazepam suggest that reflex voluntary dyssynergia is the most likely cause of dysuria after colposuspension. It may be exacerbated by recent estrogen therapy, and so any estrogen therapy should cease at least 1 month before the operation. Voluntary dyssynergia usually responds to diazepam at a dose of 0.2 mg/kg by mouth two or three times daily. An indwelling urinary catheter can be used for a few days if necessary in the few animals that are unable to urinate at all. A further potential cause of dysuria is compression of the urethra against the pubis by the vagina. Care should be taken during surgery to avoid placement of vaginal sutures too close to the urethra.

Bitches that are allowed to be active after colposuspension may tear the sutures from the vagina. This is more likely to happen if these animals are allowed to jump, and owners should be advised of the necessity to restrict the exercise of their animals to leash walks only for 1 month postoperatively.

"Hymen" formation with accumulation of vaginal secretions causing dysuria or dyschezia is a rare, longer-term complication of colposuspension. This complication is caused by breakdown of a pre-existing vestibulovaginal stricture during the operation and subsequent healing of apposing raw areas of vagina to form a barrier across the vaginal lumen. It can be treated by breaking down the "hymen".

Chapter 31

Urethra

Surgical Management of Urethral Calculi in the Dog

Don R. Waldron

Introduction

Passage of urinary bladder calculi from the urinary bladder into the urethra may result in partial or complete urinary obstruction especially in the male dog. Calculi may lodge anywhere in the urethra but most commonly cause obstruction by lodging at the base of the os penis. The urethra at this level is narrow and does not distend owing to the presence of the os. Urethral calculi are less common in females as urethral distensability allows passage of the calculi in many cases. Dogs with partial or total urethral obstruction strain to urinate and pass little or no urine. Depending upon the duration of obstruction, the animal may be anxious, depressed or weak and the urinary bladder is usually distended. If the animal is azotemic and prolonged obstruction has occurred, vomiting and hypothermia may be present.

Preoperative Management

Complete urethral obstruction causes postrenal uremia that results in electrolyte and acid-base imbalance. Hyperkalemia and metabolic acidosis are the most likely abnormailities. The goals of therapy are correction of any fluid or acid-base imbalance by intravenous fluid administration and relief of urethral obstruction. Normal saline (0.9%) is the fluid of choice although Ringer's may also be used.

Urethral obstruction is relieved by catheterization or a combination of cystocentesis and catheterization. Tranquilization or sedation with narcotics or ketamine/diazepam, or propofol may be necessary during efforts to establish urethral patency. In some cases, general anesthesia is preferred especially if the animal is metabolically normal. A urinary catheter is advanced to the level of obstruction and sterile saline infused under pressure in an effort to hydropulse the stones retrograde into the urinary bladder. Liberal lubrication of the catheter and inclusion of sterile lubricant within the fluid may assist in dislodging the obstructing calculi. The veterinarian or assistant may assist in urethral dilation by performing a digital rectal exam and occluding the pelvic urethra simultaneously with fluid infusion. Sudden release of digital urethral occlusion may allow calculi hydropulsion. If initial efforts are unsuccessful, cystocentesis to relieve bladder and urethral pressure may permit successful hydropulsion. Some veterinarians report successful flushing of stones distally out the end of the penis by the method described and quick withdrawal of the catheter. It is imperative to maintain digital urethral occlusion proximally to flush stones distally. If attempts to move the calculi by catheterization techniques are unsuccessful, the veterinarian may attempt to bypass the obstructing calculi with a smaller catheter to relieve bladder distension.

Once successful passage of the catheter to the bladder has been achieved, the catheter is attached to a closed fluid/urine collection system .

Surgical Techniques

Prescrotal Urethrotomy

In most cases, urethral calculi are successfully hydropulsed to the urinary bladder allowing cystotomy and calculi removal as an elective procedure when the patient is able to undergo anesthesia and surgery safely. Urethrotomy is performed most often at the base of the os penis to remove obstructing calculi when hydropulsion fails to flush the calculi into the bladder. Alternatively, a scrotal urethrostomy may be performed as a permanent urinary diversion procedure, this procedure requires neutering the patient (see Scrotal urethrostomy).

To perform prescrotal urethrotomy, a skin incision is made from the base of the os penis to just cranial to the base of the scrotum (Figure 31-1A). Subcutaneous tissue is sharply incised permitting identification of the retractor penis muscle which overlies the purplish colored corpus spongiosum. The retractor penis muscle is mobilized and retracted laterally. The surgeon grasps the urethra between the thumb and forefinger and elevates the urethra from the incision, this maneuver decreases hemorrhage as the corpus spongiosum and urethra are longitudinally incised directly over the obstructing calculi with a number 15 scalpel blade (Figure 31-1B). All obstructing calculi are removed by flushing or grasping calculi with a mosquito hemostat. Removal of all calculi, and patency of the urethra, is assured by successful passage of a urinary catheter to the urinary bladder proximally and distally through the penile urethra.

Surgical closure of the urethrotomy may be performed or the urethra and skin incisions allowed to heal by second intention (Figure 31-1C). If the urethra has been damaged by catheterization or calculi second intention healing is recommended. Suture closure of the urethra with 4/0 monocryl or polydioxanone on a tapered needle with simple interrupted sutures will reduce hemorrhage postoperatively but requires increased operative time. Gentle tissue handling and meticulous technique are recommended to decrease the chance of postoperative urethral stricture formation. Care is taken to appose the mucosal edges precisely. The subcutaneous tissue and skin are closed routinely. An indwelling urinary catheter is not routinely placed whether suture closure or second intention healing is selected. The incidence of urethral stricture following suture closure or second intention healing of the urethra has not been reported in clinical patients but appears to be low when urethral tissue is healthy and well vascularized.

Postoperative Management

Urine output, hydration status, renal function and electrolyte concentrations are closely monitored for 24 to 48 hours postoperatively. Post-obstructive diuresis may cause dehydration and electrolyte abnormalities including hypokalemia. If suture closure is not performed the dog will urinate from the urethral incision for 10 to 14 days as the wound heals. Bleeding from

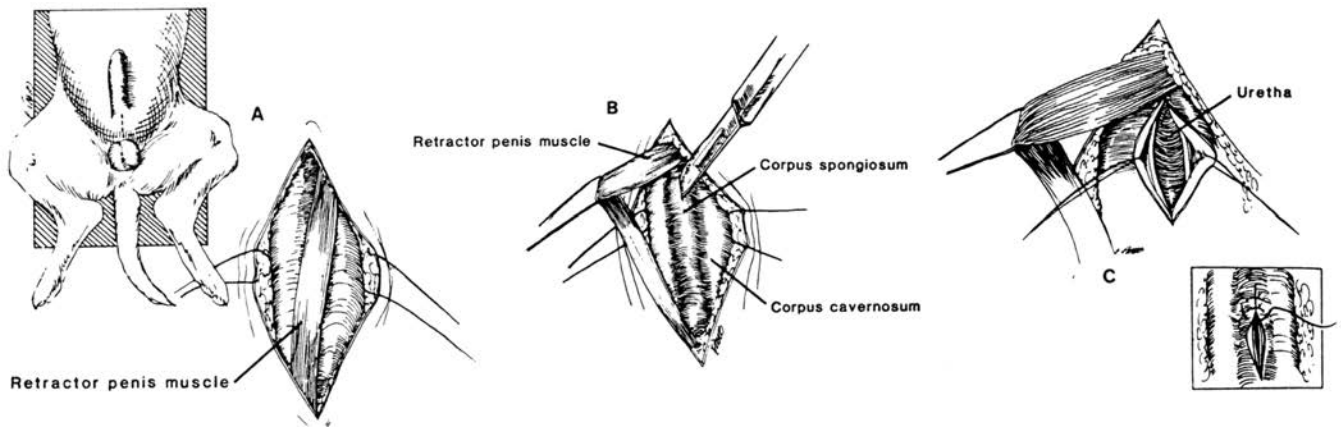

Figure 31-1. Prescrotal urethrotomy. **A.** Site of skin incision and dissection of subcutaneous tissue to the retractor penile muscle. **B.** Longitudinal incision into the corpus spongiosum and urethra after lateral retraction of the retractor penis muscle. **C.** Retention sutures in the corpus cavernosum and exposure of the urethral interior. After removal of uroliths, the urethrotomy can be left open or closed in a simple interrupted pattern (inset). (From Stone EA. Urologic surgery: an update. In: Breitschwerdt, EB, ed. Contemporary issues in small animal practice. Vol. 4. Nephrology and urology. New York: Churchill Livingstone, 1986.)

the urethra occurs concurrently with urination especially in the first few days following surgery if second intention healing is selected. Hemorrhage does not typically reach serious levels but does increase hospitalization time. Should stricture occur, scrotal urethrostomy is recommended.

Editor's Note: Laser lithotripsy of urethral calculi can be an effective mode of therapy for relieving obstruction without surgery. Cystoscopic capability and laser access are required.

Scrotal Urethrostomy

Daniel D. Smeak

Introduction

Scrotal urethrostomy is the procedure of choice in the canine when creation of a permanent urethral orifice distal to the pelvic urethra is necessary. Scrotal urethrostomy has several advantages over prescrotal, prepubic, or perineal urethrostomy. The membranous urethra in the region of the scrotum is larger and more distensible than the prescrotal urethra. These characteristics reduce the risk of stricture formation and calculi pass more readily through the stoma following urethrostomy. The urethra in the scrotal area is also more superficial and surrounded by less cavernous tissue than in the perineal region (Figure 31-2). Surgical exposure is easier, there is less tension on the urethrostomy, and the risk of hemorrhage or urine extravasation into periurethral tissues is reduced. Scrotal urethrostomy diverts urine directly downward and away from perineal skin. Skin surrounding the urethrostomy is kept dry and this reduces the risk of intractable dermatitis from urine scalding.[1] Most urethral calculi are readily removed from the distal urethra or flushed back to the bladder by scrotal urethrostomy. I do not recommend a urethrostomy in the prescrotal region since urine expelled from the stoma often becomes misdirected and tends to soil the skin of the scrotum, inguinal region, and medial thighs and this area tends to stricture more readily than urethrostomies performed in the scrotal region.[1,2] If castration is objectionable to the owner or the lesion is more proximal, however, other urethrostomy locations should be considered.[3,4]

Indications

Scrotal urethrostomy is indicated for the following conditions: (a) recurrent urethral calculi that are not responsive to appropriate medical therapy; (b) acute calculi obstruction in dogs anticipated having recurrent episodes (e.g., metabolic stone formers); (c) severe distal urethral wounds secondary to penile or os penis trauma; (d) urethral stricture distal to the scrotum from trauma or previous urethral surgery; and (e) diseases requiring amputation of the penis or prepuce and formation of a more proximal urethral stoma (e.g., extensive neoplasia in the region, penile strangulation, certain congenital diseases such as severe hypospadias, and deficiency in penile or preputial length).[1] Because a permanent stoma that bypasses the normal opening of the urethra may increase the risk of ascending urocystitis, a urethrostomy should not be performed unless due consideration is given to the indications and complications of the procedure.[5,6]

If both urethral and bladder calculi are found in dogs requiring scrotal urethrostomy, I prefer to perform the urethrostomy first. After the urethrostomy stoma is created, the surgeon can flush any remaining (more proximally located) calculi back into the bladder, and then perform a cystotomy. This allows both normograde and antegrade urethral irrigation during cystotomy to ensure that all urethral calculi have been removed. If the cystotomy is completed first, any urinary stones remaining in the proximal urethra often cannot be removed via the scrotal urethrostomy, and are then flushed back into the bladder during retrograde irrigation.

A modified urethrostomy technique is described here because the standard simple interrupted scrotal urethrostomy technique often results in unacceptable bleeding and bruising complications.[6] In a retrospective study of dogs undergoing standard scrotal urethrostomy, active hemorrhage (requiring patient hospitalization) was noted an average of 4.2 days following surgery; in some patients bleeding persisted up to 10 days.[6]

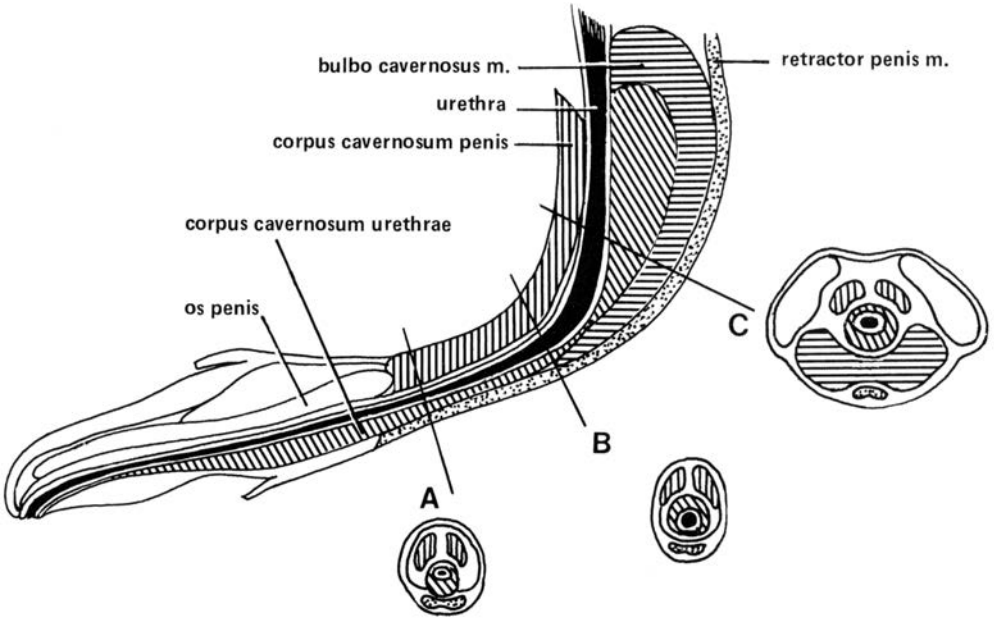

Figure 31-2. Schematic diagram showing cross sections of the penis and urethra in the prepubic *A.* scrotal *B.*, and perineal *C.* locations. The urethra in the prescrotal and scrotal area is more superficial and is surrounded by less cavernous tissue than the perineal area. The scrotal urethra is more distensible and larger in diameter than the prepubic urethra, allowing easier passage of calculi and reducing the risk of postoperative stricture formation.

The following modified scrotal urethrostomy technique uses a continuous suture pattern and a three-needle bite sequence for urethrostomy closure.[5] In my experience, this modification has dramatically reduced active bleeding, bleeding after urination, and bruising postoperatively. Furthermore, no stricture or suture line breakdown has been observed to date. This closure is also faster to perform.

The rationale for the modified technique is several fold. Simple continuous suture patterns produce a better seal by apposing tissues more completely. Continuous suture patterns require fewer knots, and irritation from "prickly" knot ears is reduced. Needle bites are placed closer together and this also improves urethra-to-skin apposition. *Incorporation of a bite of tunica albuginea adds additional strength to the incision line and helps seal incised cavernous edges* (see surgical technique). When the needle is passed outward from the urethra to skin, better apposition of cut surfaces results. All these advantages, I believe, help reduce suture line breakdown and hemorrhage.

Surgical Technique

The surgeon must obtain the owner's consent for the animal's castration before performing scrotal urethrostomy in intact dogs. Metabolic disturbances are stabilized in the obstructed patient preoperatively. I prefer to give an epidural administration of a narcotic to help alleviate pain in the immediate perioperative period. While the patient is under general anesthesia, the surgeon places the patient in dorsal recumbency with the rear limbs gently abducted and secured caudally. The proposed surgery site including the scrotum is clipped and scrubbed routinely and is draped for aseptic surgery. An elliptic full-thickness skin incision is made around the base of the scrotum. Hemostasis is maintained and the isolated scrotal skin is discarded (Figure 31-3). Enough skin should be left on the lateral aspect of the incision so no tension is placed on the urethrostomy during closure or with rear limb abduction. If there is any doubt, ample scrotal skin should be preserved and any redundant skin can be removed later in the procedure. If the dog is sexually intact, the testicles and spermatic cords are isolated and the dog is neutered in a routine manner (Figure 31-4). The underlying connective tissue is dissected to expose the paired retractor penis muscles, which appear as a thin brownish-tan band on the ventral surface of the penile shaft. The surgeon sharply dissects and mobilizes the retractor penis muscles, and

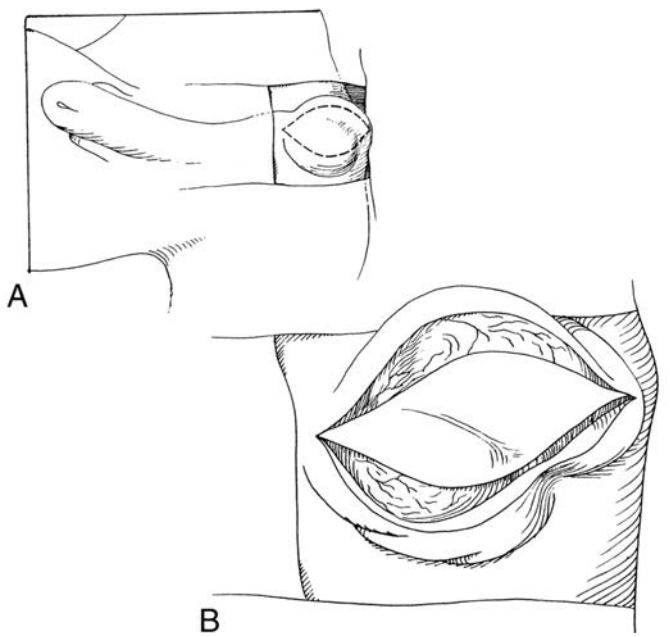

Figure 31-3. A. and **B.** An elliptical incision is made at the base of the scrotum. Enough lateral skin is retained to allow tension-free closure of the urethrostomy. Redundant skin can be resected later in the procedure.

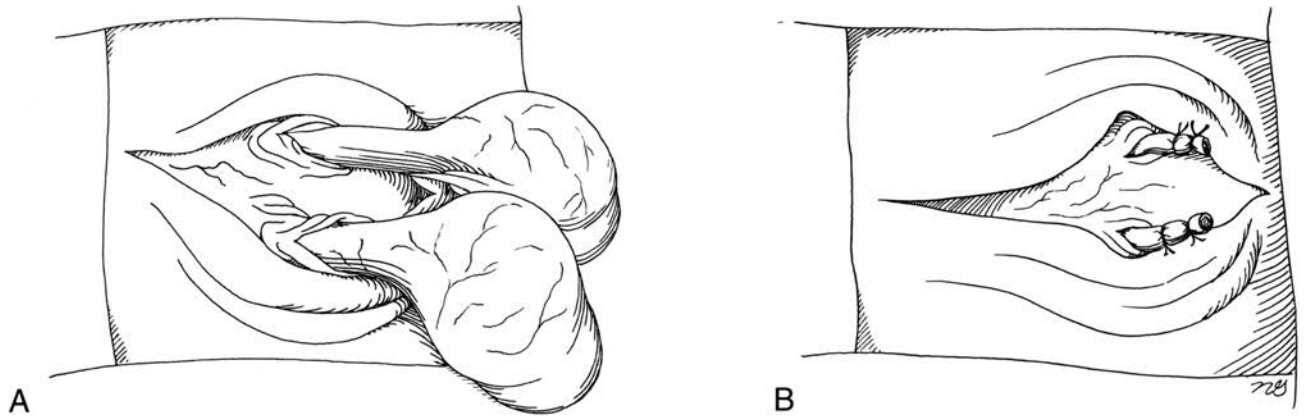

Figure 31-4. A and **B.** The isolated scrotal skin is removed, and castration is performed.

retracts them laterally to expose the bluish corpus spongiosum urethrae (Figure 31-5). An appropriately sized red rubber urinary catheter is inserted retrograde from the normal penile opening, if possible, to outline and distend the urethra. The ventral midline of the urethra is sharply incised over the catheter with a #15 Bard-Parker scalpel blade. If a catheter cannot be inserted, the incision must be made carefully to avoid accidental laceration of the dorsal urethral surface. Blunt tenotomy or iris scissors are used to enlarge the urethral incision to 2.5 to 4 cm in length (approximately five to eight times the diameter of the urethra) to ensure sufficient urethral lumen size after healing is complete. The incision length appears excessive at first but after complete healing of the urethrostomy, the opening is approximately 2/3 to 1/2 the original length. The surgeon should stay directly on midline with scissors to reduce intra-operative and postoperative hemorrhage from cavernous periurethral tissue. Intra-operative hemorrhage is controlled with direct digital pressure. Electrocoagulation should not be used in tissues in the immediate vicinity of the urethrostomy site. The caudal limit of the incision is chosen to ensure that the new urethral stoma will allow urine to be diverted directly ventral from the ischial arch (Figure 31-6). A monofilament, nonabsorbable suture material (size 4-0 or 5-0) is selected for the urethrostomy because this material incites little inflammatory response and has minimal tissue drag. A taper-cut swaged-on needle is preferred to reduce the size of the needle tract through the cavernous tissue.

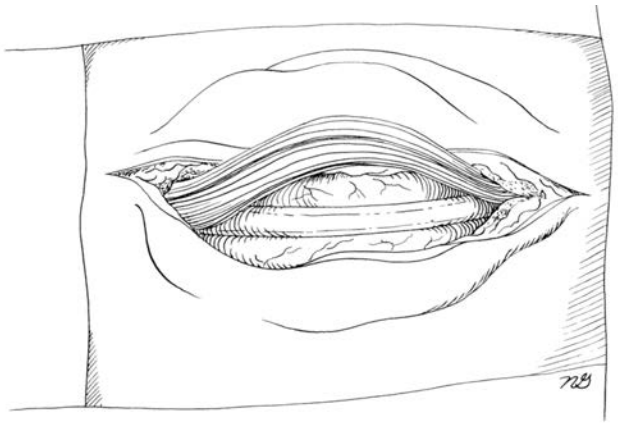

Figure 31-5. A urinary catheter is placed retrograde from the penile orifice to help to identify the urethra. The retractor penis muscles are retracted laterally and the ventral midline of the urethra is visalized.

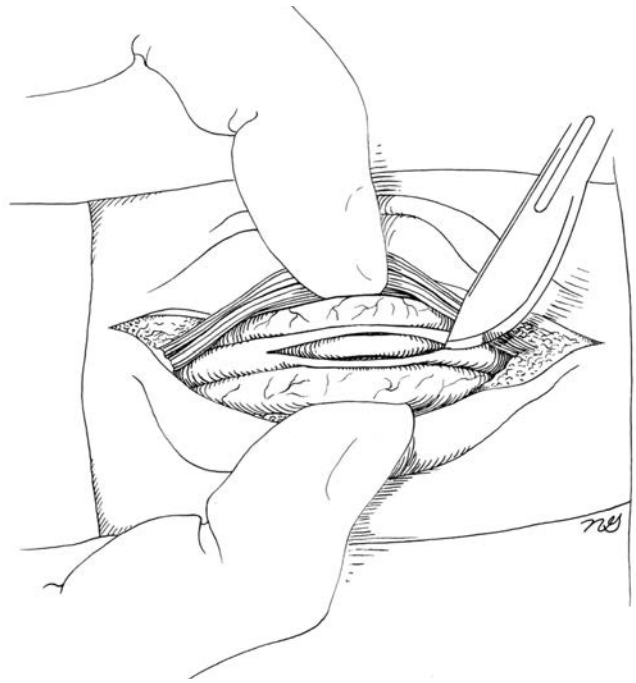

Figure 31-6. The ventral midline of the urethra is incised for 2.5 to 4 cm while immobilizing the penile shaft between the thumb and forefinger. The incision extends far enough caudally to ensure that direct ventral urine drainage can occur from the level of the ischial arch.

In addition, this needle can be inserted through the skin without difficulty and is less likely to cut friable urethral mucosa.

Sutures should appose the skin and urethral mucosa accurately, to avoid possible stricture formation. When excess tension is present, the surgeon should try to adduct the patient's rear limbs before attempting closure. A deep suture line should be placed from the subdermal layer to the tunica albuginea if additional tension relief is necessary before closure of the skin and urethra.

The needle is inserted in an outward direction from the urethral lumen to the skin for best apposition. The first suture is placed from the corner of the caudal urethral incision to the corner of the caudal skin incision. Each suture pass comprises three tissue bites. The sequence begins with a 2 mm bite of urethral mucosa. Next, the needle is passed through a 2 mm bite of

fibrous tunica albuginea and, finally a 2 to 3 mm split-thickness bite of skin (Figure 31-7). A simple continuous suture line is used, with tissue bites 2 to 3 mm apart beginning caudally and working cranially (Figure 31-8). The urethral mucosa and skin margins are grasped gently and only when necessary to avoid excessive inflammation, which can lead to dehiscence and stricture. The urethral mucosa and skin are approximated without gapping. The suture line should not be tight and each suture pass should have even tension. After the first side of the urethrostomy is closed, a separate simple continuous suture closure completes the new stoma. The surgeon should excise any redundant skin in the cranial aspect of the incision to create a cosmetic closure. If the cranial aspect of the skin incision extends beyond the urethral incision, it is closed with simple interrupted sutures.

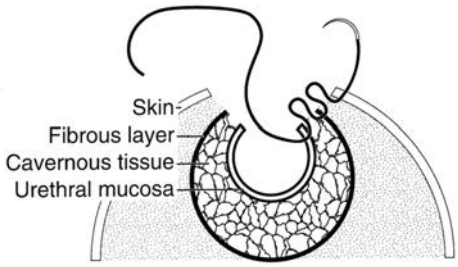

Figure 31-7. Three-needle bite sequence for closure of urethra to skin. The needle is inserted first through the urethral mucosa, followed by the tunica albuginea, and then a split-thickness bite of skin. The incised cavernous tissue is sealed between the urethral mucosa and tunica albuginea.

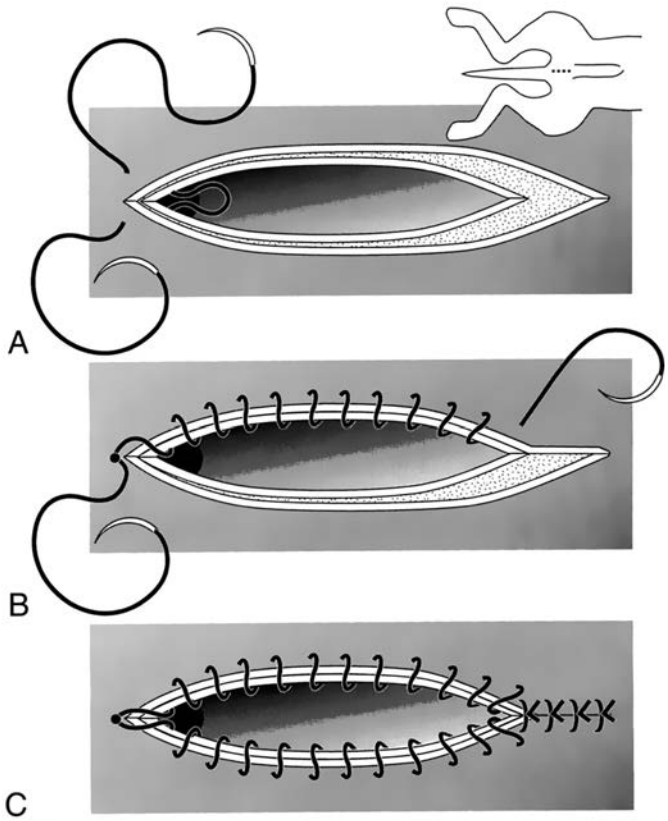

Figure 31-8. Suture the urethral mucosa to the skin beginning at the caudal aspect of the wound and continuing cranially. Place subsequent sutures in continuous fashion to complete one side of the urethrostomy. Another continuous line on the opposite side of the incision completes the procedure. Routinely close any remaining skin outside the urethrostomy.

Postoperative Considerations

Creation of a urethrostomy will not cure urinary tract infection or remove the source of urinary calculi. It can be expected that any procedure that shortens the functional length of the urethra such as urethrostomy, increases the risk of urinary tract infection.[3] Strict aseptic procedures should be adopted during stoma inspection and urethral catheterization to reduce this risk. Since the urethrostomy is located distal to the pelvic urethra (the area that controls urethral flow) there is no concern about creating incontinence following surgery. Owners should understand that urethrostomy reduces but does not completely eliminate the risk of urethral obstruction by calculi. If obstruction occurs, these patients are usually readily managed by catheterization and hydropropulsion of the calculi.

An Elizabethan collar or side body brace is placed on all dogs immediately after urethrostomy until healing is complete; or about 2 to 3 days after suture removal. The incision area is kept clean but blood clots are not removed unless they obstruct urine flow. A film of petrolatum jelly is applied to the skin around the urethrostomy site once or twice daily until postoperative swelling is reduced (3 to 5 days) to reduce urine scalding of surrounding skin. Topical anesthetic agents (5% Xylocaine ointment, Astra Pharmaceutical Prod., Inc., Westborough, MA 01581) can be applied to the exposed urethra if the patient is showing discomfort during urination. Minor bleeding can be treated with application of direct pressure over the urethrostomy site and cold compresses. On rare occasions, if bleeding from the stoma is profuse and localized, additional sutures may be placed in gaps between the urethra and skin. Sedatives can also be used to reduce bleeding if the patient is hyper-excitable. Exercise is strictly limited because any episodes of excitement, could lead to excessive hemorrhage from the urethrostomy, and to reduce motion and tension at the stoma to reduce the risk of dehiscence. Dogs are usually hospitalized for the first two days since owners are often concerned about mild postoperative hemorrhage that is usually present especially during and just after urination. Urine samples collected via cystocentesis should be cultured routinely after antibiotics are discontinued to determine if urinary tract infection is present. Urinary calculi are submitted for quantitative analysis and the patient treated with appropriate antibiotic, dietary, and medical therapy once calculus type is known. Urine voiding habits should be monitored indefinitely to identify early signs of obstruction or infection. Nonsteroidal anti-inflammatory drugs are used judiciously for 3 to 5 days after surgery to help reduce inflammation and pain.

Sutures are removed 10 to 12 days following the surgical procedure. Removal of a continuous suture line is more difficult than removal of simple interrupted sutures placed in the urethra. Migrating epithelium often partially covers exposed suture and sedation is necessary to remove sutures without causing pain and trauma.

Swollen, bruised, and painful areas of skin surrounding the urethrostomy may signal leakage of urine into the subcutaneous tissues. Placement of an indwelling soft urinary catheter is indicated in these dogs for three to five days, or until the edges of the urethrostomy are sealed. In general, catheters should be avoided because they increase the risk of urinary tract infection and may increase the risk of stricture. Dehiscence of the urethrostomy should be repaired primarily, without tension, using the materials and suturing techniques described previously if the tissues are healthy; otherwise allow the area is allowed to heal by second intention and either reconstruct the strictured stoma or divert urine through a more proximal urethrostomy site.

Perineal Urethrostomy in the Cat

M. Joseph Bojrab and Gheorghe M. Constantinescu

Feline urologic syndrome (FUS), a synonym for lower urinary tract disease in the feline, can result from various single, multiple and interacting, or unrelated etiologic factors. Factors implicated in the development of FUS are infectious agents such as viruses and bacteria, diet, and urachal anomalies, especially bladder diverticula.

Crystalluria is a common clinical finding in cats and is characterized by microscopic precipitates in the urine. The most prevalent crystal type is struvite (magnesium ammonium phosphate). In normal cats, these crystals are passed in the urine during normal micturition. Urine from cats with FUS contains crystals that coalesce with a matrix of mucus and debris, to form a macroscopic semisolid mass, or concretion. Crystal formation is enhanced in an alkaline pH and is inhibited in a more acidic pH.

Urethral obstruction has been associated with concretions and urethral plugs. Other causes of urethral obstruction are strictures, lesions of the prostate gland, and extraluminal masses that compress the urethral lumen. Obstruction of the urethra by plugs occurs commonly in male cats but infrequently in females. The explanation for this difference resides in the anatomic differences in urethral structure between the sexes. The urethra in the male cat is long and narrow, whereas it is short and wide in the female.

Crystals composing a concretion have razor-sharp edges, which protrude from the concretion margins. In the male cat, at the root of the penis just proximal to the bulbourethral glands, the urethral lumen diameter narrows, creating a funnel effect. As a concretion passes down the urethra, it may become lodged at this point. Initially, the cat can usually force a concretion through the penile urethra by straining. This action, however, forces the sharp edges of the crystals into the urethral mucosa, resulting in multiple lacerations. This trauma results in hemorrhage, urethral inflammation, edema, and swelling, which decrease the urethral diameter even further. Passage of another concretion through the urethra results in an obstruction that cannot be dislodged by the animal. This situation requires emergency treatment to remove the urethral obstruction and reestablish urine flow.

Diagnosis

The diagnosis of FUS is based on history, clinical signs, and palpation of a large, firm, tense bladder. The history may include urination in unusual locations along with increased frequency in attempts to urinate. This increased frequency may be mistaken for tenesmus by the client. Frequent licking at the genital area and occasional hematuria may also be present. With progression of the condition, the cat may become depressed, listless, or comatose. Prolonged obstruction results in hyperkalemia, which can lead to cardiac irregularities and subsequent death.

Medical Treatment

The first step in emergency treatment of urethral obstruction is to relieve obstruction. This can be done by catheterization of the urethra, which in the severely depressed or comatose patient can be accomplished without the use of anesthetics. If attempts to dislodge the obstruction are likely to result in additional urethral damage or to induce urinary tract infection, pharmacologic restraint should be considered. An ultrashort acting anesthetic should be selected for sedation since the cat may have metabolic abnormalities. Anesthetics must be given cautiously, because effective doses in patients with postrenal azotemia tend to be lower than in animals with normal renal function.

To relieve the obstruction, concretions lodged in the distal penis are first milked out by gently rolling the penis between the thumb and forefinger. Additionally, massaging the urethra through the animal's rectum may help to dislodge abdominal or pelvic urethral concretions. Voiding is then induced by gentle urinary bladder palpation. If urethral massage and bladder expression fail to dislodge the obstruction, retrograde urethral flushing is attempted to dislodge the concretion into the bladder by hydropropulsion.

The penis is exposed, washed, and a 3.5-French open-ended tomcat catheter, lubricated with a sterile gel, is placed into the distal urethra. Once the catheter has been placed, the prepuce is grasped digitally and is retracted caudodorsally, so the urethra

is parallel to the vertebral column. A 12-mL syringe containing sterile saline or lactated Ringer's solution is then connected to the catheter by an assistant. Subsequently, fluid is forced through the catheter while the catheter is gently advanced; the catheter should remain parallel to the spine during this maneuver. This technique should force the concretion into the bladder. The catheter is then advanced into the bladder, which is then repeatedly flushed and emptied to remove as much debris as possible. This catheter is then removed and is replaced with a 5-French catheter cut to a length of 6 cm. This catheter is positioned so the tip is just past the root of the penis. This reduces the possibility of ascending cystitis. The catheter is sutured in place and is removed in 5 days. If urethral patency cannot be restored by this method, one should suspect a mural or periurethral lesion with or without an associated urethral plug.

Antibiotics are given for 30 days; three different drugs are used for 10 days each. The cat's diet is changed to Prescription Diet Feline Multicare (Hills Packing Company, Topeka, KS). This diet is low in magnesium and tends to acidify the urine, thus decreasing crystal formation. The food should be salted to increase fluid intake and to promote diuresis, to flush out urinary bacteria and precipitates. Instead of salting the food, the owner may administer a 1-g salt tablet orally once a day. If obstruction recurs, perineal urethrostomy is indicated.

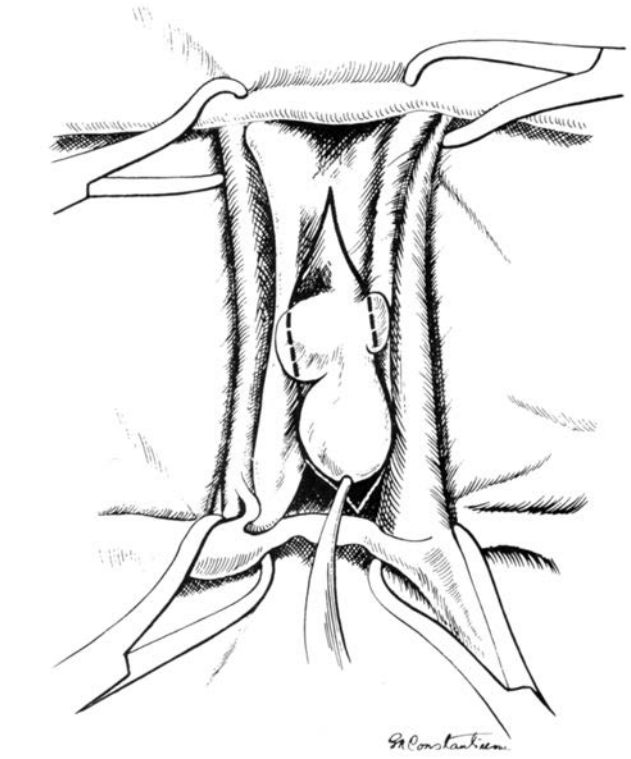

Figure 31-9. After the perineal area is draped and a urinary catheter is placed, an elliptic incision is made around the scrotum and prepuce.

Perineal Urethrostomy

Preoperative Considerations

Cats who have had urinary tract obstruction are poor anesthetic risks. Diuresis after unblocking is indicated. Induction of anesthesia with an ultrashort-acting anesthetic agent followed by maintenance with a gas anesthetic is recommended.

Surgical Technique

The animal is prepared for aseptic surgery. The hair is clipped from the entire perineal area including the base of the tail. A pursestring suture is placed in the anus, and a 3.5-French open-ended tomcat catheter is placed. The animal is positioned on the surgery table in ventral recumbency with the hind legs draped over the end of a titled table. The tail is taped over the dorsal midline of the back, and the genital area is draped.

An elliptic incision starting halfway between the anus and scrotum is made around the scrotum and prepuce (Figure 31-9). If the animal is sexually intact, castration is performed. After the penis with accompanying prepuce and remaining scrotum are retracted dorsally, ventral dissection is begun with Metzenbaum scissors (Figure 31-10). All preliminary dissection is done ventrally until the bilateral ischiocavernosus muscles are located and cut with scissors at their urethral attachments (Figure 31-11). This technique frees the penis and allows the visualization of a ventral penile fibrous band from the pelvic diaphragm located on the midline between the penis and the ischial arch. This structure is then cut, further freeing the penis.

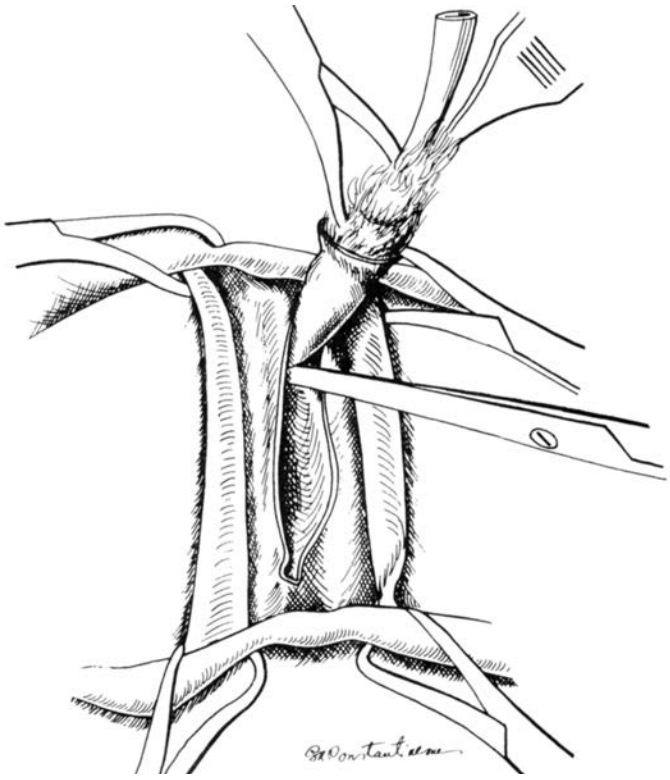

Figure 31-10. The penis and prepuce are retracted dorsally, and ventral dissection is begun.

At this point, dorsal dissection is begun. All dorsal dissection is accomplished close to the urethra. Metzenbaum scissors are

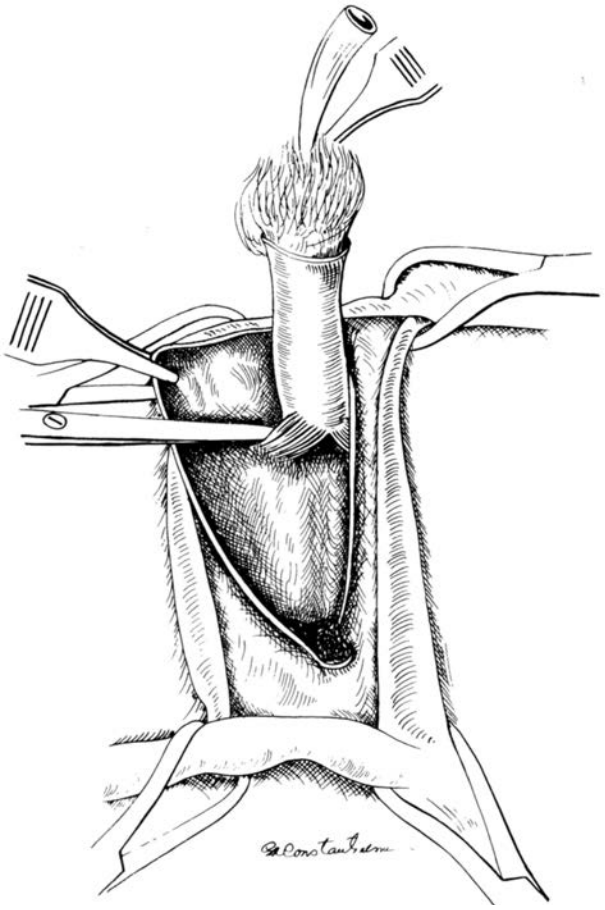

Figure 31-11. The ischiocavernosus muscle is identified and is cut with scissors close to the penile attachment.

used to cut and bluntly dissect the attachments circumferentially, further freeing the urethra and allowing it to be retracted caudally. The dorsal white V-shaped uterus masculinus is now visible and is cut close to the urethra (Figure 31-12). Care must be exercised during the entire dissection not to damage the rectum (dorsally) and the nerves that innervate the rectum and bladder neck. Such damage is avoided by keeping all dissection close to the urethra.

The dissected penis is grasped in the surgeon's left hand, with the index finger under the penile crus. A No. 10 scalpel is used to incise over the catheter on the dorsal midline of the urethra (Figure 31-13). The incision is carried into the lumen. The incision is extended 1 cm cranial and 2 cm caudal to the crus of the penis. Extension of the pelvic urethral incision more than 1cm cranial to the crus leads to severe incisional invagination when the incision is sutured. A 1-cm incision in the pelvic urethra is adequate to provide the enlarged opening needed. The catheter is removed, and forceps are inserted into the pelvic urethra (Figure 31-14). The incision is now ready for suturing.

We recommend using 4-0 polydioxanone or polypropylene (Ethicon, Inc., Somerville, NJ) with a swaged-on taper-cut needle for urethral suturing. The first suture is placed to approximate the most dorsal skin edges. The next suture, which begins the urethral suturing, picks up one skin edge and then passes through the dorsal roof of the urethra just cranial to the most cranial incision edge and then through the other skin edge (Figure 31-15A). When

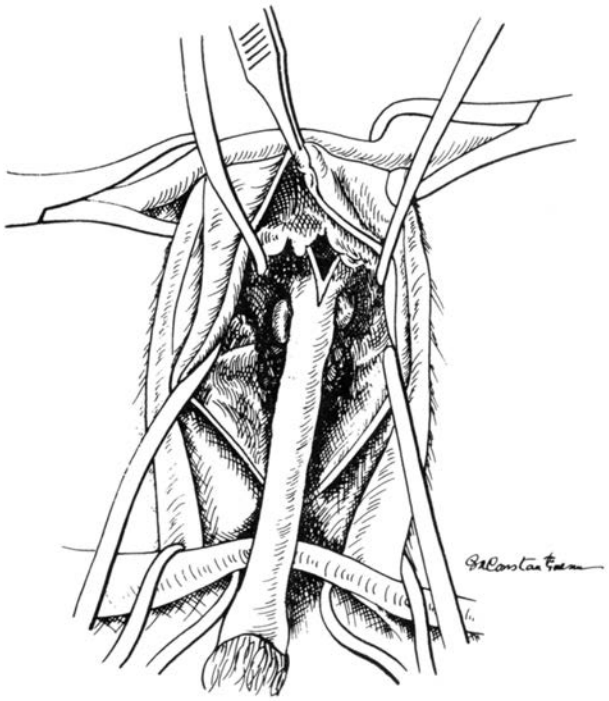

Figure 31-12. Urethral dissection is completed by transecting the V-shaped uterus masculinus close to the urethra.

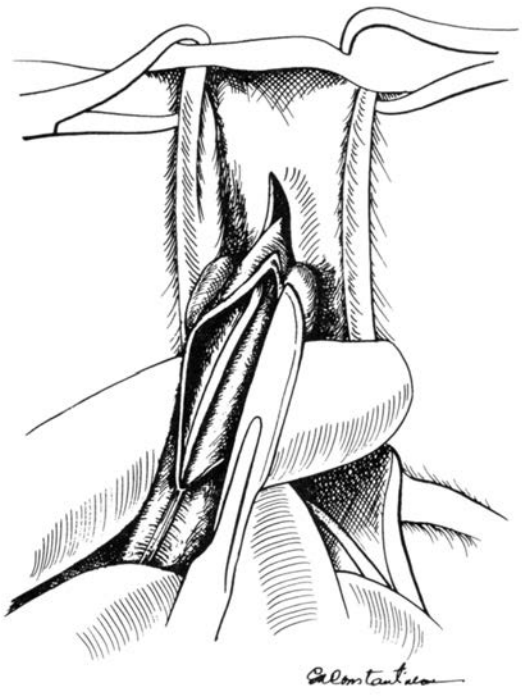

Figure 31-13. The urethra is incised into the lumen with a No. 10 scalpel.

this suture is tied, the roof of the urethra is pulled up to the skin edge, thus lifting the urethra to the surface. Suturing is continued down the skin incision on each side, including the cut edge of the urethral mucosa in each stitch (Figure 31-15B). It is important also to include the edge of the corpus spongiosum (corpus cavernosum urethrae) within these urethral edge stitches to help control hemorrhage from the cut edge of the corpus spongiosum.

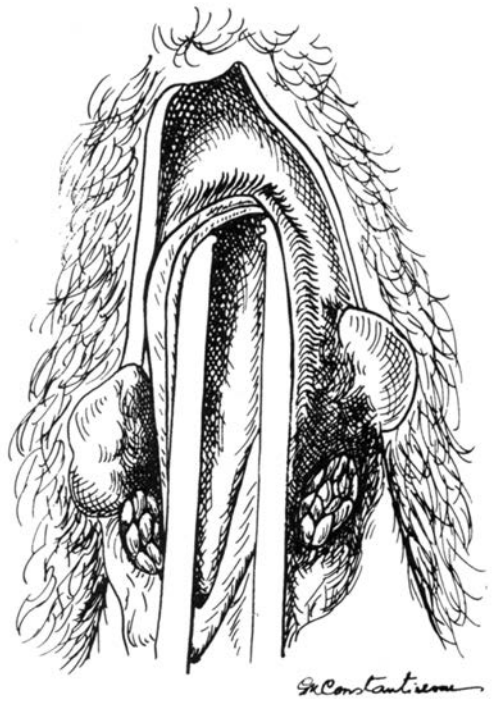

Figure 31-14. After the incision is completed, the catheter is removed, and forceps are inserted into the pelvic urethra.

After both sides of the skin incision have been sutured, the penis is cut off with scissors (Figure 31-16A) at the level of the caudal urethral incision. The cut end (Figure 31-16B) is sutured as shown in Figure 31-17. This helps to seal the cut end of the corpus cavernosum penis and eliminates much of the excessive postoperative hemorrhage often encountered with this surgical procedure. The final sutures are placed approximating the caudal skin edges (Figure 31-18). The wide end of the tomcat catheter is cut (approximately 2.5 cm), inserted into the new urethral opening, and sutured to the skin on each side (See Figure 31-18).

Postoperative Care

The pursestring suture in the anus is removed. An Elizabethan collar is placed on the cat to prevent licking of the incision. The same medical therapy as outlined previously is begun. The catheter is removed on the fifth postoperative day. The sutures and Elizabethan collar are removed on the tenth postoperative day.

The animal can be sent home during much of this postoperative period because urinary control is maintained even with the catheter, which is short and does not enter the bladder, in place. Owners must be instructed not to allow the cat to go outside while the sutures are still in place and to place shredded papers in the cat's litter box, so litter will not stick to, contaminate, and irritate the incision.

Complications

The major complications of perineal urethrostomy are postoperative hemorrhage, subcutaneous urine leakage, infections,

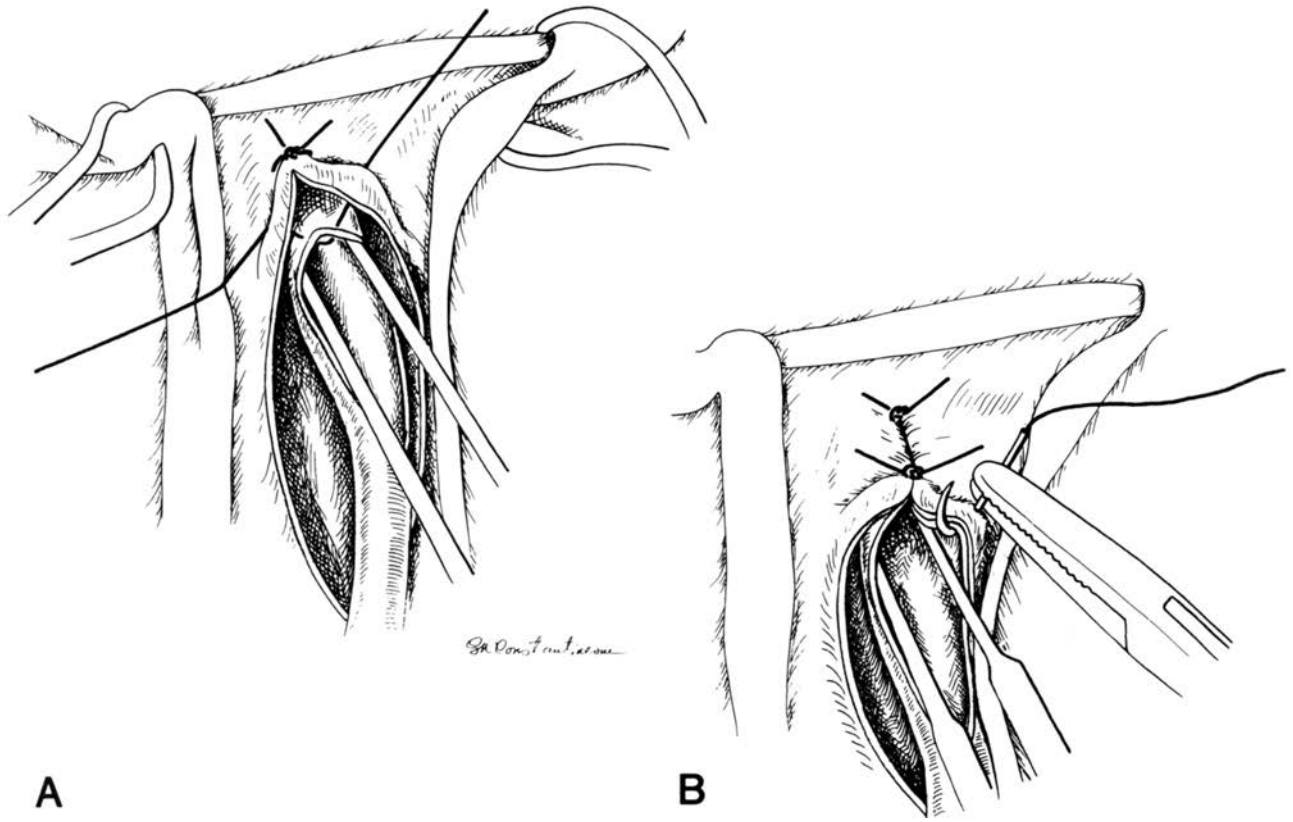

Figure 31-15. A. The first suture approximates the dorsal skin edges; then the first urethral suture is placed, engaging both skin edges and the pelvic urethral roof. **B.** Urethral suturing continues down the skin incision on each side.

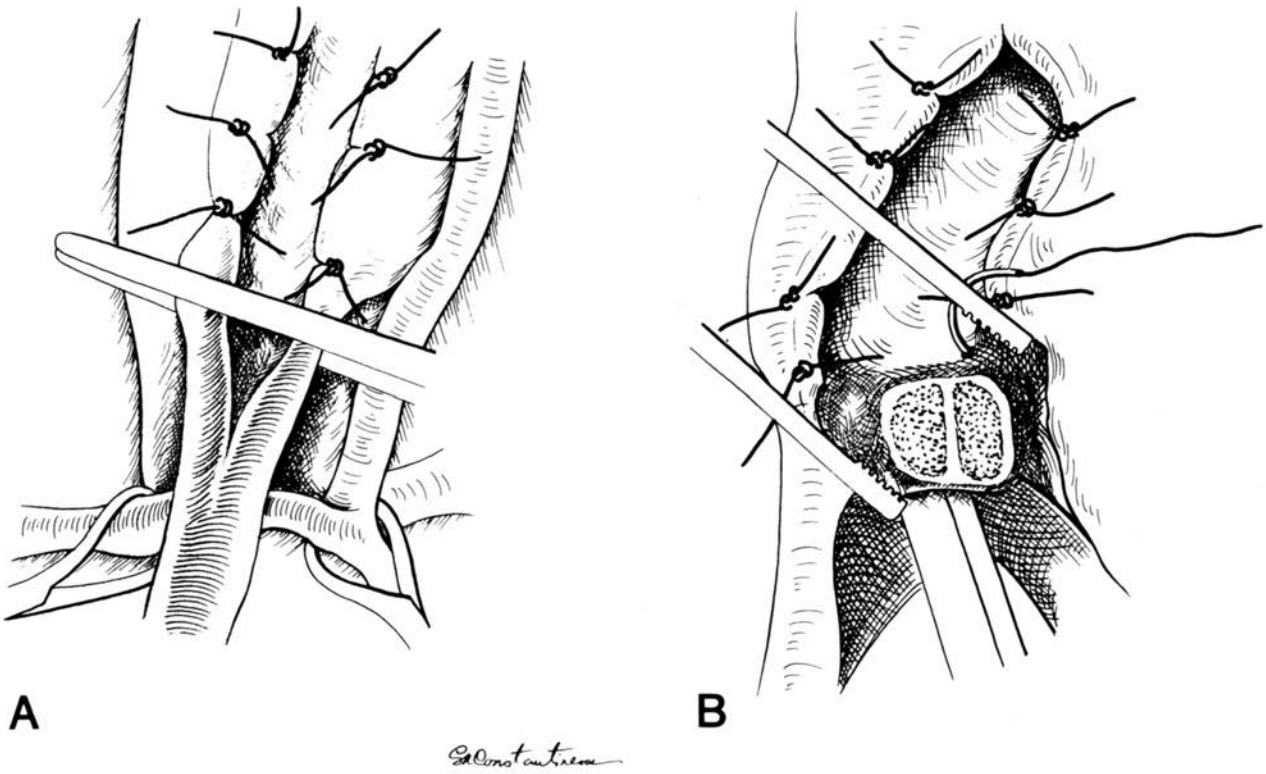

Figure 31-16. A. Excess penis is cut off with scissors at the level of the caudal incision. **B.** The cut end of the penis is shown, revealing the corpus cavernosum penis.

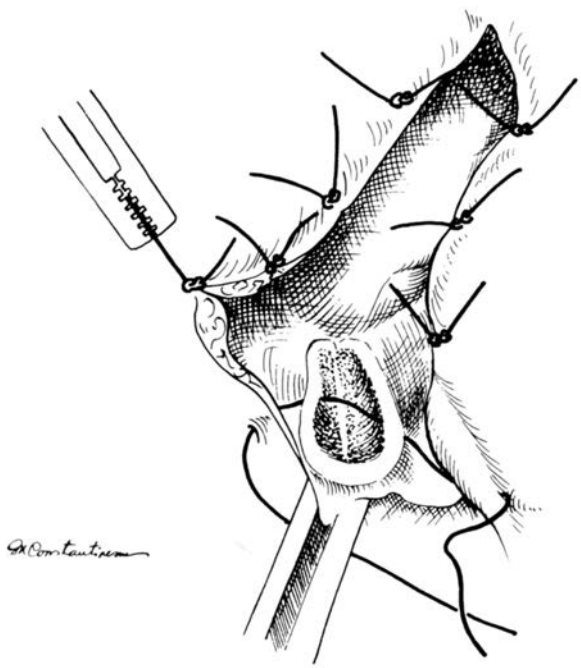

Figure 31-17. The exposed cut surface of the corpus cavernosum penis is sutured.

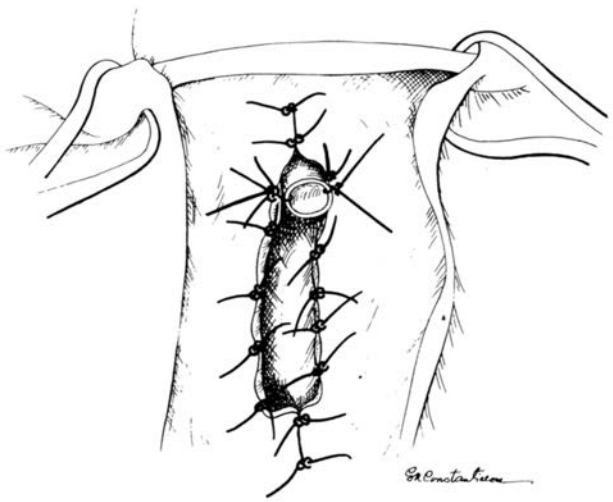

Figure 31-18. After suturing of the incision is completed, a 2.5-cm segment of catheter is sutured into the urethrostomy opening.

strictures, fecal and urinary incontinence, and rectal prolapse. Hemorrhage can be greatly reduced by taking care to include the cavernous tissue in the skin sutures. Infections can be decreased by eliminating postoperative contamination of the incision with litter and licking and by use of prophylactic antibiotics. Strictures can be prevented by adequate freeing of the urethra, to eliminate inpulling and suture line tension.

Urethroplasty for Stricture After Perineal Urethrostomy

Cats with urethrostomy stenosis present with stranguria producing only scanty urine and a palpably full bladder. If the stricture is due to improper dissection in the original surgical procedure (i.e., failure to transect ligaments and muscle attachments and free the urethra) or to failure to open the urethra properly, then the operation should be redone. If the original urethrostomy was done properly and a stricture subsequently occurred, a urethroplasty is performed.

The area around the stricture is clipped and prepared for surgery. The opening is located. The surgeon should use a 10X loupe to aid in visualization during surgery. A procedure similar to that for anal stricture (See Chapter 20) is used. Four cuts (dorsal, ventral, left lateral, and right lateral) are made with a No. 15 scalpel. Each cut incises the skin and underlying urethral mucosa. As each cut is made, the incisions open and form a diamond shape. The incisions are then sutured with 5-0 polydioxanone in the opposite direction in a manner similar to that shown in Figures 20-41 through 20-45. This technique alleviates the stricture.

Prepubic Urethrostomy in the Cat

Richard A. S. White

Surgical Anatomy

The unique anatomy of the cat's urinary bladder neck and proximal urethra allows the feline urethra to be sectioned and urethrostomy performed at the prepubic level whilst preserving urinary continence. In male cats, the bladder is situated considerably more rostrally to the pelvic brim than in other domestic species; the trigonal region gives rise to an elongated bladder neck, often erroneously regarded as the preprostatic urethra, that reaches the pubic level before differentiating into the urethra proper. The urethral sphincter mechanism is located immediately distal to the trigone and hence section of the urinary conducting system at the junction of bladder neck and urethra, can be expected to preserve normal urinary continence. The combination of this relatively long bladder neck and the absence of a prostate gland encircling the urethra facilitates the creation of a urethral stoma at the posterior abdomen / prepubic level in the cat.

Indications

Indications for prepubic urethrostomy (PPU) include conditions that result in persisting urethral obstruction distal to the pelvic level. In contrast with the more common but increasingly controversial indications for perineal urethrostomy (PU), the indications for PPU are more easily recognized despite being less frequently indicated. Conditions in which distal urethral function is lost include salvage of perineal urethrostomy (PU) complications, management of cats with perineal skin deficits that preclude PU, complex urethral ruptures and strictures, granulomatous urethritis and neoplastic disease. Paradoxically, PPU requires considerably less surgical expertise and experience than PU and is easier to perform and this occasionally leads to its inappropriate substitution for PU.

The potential risks and complications of PPU are probably less frequently encountered than those associated with PU, however, the procedure should only be performed when all medical strategies have been exhausted and where PU is not considered to be a feasible option.

Preoperative Preparation

The more common indications for this procedure may be associated with some risk of urinary tract infection or bacteruria and hence perioperative antibiotic therapy based on urine culture from a sample obained by cystocentesis is usually appropriate. An opioid analgesic that can be continued into the postoperative period (e.g. buprenorphine) should be administered, and if renal function is normal, non-steroidal anti-inflammatory therapy may be appropriate to provide additional analgesia. The patient should be positioned in dorsal recumbency and the ventral abdomen including the pubic region should be aseptically prepared for surgery. Urethral catheterization is helpful but often not possible due to the obstructing indication; the absence of a urethral catheter should not unduly hinder the procedure.

Surgical Technique

A short caudal ventral midline incision is created immediately rostral to the pubic brim and a small pair of Gelpi retractors inserted to improve abdominal exposure. The bladder neck/urethra is identified and gently freed from the surrounding periurethral adipose tissue as far distally as possible into the pelvic region (Figure 31-19). Care should be taken to avoid damage to the pelvic nerves located in the bladder neck area. The urethra is elevated using moistened umbilical tape or large hemostats (Figure 31-20) and then sectioned as far distally as possible; any bleeding from the distal urethra may be controlled by ligation or thermocautery. A catheter may be inserted into the proximal urethra at this stage to facilitate identification of the urethral lumen. The urethral stoma may be positioned in either a midline or a paramedian position. For the former option, the urethral opening is exteriorized through the laparotomy wound and the linea alba closed routinely proximal and distal to it, avoiding constriction of the urethra (Figure 31-21). Alternatively, the urethra can be drawn through a separate paramedian stab incision and the linea alba closed routinely. The subcutaneous dead space is closed with absorbable suture and the urethral stoma anchored to the skin with four simple interrupted (4/0 or 5/0) monofilament sutures (Figure 31-22). The urethral opening may be spatulated to increase the diameter of the opening and facilitate creation of the stoma if necessary.

Postoperative Care

Patients normally benefit from receiving opioid analgesia for 48 hours and should be prevented from self-trauma by means of an Elizabethan collar. Litter trays with shredded paper instead of litter are provided to minimize the potential for debris adhering to the stoma site. Depending on the original indication for the procedure, it may be necessary to initiate management of underlying pre-existing lower urinary tract disease. Patients will need to modify their squatting posture for urination somewhat and the interval until this is successfully accomplished will vary between individuals. In the intervening period, any urine-staining or scalding of the skin in the inguinal region should be carefully managed to prevent secondary pyoderma complicating the healing of the urethral stoma. Urinary retention due to discomfort and pre-existing lower urinary tract disease should be managed with analgesia, striated muscle relaxants (e.g. diazepam) or smooth muscle relaxants (e.g. phenoxybenzamine); repeated catheterization of the urethra is avoided if possible.

Complications

Healing of the stoma is usually uncomplicated but, as with any urethrostomy procedure site, leakage of urine into the subcutaneous tissues surrounding the stoma before an effective seal has formed may lead to peristomal skin irritation and in severe cases, incisional dehiscence postoperatively. More chronic urine leakage can promote low-grade periurethral cellulitis which can lead to stenosis and stricture of the stoma; revision of stenosis may be complex. Stricture of the stoma occasionally occurs but the overall incidence is low. Occasionally, peristomal cellulitis can spontaneously occur in long-term PPU patients although the etiology for this is uncertain. Temporary urinary diversion by urethral catheterization or in some cases by tube cystostomy allows the cellulitis to resolve and patients will resume normal continent urination. Cutaneous urine scalding can be a transient problem in cats that do not modify their urination stance. Cranial transplantation of the prepuce with the stoma located inside or subpubic urethrostomy have been recommended to avoid this complication. These are more complex procedures and not usually necessary. Transient urinary incontinence may

occur in some cats in the immediate postoperative period but usually resolves as the stoma heals. Some cats with pre-existing lower urinary tract disease may continue to be dysuric postoperatively which can be mistaken for incontinence; appropriate management of lower urinary tract disease should be initiated.

Conclusion

PPU is an acceptable surgical procedure for the management of cats where distal urethral function has been lost. The procedure is comparatively easy to perform and does not necessitate complex or prolonged postoperative care. Cats remain continent and most accommodate quickly to the change in posture necessary for urination without inguinal skin scalding. They will continue to lead a normal life. PPU should however be regarded as a salvage procedure and not substituted where medical management or PU would be a more appropriate operation.

Editor's Note: Urinary incontinence may occur postoperatively in cats that have had PPU.

Management of Urethral Trauma

Jamie R. Bellah

Introduction

Blunt abdominal trauma and traumatic displacement of bone fragments, especially pubic fragments, can lacerate the membranous urethra.[1] Urethral injuries from other sources are less common but include gunshots, bite wounds, and iatrogenic trauma. The pelvic urethra may also be entrapped between pelvic fragments or mechanically compressed after elective pelvic surgery.[2,3] Absence of skeletal injury does not preclude urethral damage. Traumatic urethral injury usually occurs in male dogs because the postprostatic pelvic urethra is fixed at the greater ischiatic notch. The incidence of urethral injury after car accidents is reported to vary from less than 5% to 11%.[4]

Diagnosis

Urethral injury is suspected when dysuria or anuria is observed. Hemorrhage from the urethral opening or hematuria, usually at the first portion of the urine stream, may be noted soon after injury. Urethral trauma is not excluded on the basis of an animal's ability to void urine, however. Animals with urethral rupture may be depressed and anorexic, and penile urethral urine leakage may cause pyrexia and perineal or inguinal bruising and swelling. Uremia may or may not be present. A distended urinary bladder may be palpable. Proximal urethral lacerations or rupture may result in uroperitoneum, and clinical signs mimic those of a ruptured urinary bladder. Urine leakage may he detected from open wounds in the region of the pelvic cavity. If urine leakage is chronic a cutaneous urine fistula may result.[4] Suspicion of urethral injury should be evaluated initially by positive-contrast urethrography using a water-soluble organic iodide preparation. Injection of air is avoided because it is difficult to delineate the site of urethral injury after air dissects periurethrally, and also because the use of air as the distending gas can result in fatal air embolism.[5] Extravasation of contrast material occurs with both urethral laceration and urethral rupture, but in the latter instance, contrast material usually does not pass proximal to the complete tear. Cystoscopic examination may be used for evaluation of the lower urinary tract.[6] Animals with proximal urethral trauma should also be evaluated by intravenous pyelography because concomitant ureteral injury may be present.

Surgical Techniques

Management of urethral injuries depends on the type of injury sustained and on the overall health of the animal. Uroperitoneum and its systemic metabolic effects must be resolved before lengthy surgical intervention. If uroperitoneum is present, its effects are resolved by urine diversion and intravenous fluid therapy to alleviate dehydration, acidemia, and hyperkalemia. Gentle catheterization of the urethra may be accomplished, depending on the site of the urethral laceration, but often the catheter tip finds the urethral defect and cannot be passed successfully. Urine can be diverted by percutaneous placement of a prepubic drainage catheter (Stamey catheter) or by insertion of a cystostomy tube (Foley or Pezzar catheter). Both techniques require sedation and (narcoleptic) local anesthesia unless the animal is moribund. Abdominal drainage may be necessary if more proximal urinary tract injury does not allow urine diversion by the aforementioned techniques.

Definitive surgical treatment of urethral injuries requires careful preparation because often the site of injury is difficult to access (postprostatic rupture). Lacerations may be managed solely by urethral stenting if a catheter can be successfully manipulated into the urinary bladder, and it may need to remain in place for 7 to 10 days. Conservative treatment of urethral injury requires that longitudinal mucosal continuity across the region of urethral

trauma be present for successful urothelial repair. Despite the ability of urothelium to migrate, larger urethral defects require stenting for as long as three weeks for complete repair.[7] Surgical correction of urethral rupture often requires pubic osteotomy to expose the severed urethra adequately. Sufficient exposure so debridement and precise anatomic anastomosis are feasible cannot be overly stressed.[7] After debridement, simple interrupted sutures of absorbable material are used to perform the anastomosis over a urethral stent (catheter), with the knots outside the lumen of the urethra (Figure 31-23). The urethral mucosa must be anatomically apposed (without tension) or granulation tissue will be produced and contract the anastomosis, resulting in stricture despite the presence of a stent. Use of a catheter stent in addition to accurate suturing is believed to help prevent urethral stricture, however, overstretching the urethra may enhance fibrous tissue formation.[8] Monofilament absorbable suture material such as polydioxanone (PDS), polyglyconate (Maxon), and poliglecaprone (Monocryl) are appropriate for urethral anastomosis. Interrupted appositional sutures are recommended and continuous patterns are avoided as the latter tends to "purse-string" the urethral lumen. Fine nonabsorbable monofilament sutures such as nylon and polypropylene may be used for urethral apposition, but because the sutures remain long after tissue healing is complete, they are not desirable.[9] Urine diversion may be accomplished by placing a cystostomy tube (if necessary), and the urethral stent (catheter) remains to support the anastomosis and to divert urine away from the urethral wound to promote normal wound healing. The urethral stent should be large enough to maintain lumen size, but it should not be so large that it causes excessive pressure or tension on the anastomosis. If a large segment of pelvic urethra must be debrided, a permanent urine diversion procedure may be required. Antepubic urethrostomy or extrapelvic urethral anastomosis may be performed in those cases.

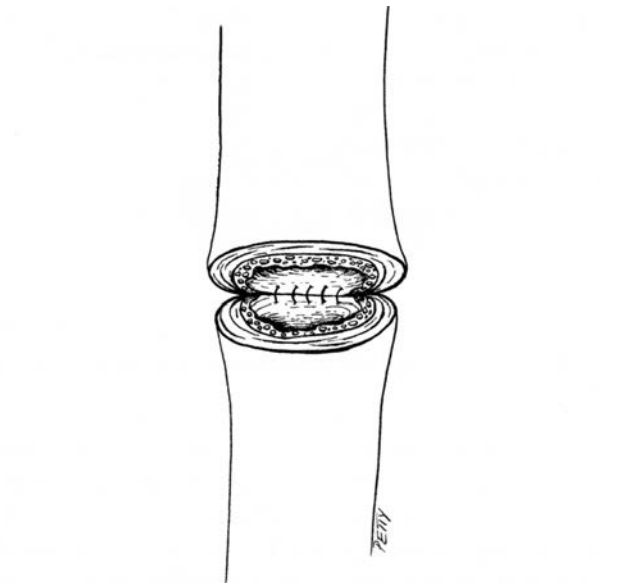

Figure 31-23. Anastomosis of the urethra requires accurate apposition of the urethral mucosa. Failure to do so results in stricture and dysuria.

Postoperative Care

Postoperative management of patients with urethral trauma and obstruction is intensive. Management of pain is often required for 12 to 24 hours. Animals must be restrained from prematurely removing urethral stents and cystostomy tubes. Restraint must be adequate, and may require Elizabethan collars, side braces, wire muzzles, and in some instances tranquilization. Prolonged catheterization (4 days or longer) often results in urinary tract infection, and periodic culture and susceptibility screening are important to avert a serious ascending infection. Proper use and care of closed urine drainage systems are mandatory. When urethral stents are removed, urine culture and susceptibility testing are done and antimicrobial therapy is based on those results.

Urethral stents (catheters) may be pulled when urothelium has bridged the urethral defect, as early as 5 days after repair. Careful injection of contrast material at low pressure is performed when contrast urethrograms are repeated, so the urethral wound is not disrupted. Difficult anastomoses, when repair is tenuous (or unsutured defects), may require urethral stenting for as long as 14 to 21 days.

The most common complication of urethral trauma repair is stricture. Stricture may occur early, resulting from dehiscence of the anastomosis, or a technically poor repair (tension or inadequate mucosal apposition), with a fibrous scar that may partially or completely occlude the urethral lumen. Stricture may also occur months after surgery or conservative management if contraction of periurethral scar tissue results in stenosis of the urethral lumen. Correction of urethral stricture may require resection and anastomosis or a urinary diversion procedure, however balloon dilatation of a urethral stricture in a dog has been reported. Strictures involving the more distal aspects of the urethra may be resolved by performing scrotal urethrostomy.

Urethral Prolapse in Dogs

John A. Kirsch and J.G. Hauptman

Introduction

Urethral prolapse is an uncommon condition in the dog, and is most often seen in young male English Bulldogs.[1,2] It has not been reported in female dogs. Urethral prolapse typically appears as a red to purple mass protruding from the orifice of the urethra. Clinical signs of urethral prolapse in the dog include excessive licking of the prepuce, preputial bleeding, and stranguria. Suspected causes of urethral prolapse in the dog include excessive sexual excitement, masturbation, and genitourinary infections or calculi.[3,4] Its strong breed relation has also led to speculation that it occurs as a result of increased abdominal pressure secondary to chronic upper airway obstruction in brachycephalic breeds.[1] This theory is consistent with the condition in humans, where it is proposed that there is poor attachment between muscle layers of the urethra associated with episodic increases in abdominal pressure.[5] The strong breed association suggests a genetic predisposition. Differential diagnoses of urethral prolapse in the dog include trauma, urethritis, and neoplasia, particularly transmissible venereal tumor. Current described techniques for surgical treatment of urethral prolapse include manual reduction of prolapsed mucosa and placement of a temporary purse-string suture at the penile tip, which must be removed in five days,[3,4] urethropexy,[6] or resection of the prolapsed tissue and apposition of urethral and penile mucosa.[1-4] Common post-operative complications associated with surgery are swelling and hemorrhage at the surgical site. The incidence of recurrence based on technique is unknown, although we have observed recurrence after all described techniques; subjectively, the catheter reduction and purse-string technique is the least likely to result in permanent correction. Treatment decisions for urethral prolapse should be made based on the following factors: 1) viability of prolapsed tissue, 2) history of recurrence in the patient, and, 3) which procedure, if any, has been performed prior to presentation for the current episode. Non-viable or severely traumatized urethral tissue is an indication for resection of prolapsed tissue.

Preoperative Care

Every effort should be made to rule-out underlying genitourinary disease. Radiographs, with or without contrast, may be performed to evaluate for calculi. Catheterization is helpful to assess patency of the urethral lumen. A rectal exam should be performed to evaluate the prostate and pelvic urethra. Urinalysis and urine culture are performed to rule-out underlying disease and infection. Castration should be discussed with the owner prior to surgery, since the procedure can be performed at the time of prolapse correction, and due to the purported connection of urethral prolapse to sexual excitement.

Surgical Techniques

Clipping the prepuce may not be recommended, as it may contribute to postoperative irritation. Prior to surgery, the prepuce is flushed with a dilute povidone iodine solution. Elective castration should be performed prior to correction of urethral prolapse, as it is the more sterile of the two procedures. The penis is manually extended from the prepuce and maintained in this position either by an assistant or by a Penrose drain tourniquet placed around its base (Figure 31-24). Extreme care should be taken with all techniques to employ gentle tissue handling and accurate suture placement, which will maximize success and minimize postoperative morbidity.

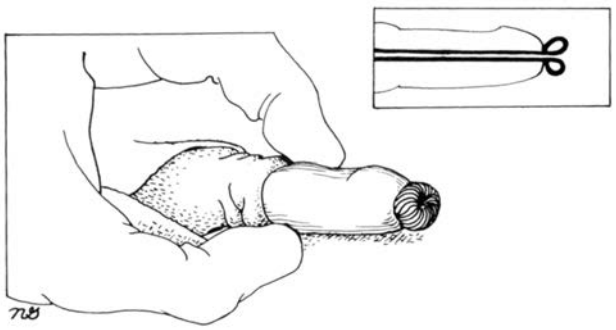

Figure 31-24. Extended penis with urethral prolapse.

Purse-string

A catheter or grooved director is used to reduce the urethral prolapse, and a purse-string suture is placed at the urethral orifice. The suture is tightened just enough the maintain mucosal reduction upon removal of the catheter. Care must be taken to ensure an adequate opening, as some localized swelling is expected following suture placement. If urethral patency is in question, one should elect a different corrective procedure.

Urethropexy

A lubricated grooved director is introduced into the urethral orifice, reducing the prolapsed urethral mucosa (Figure 31-25B). The director should be passed beyond the distal aspect of the os penis. If this fails to achieve reduction of all urethral mucosa, an assistant can grasp the penis at its tip and apply distal traction to invert the mucosa. Monofilament, 2-0 or 3-0, absorbable or nonabsorbable suture on the largest radius swaged-on tapered needle available is passed full thickness through the penis from the external surface, as far proximally as the needle curvature will allow, to the intraluminal surface directing the needle distally out the urethral orifice (Figure 31-25C). The grooved director is used as a receiving surface for the needle to prevent penetration of the opposite wall of the urethral lumen. The needle is then passed, in reverse fashion, from the urethral lumen to the external surface of the penis exiting just distal to the initial needle entry site (Figure 31-25D). The resulting full thickness suture is tied snugly with four throws, the initial throw being a surgeon's throw (Figure 31-25E). This technique is repeated until three equally spaced sutures are placed. The grooved director can be removed/rotated between sutures. Following suture placement, an 8-10 French red rubber catheter is passed to confirm patency of the urethra. Sutures are not removed.

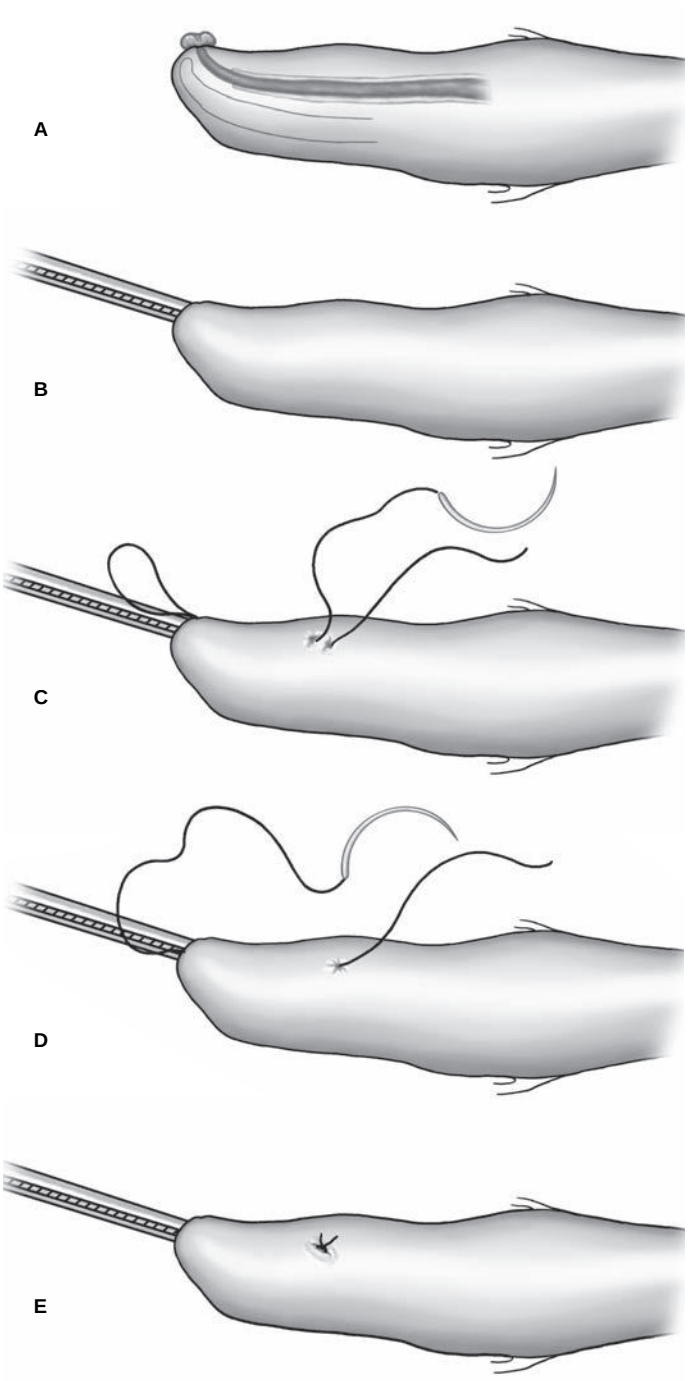

Figure 31-25. Urethropexy technique for treatment of urethral prolapse in the dog. **A.** Prolapsed mucosa visible at distal tip of penis, **B.** introduction of grooved director into urethral lumen to reduce prolapsed mucosa, **C.** first suture pass is external-to-internal, exiting urethral orifice, **D.** second suture pass from internal to external, exiting just distal to initial suture entry point, **E.** resulting full thickness suture is tied snugly. Process is repeated until reduction is maintained. All diagrams represent patient in dorsal recumbency.

Resection

A sterile catheter is placed in the urethra. An incision is made 90 to 180° at the base of the prolapsed tissue, resulting in a clean incision in healthy mucosa of urethra internally, and glans penis externally, using the catheter for support. The mucosal edges are apposed with 4-0 or 5-0 absorbable monofilament suture, preferably with a taper-point needle, in a simple interrupted pattern, spaced 1-2 mm apart. Absorbable braided suture (e.g.. Polyglactin 910) is also acceptable, but results in more tissue drag, and requires more throws for knot security, adding bulk to the repair. Care must be taken to achieve adequate bites of the urethral mucosa, and good mucosal apposition. This results in less second-intention healing and hemorrhage. Once apposed, the incision is completed around the orifice, and the process repeated. Proceeding as above, in stages, minimizes retraction of urethral mucosa, enabling better visualization and apposition.

Postoperative Care

The urinary catheter is removed following correction. Recovery should employ the use of sedatives and pain medication as judged necessary to ensure a quiet and smooth emergence from anesthesia. An Elizabethan collar should be worn at all times by the patient for a minimum of 10 days following the procedure, to prevent self-trauma. Exercise is limited to leash-controlled walks for 10 to 14 days. The prepuce should be monitored daily for irritation and swelling. It is normal for minor bleeding to be observed, intermittently and during urination, for 3 to 5 days post-operatively. Mild straining is also occasionally observed, but the urine stream should be consistent and adequate at all times following surgery. Underlying urinary tract disease or infection should be treated appropriately. Patients may be discharged with standard post-operative pain medication for elective soft-tissue procedures (NSAIDS). On an individual basis, short term (5 to 10 days) oral sedation with acepromazine is beneficial, and even advisable. Prognosis is good. We recommend the urethropexy technique as the easiest and most effective technique.[6]

Chapter 32

Prostate

Surgery of the Prostate

Clarence A. Rawlings

Prostate disease includes hyperplasia, infection, cysts, abscesses, and cancer. Severe diseases of cysts, abscesses, and cancer are treated by excisional and partial prostatectomies. All prostatic disease, except cancer, can be prevented by castration during the first year of life. Castration, as a treatment of prostatic disease, reduces hyperplasia and the potential for persistent infections. Despite castration as a treatment for prostatic disease, prostatic abscesses can persist and present later as a clinical problem. When prostatic disease develops, castration is recommended in all patients except those with prostatic cancer. The terminal prognosis for prostatic cancer mandates an attempt to early diagnosis.

Prostatic abscesses and cysts are difficult to treat. Surgery is required, and treatment is frequently complicated by disease recurrence, incontinence, infection, sepsis, and even death. Treatments initially attempted for abscesses and cysts included extra-abdominal drainage by Penrose drains or marsupialization. Early complications of these drainage procedures included sepsis in one-third of patients and death in one-fifth. The remainder of these dogs had transient improvement, but abscessation recurred in nearly one-fifth and incontinence in one-fourth of the dogs. To reduce the postoperative complications associated with prostatic tissue as a septic focus and mediator of infection, excisional prostatectomy was performed to remove all prostatic tissue. Although excisional prostatectomy reduced the incidence of early postoperative sepsis and eliminated recurrence, over 90% of dogs with excised diseased prostates also developed incontinence.

I prefer to treat most patients with abscesses and cysts by castration and partial prostatectomy using an ultrasonic aspirator followed by omentalization. This technique eliminates nearly all the prostatic tissue while preserving the urethra and most nerves. Closed-suction drains have been successfully used to drain noninfected cysts, such as those with vascular and lymphatic drainage problems in perineal hernia. These dogs should be castrated. Many patients with abscesses and cysts appear to be adequately treated using peritoneal omentalization. All fluid-filled pockets must be explored and adequately drained. Before omentalization of paraprostatic cysts, the cysts should be excised as much as possible without damaging the urethra or the neurovascular supply.

Diagnosis

Diagnostic studies are designed to establish the anatomic distribution and histologic type of disease, to characterize the systemic response to the prostatic disease, to identify coexistent problems, to identify infections, and to characterize incontinence and outflow obstruction. The presenting complaints vary with the severity and type of disease. Tenesmus can be produced by any prostatic enlargement, that is, by hyperplasia, cyst, abscess, and neoplasia. Urethral obstruction is most typical of cancer, but it may occur in patients with cysts, abscesses, and hyperplasia. Incontinence is common in severe prostatic disease. Urethral discharge can be produced by nearly any prostatic disease with an opening into the prostatic urethra. Persistent urinary tract infections are frequently related to prostatic infections, particularly abscesses and infected cysts. Abdominal masses can be produced by cysts and abscesses. Many systemic responses develop in response to prostatic disease.

The size and character of the prostate should be determined by physical examination, including combined rectal and abdominal palpation, radiography, and ultrasonography. Contrast studies, especially retrograde urethrography, can be useful to identify the urethra, bladder, and prostate. Cystic structures as seen with an ultrasonogram have a more serious prognosis than hypertrophy, especially if a urinary tract infection is present. Cytologic and bacterial cultures can be obtained by sampling the urethral discharge, by semen ejaculation, by prostatic massage, by traumatic catheterization, or by direct sampling by needle aspiration or use of a larger biopsy needle. Placement of a needle into the prostate can be facilitated by ultrasonography or palpation. Care must be taken in placing a large-bore needle into a fluid-filled pocket of an infected prostate gland.

Most dogs with severe prostate disease do not urinate normally. Incontinence is common and frequently worsens after surgery. Even dogs that have undergone only a biopsy have dribbled urine after surgery, probably as a result of disease progression. Although obstruction in the absence of cancer is commonly thought to be infrequent, obstruction does occur and may be associated with calculi and strictures unrelated to cancer. Detrusor instability can develop in dogs with prostatic disease. A urethral pressure profile can identify decreased urethral pressures, which are common in dogs with prostatic disease, and a cys-tometrogram can identify an inability to develop a detrusor response or an irritable bladder. If incontinence persists after surgery, medical treatment can be attempted for each of these conditions.

Preoperative Care

Dogs with prostatic infections, especially those with abscesses, frequently become septic and develop toxic shock. Diagnosis is based on physical examination, urinalysis, complete blood and platelet counts, and serum chemistry profile, particularly liver enzymes, glucose, and albumin. Perioperative antibiotics must be given, preferably based on culture results. Although *Escherichia coli* is the most common organism isolated in bacterial prostatitis, some dogs have already been treated with long-term antibiotics and have developed resistant infections. Septic dogs, without culture results, are started on a combination of clindamycin and enrofloxacin. Measures to prevent and treat shock must be done and include fluid support, blockers of ischemia and reperfusion injury, and cardiotonic drugs (dopamine or dobutamine). Hypovolemia and hypotension must be treated by large volumes of intravenous fluids. If the albumin and total solids are low, plasma,

hetastarch, or dextrans should be considered. Blockers have been used and included dexamethasone (2 mg/kg intravenously), flunixin (1 mg/kg intravenously), and deferoxamine (20 to 40 mg/kg intramuscularly or slowly intravenously) but their efficacy remains controversial. Monitoring must include either indirect or direct arterial blood pressure. The anesthetic regimen should be based on the patient's disease status. Finally, surgery must be both expeditious and accurate to reduce the spread of sepsis.

Surgical Techniques

Excisional Prostatectomy

Excisional prostatectomy is used to treat cancer. This treatment is usually palliative, but it can be effective in extending the patient's normal life for several months because transitional and prostatic carcinomas usually grow slowly. Another treatment option for proximal urethral cancer is excision of the lower urinary tract and implantation of the ureters into the colon. This produces ascending renal infections. Dogs with neoplastic urethral obstruction can be successfully managed for months by a cystostomy tube. Neither medical therapy nor radiation treatment provides significant benefits in patients with prostatic cancer. Urethral stents can provide temporary relief of urethral obstruction. Prostatectomy also can successfully cure prostatic abscesses and cysts, but the high rate of incontinence makes this procedure less desirable than partial prostatectomy or peritoneal omentalization.

Incisional biopsies are done by cutting deeply into the prostatic gland and then placing deep mattress sutures into the capsule to produce hemostasis (Figure 32-1). The prostate is approached by a midline laparotomy (Figure 32-2A). The periprostatic fat is incised on the ventral midline and is reflected laterally (Figure 32-2B). An excisional prostatectomy requires dorsal dissection. Before prostatic surgery, a temporary tourniquet is placed about the distal aorta, just cranial to its bifurcation into the external iliac arteries. After placement of a urethral catheter, a retraction suture is placed around the urethra caudal to the prostate. Caudal dissection is facilitated by cranial incision of the ventral ligament of the penis. The prostate is rotated to ligate vessels close to the prostatic capsule and to ligate the vas deferens. The surgeon attempts to preserve the caudal vesical artery bilaterally and to preserve much of the urethra, both on the side of the neck and distally. Prostate tissue or fluid should be cultured. Multiple biopsy specimens are taken from the prostate and sublumbar lymph nodes. Neoplastic tissue must be excised, and this can require extensive urethral resection. Margins, especially of the urehra, are sampled in order to stage the cancer spread. Retraction sutures in the urethra caudal to the prostate can reduce traction problems. The urethra is transected cranial (Figure 32-2C) and caudal to the prostate (Figure 32-2D). The prostate is removed, and the urethral catheter is redirected into the bladder. The urethra is anastomosed with interrupted sutures using an absorbable monofilament synthetic suture material, usually of 4-0 or 5-0 size (Figure 32-2E). Some urethras are thick enough that a second layer of sutures can be placed in muscle tissue. A cystostomy catheter is placed in addition to the urethral catheter to ensure that urine is diverted and that little tension is placed on the anastomosis (Figure 32-2F). Both catheters

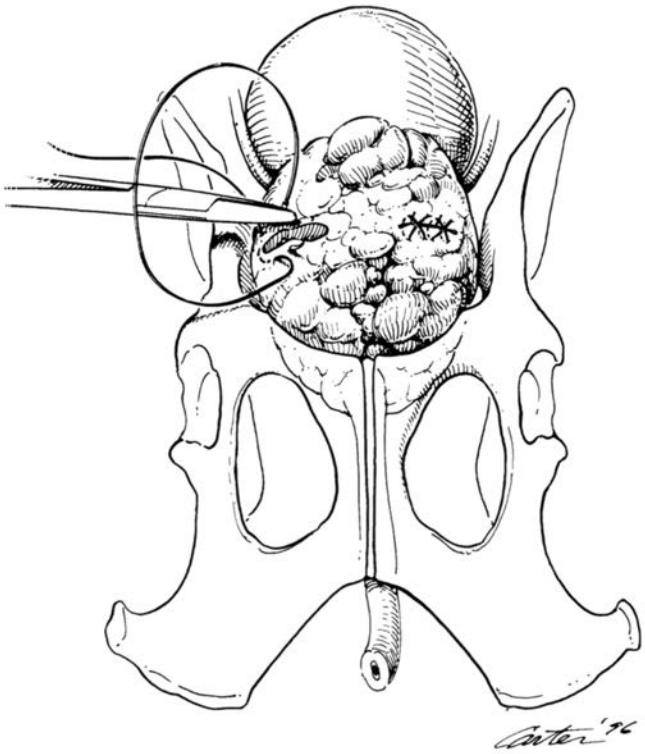

Figure 32-1. Incisional biopsies are performed through a ventral midline laparotomy. Multiple biopsy specimens should be obtained, with each sample at least I cm wide and 2 cm deep. After each biopsy specimen is taken, interrupted cruciate sutures are placed at least 5 mm from the biopsy margins. Hemostasis is achieved as the sutures are tightened.

are left in place for 1 week, and urine is collected by a closed system. The balloon of the cystostomy catheter is deflated, and the catheter is withdrawn 1 week after the surgical procedure. The urethral catheter is left in place for another day and then is withdrawn.

Partial Prostatectomy

Partial prostatectomy is my preferred procedure for treatment of patients with prostatic cysts and abscesses, but it is contraindicated for cancer. The use of the ultrasonic surgical aspirator permits removal of up to 85% of the prostatic glandular tissue in addition to all cysts and abscesses. Because the remaining prostatic tissue is dorsal and close to the urethra, most of the urethral innervation and muscles appear to be left intact. Incontinence is much less frequent and severe after partial prostatectomy of dogs with severe cavitary disease than before the surgical procedure or after ex-cisional prostatectomy. As with excisional prostatectomy, castration should be performed.

The prostate is approached in the same fashion as previously described, except dorsal and lateral dissections are avoided or at least limited. After obtaining biopsy specimens and after placing the aortic tourniquet and retraction suture about the urethra caudal to the prostate, the surgeon incises poles of the prostate ventrally with electrocautery (Figure 32-3A). The Cavi-tron Ultrasonic Surgical Aspirator (CUSA System 200 Macro-Dissector, Valleylab, Inc., Pfizer Hospital Products Group, Boulder, CO) is used to fragment, irrigate, emulsify, and

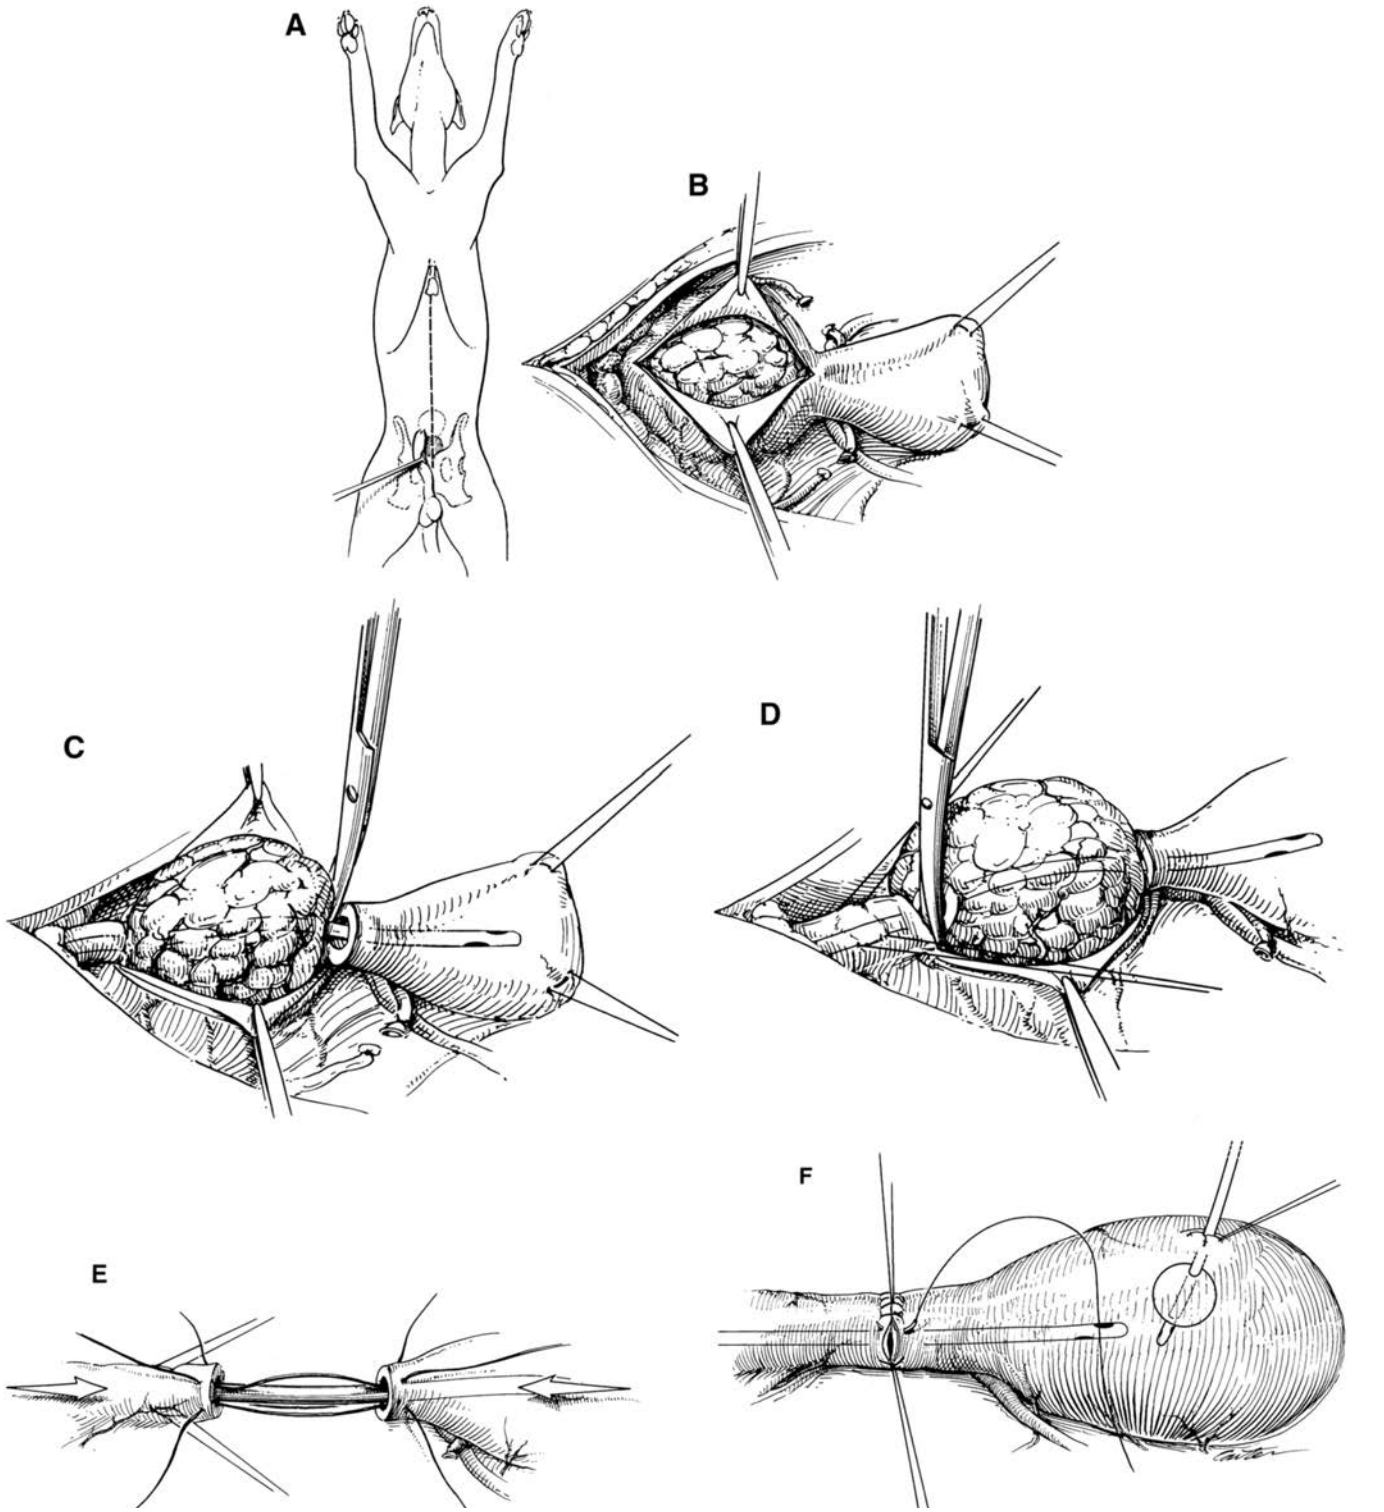

Figure 32-2. A. A ventral midline laparotomy is performed to approach the prostate for an excisional prostatectomy. Most prostate glands can be adequately exposed if the incision is extended caudally to the brim of the pubis. **B.** The periprostatic fat is incised on the midline and is reflected from the ventral and lateral surfaces. Hemostasis is improved if a tourniquet is placed about the aorta just cranial to its bifurcation. The vasa deferentia are ligated and divided, as are the prostatic vessels. Care must be taken to preserve the caudal vesical artery on both sides. Dissection should be close to the capsule, especially dorsal, cranial, and caudal to the prostate. A traction suture placed around the urethra, caudal to the prostate, and incision of the ventral ligament of the penis aid prostatic exposure. **C.** The urethra is transected cranial to the prostate. If excisional prostatectomy is done for cancer, the resection may need to be wider to ensure tumor-free margins. **D.** The urethra is transected caudal to the prostate. After the prostate is removed, the urethral catheter is replaced in the bladder. **E.** The urethral anastomosis is made with interrupted sutures of 4-0 or 5-0 absorbable synthetic monofilament material. The sutures are placed through all layers of the urethra, but additional sutures may be placed in a second pattern in some urethras. **F.** In addition to the urethral catheter, a cystostomy catheter is placed into the ventral region of the bladder. A double pursestring is used to secure the catheter.

aspirate approximately 85% of the glandular tissue (Figure 32-3B and C). A catheter is placed within the urethra to identify and avoid damaging it. Urethral fistulas are identified by inflating the urethra with fluid (Figure 32-3D). After glandular dissection and excision of the ventral hemisphere on the ventral midline of the capsule, omentum is placed over the urethra and the dorsal prostatic capsule is suture around the omentum and urethra on the ventral side to form a cuff around the prosatic urethra.

Postoperative Care and Complications

Early potential complications can include shock potentially leading to death, infection (sepsis), pain, and renal shutdown. Fluid support should be continued at greater than maintenance rates based on monitoring results of, initially, arterial blood pressure and, later, volume of diuresis. If shock develops, treatment must be aggressive. Urinary output is recorded, and the bladder is evaluated frequently to ensure that it remains decompressed. Urinary catheters are usually removed during the first

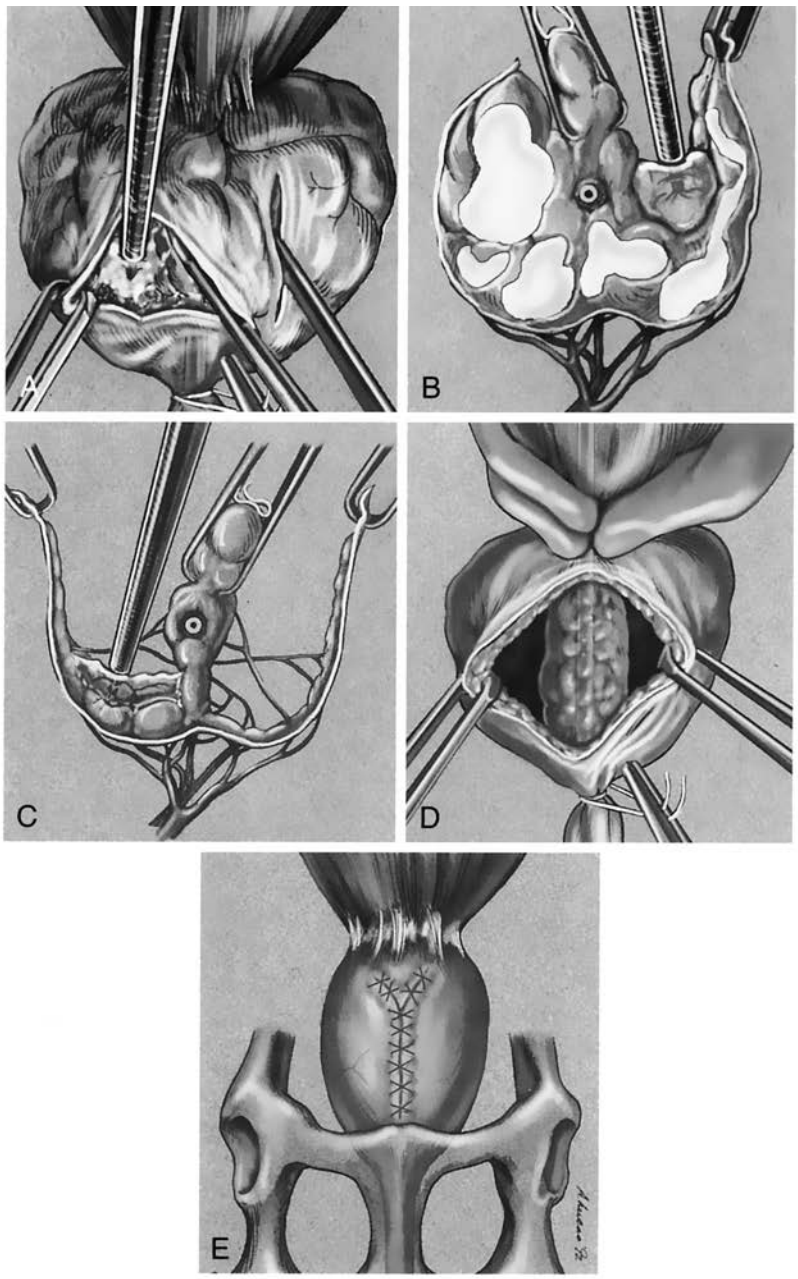

Figure 32-3. A. Ventral view of a partial prostatectomy. After lymph node biopsy and placement of an aortic tourniquet, a 14- to 18-French urethral catheter is placed through a cystotomy, and a traction suture is placed about the urethral caudal to the prostate. Two parallel incisions are made into the ventral prostatic capsule using electrocautery. **B.** Transverse view. The ultrasonic aspirator is used to resect glandular tissue. All identifiable cystic pockets are entered. **C.** Transverse view. The surgeon attempts to remove 85% of the glandular tissue, including all abscess pockets. During ultrasonic aspiration, the urethral catheter and the dorsal capsule are frequently palpated and are avoided. **D.** Ventral view. The urethral catheter tip is withdrawn into the prostatic urethra, and the urethra is inflated by injecting saline. Urethral openings are identified and closed by suturing. **E.** Ventral view. Prostatic tissue between the paramedian incisions and ventral to the urethra and the excessive capsule are excised. The capsule is closed with interrupted sutures. An indwelling urethral catheter is left to decompress the bladder during the early postoperative period. From Vet Surg 1994;23:182-186.

2 days after partial prostatectomy. For excisional prostatectomy, catheters are left for 1 week and require protection with side braces or Elizabethan collars. Antibiotics are continued. Pain medications are normally given at least during the initial 8 hours after surgery. Intensive care monitoring is critical for several hours postoperatively. In addition to monitoring of urine output, temperature, pulse, and respiration, and attitude, complete blood counts with platelet counts, blood urea nitrogen, albumin, glucose, and urinalysis should be performed. Liver enzymes are also useful to detect signs of sepsis and septic shock. In dogs with signs of sepsis, decreasing albumin concentrations indicate a need for plasma. Nutritional status should be documented by measuring food intake and body weight daily. No deaths have been reported in dogs treated by partial prostatectomy.

Long-term complications of surgical treament in dogs with severe prostatic disease include persistent infections and disease, as well as incontinence. Dogs usually urinate normally after partial prostatectomy, and fewer than 20% of dogs have even minor urinary control problems. After excisional prostatectomies, most dogs develop mild incontinence, and a few (approximately 10%) have continual dribbling of urine. Prostatectomy of normal dogs produces no decrease in urinary control function and only minor urodynamic changes, but the combination of prostatic disease and removal of the prostate increases incontinence. Some incontinent dogs with low urethral pressures have been successfully treated with phenylpropanolamine (1.5 mg/kg orally three times daily), and those with detrusor instability have been treated with oxybutynin (2.5 mg orally three times daily). Recurrent prostatic infections and disease should not occur when the prostate has been excised. Dogs with partial prostatectomy have not had recurrence during the first year after discharge from the hospital. Complications have been seen during hospitalization when a urethral to cyst fistula either persisted or recanalized. This fistula can been repaired during an additional surgery. Since a small amount of prostatic tissue is present and can be infected, at least two dogs have developed recurrent disease more than 1 year after surgery. The potential for urinary tract infection is high in any dog following surgery for major prostatic disease. These dogs must have regular urinalysis and cultures combined with aggressive antibiotic therapy. Intense surveillance and treatment should reduce problems with recurrent infections.

Use of Omentum in Prostatic Drainage

Richard A. S. White

Causes of Prostatic Abscesses and Cysts

Abscessation of the prostate gland in dogs is considered to result from an ascending bacterial infection that overcomes the normal urethral defense mechanisms and thereafter colonizes the prostatic parenchyma. A suppurative infection resulting in parenchymal microabscesses is thought to develop subsequently, but the precise mechanism by which these microabscesses coalesce into larger, loculated abscesses rather than remaining as diffuse prostatitis is unclear. The most commonly recovered organism is *Escherichia coli*, with *Staphylococcus* spp. and *Proteus* spp. occasionally encountered.

Discrete cysts involving the prostate gland are a well-defined but uncommon manifestation of prostatic disease. Two distinct categories of cyst have been previously described namely, *paraprostatic* and *prostatic retention cysts*. It now seems clear that both types of cysts in fact share a common etiology and are thought to develop as the result of obstruction of ducts within the parenchyma of the gland promoting the accumulatic of prostatic secretions. Concurrent prostatic disease is always present, and this may include benign prostatic hyperplasia, squamous metaplasia, abscessation, or neoplasia. Discrete cysts are capable of attaining considerable size and should be distinguished from the diffuse cystic changes that often occur in combination with benign prostatic hyperplasia.

Clinical Signs and Diagnosis

Dogs with *prostatic abscesses* are pyrexic and have signs of caudal abdominal pain on rectal and transabdominal palpation of the prostate gland. The prostate gland is invariably enlarged and may have a doughy feel when palpated. Many dogs have neutrophilia (white blood count higher than 17 x 10^9/L), but this is not a consistent feature of the disease. Alkaline phosphatase concentrations may be elevated in some patients. Radiography enables one to confirm the prostatic enlargement, but ultrasound imaging is necessary to demonstrate the characteristic loculation within the parenchyma that contains the slightly echodense purulent fluid. Fine-needle aspiration may be used to recover purulent material, but it should be performed with care to avoid the risk of peritonitis after this procedure.

Prostatic retention cysts are encountered mostly in large breed dogs, especially boxers. Signs of urinary dysfunction, including stranguria, dysuria, hematuria, and incontinence, are invariably seen. Palpation identifies a caudal abdominal mass. A presumptive diagnosis of prostatic cyst can be made by evaluation of survey abdominal radiographs and ultrasound examination of the prostate in all dogs. Mineralization of the cyst wall is evident in some dogs. Biopsy may be indicated because some retention cysts accompany prostatic neoplasia, but fine-needle aspiration should again be performed with care.

Conventional Drainage Strategies

Chronic parenchymal lesions of the prostate gland, most notably abscesses and discrete cysts, are difficult clinical entities to resolve consistently by means of medical or surgical therapy. Various surgical techniques have been described for the management of prostatic abscesses and cysts.

Abscesses

The use of antibiotic therapy, even in conjunction with castration, is notoriously ineffective in resolving prostatic abscessation because of its failure to achieve adequate therapeutic concentrations throughout the prostate. Previously described techniques for drainage or removal of abscesses include marsupialization of the abscess, local resection, subtotal prostatectomy, and excisional prostatectomy. For many years, the most widely practiced technique was ventral drainage by means of dependent Penrose drains. All the foregoing techniques necessitate prolonged postoperative management, and long-term complications associated with these procedures include recurrent abscessation, chronic drainage after marsupialization, urinary incontinence, urinary tract infection, and the development of urethrocutaneous fistula.

Prostatic Retention Cysts

Marsupialization of prostatic cysts is a comparatively simple technique, but persistent discharge from the stoma, chronic urinary tract infection, and abscessation are recognized complications. Drainage and surgical resection of the cyst comprise a successful technique and should be regarded as the technique of choice for the management of paraprostatic cysts, for which the dissection is often uncomplicated. Many prostatic retention cysts, however, have extensive adhesions to the ureters, bladder neck, and prostate, and complete resection may increase the risk of postoperative incontinence or urinary retention resulting from neural or vascular compromise. Partial cyst resection may therefore be a preferable strategy to minimize the risk of incontinence, although this procedure may permit continued fluid secretion, redevelopment of the cyst, or formation of adhesions between the cyst remnant and other abdominal organs.

Omentum for Prostatic Drainage

The value of the omentum as an alternate source of vascularization and lymphatic supply in veterinary surgery is well established. Recognized applications include reconstruction of body wall deficits, filling of dead space, support for grafted tissue, reinforcement of gastrointestinal or urogenital repairs, and resolution of chronic wounds. The omentum is able to resolve bacterial contamination from perforated viscera and even can function in the presence of infection. The omentum can be used as a "physiologic drain" to resolve lesions of the prostatic parenchyma such as abscesses or to provide continued drainage of ongoing secretions from residual cystic tissue without merely walling them off from the abdominal cavity. Additionally, the omentum creates adhesions at the operative site, thereby minimizing the risk of visceral adhesion.

Intracapsular Prostatic Omentalization for Prostatic Abscesses

A caudal celiotomy extending from the umbilicus to the pubic brim is performed to permit adequate elevation of the prostate gland, which is then packed off from the remainder of the abdomen with moist laparotomy sponges. Stab incisions are made bilaterally in the lateral aspects of the prostate gland, and pus is removed by suction to minimize abdominal contamination. All abscess loculations within the parenchyma (Figure 32-4) are explored and are broken down by digital exploration. The prostatic urethra is carefully preserved and can be identified by palpation of a previously placed urethral catheter. A Penrose drain may be temporarily placed around the prostatic urethra within the parenchyma to help elevate the gland and to facilitate irrigation of the abscess cavities with warm saline. The stab incisions are then enlarged by resection of the lateral capsular tissue. Artery or tissue forceps are introduced into one capsulectomy wound and are used to draw a leaf of omentum into the contralateral wound and through the dorsal abscess cavity (Figure 32-5). The omentum is passed back through the ventral cavity, resulting in complete periurethral packing, to exit the prostate, and is then anchored to itself with absorbable mattress sutures outside the prostate gland (Figure 32-6). The celiotomy wounds are closed routinely, and castration is performed. Dogs should receive broad-spectrum antibiotic therapy periopera-tively, but this therapy does not need to be extended postoperatively unless complications occur, such as major contamination of the abdominal cavity before or during the surgical procedure.

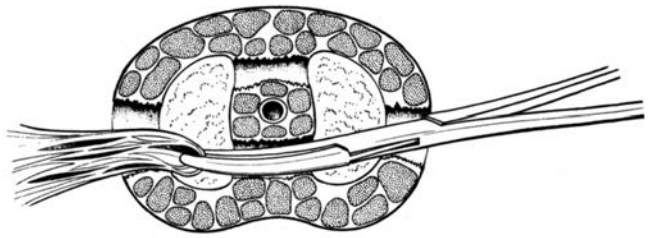

Figure 32-5. Bilateral stab incisions are made into the abscess to permit drainage and digital disruption of the loculations within the cavities. The stab incisions are then enlarged by resection of the capsular tissue to permit the introduction of a leaf of omentum into the dorsal abscess cavity by means of forceps positioned through the contralateral capsulectomy wound. From Vet Surg 1995;24:390-395.

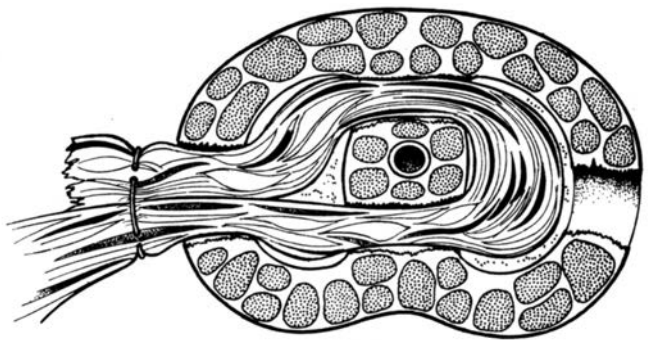

Figure 32-6. The leaf of omentum is then returned through the ventral cavity of the abscess to complete the periurethral packing. The omentum is anchored to itself by means of horizontal mattress sutures using absorbable material. From Vet Surg 1995; 24:390-395.

Partial Resection and Omentalization for Prostatic Retention Cysts

A caudal celiotomy extending from the umbilicus to the pubic brim is performed. The cyst is identified (Figure 32-7), and a single stab incision is made through the cyst wall. Complete drainage using suction to avoid con tamination of the abdominal cavity is performed (Figure 32-8), and the majority of the cyst wall is resected (Figure 32-9). Extensive dissection of the cyst in the region of the bladder neck and prostate should be avoided, to minimize the risk of damaging nerves that control continence. Omentum is packed into the cyst remnant and is secured in place (Figure 32-10) with mattress sutures of 2-0 absorbable suture material. The prostate gland should be carefully examined and palpated during the surgical procedure, and if neoplastic infiltration is suspected, an incisional biopsy should be performed. The celiotomy wounds are closed routinely, and castration is performed. Dogs should receive perioperative broad-spectrum antibiotics, which may need to be extended postoperatively if purulent debris is apparent in the cyst during the surgical procedure.

Postoperative Care and Complications

A significant advantage of omentalization drainage techniques for prostatic disease is that patients can normally be discharged from the hospital within 24 hours of the surgical procedure. As already indicated, prolonged antibiotic therapy is only necessary if complications are encountered.

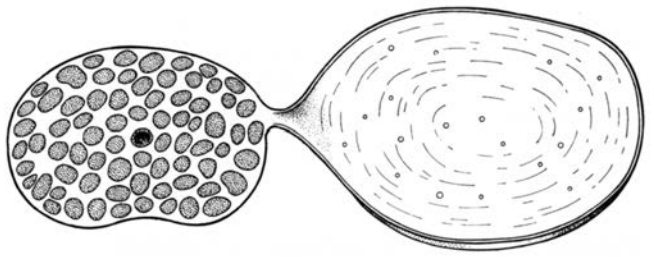

Figure 32-7. Schematic illustration of a prostatic retention cyst in transverse section. The cyst wall develops as a dilatation of the prostatic parenchyma caused by the accumulation of secretions within the gland. From Vet Surg 1997;26:202-207.

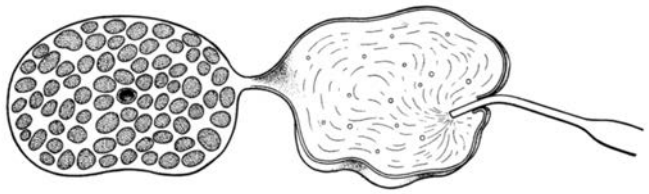

Figure 32-8. The cyst is drained by a single stab incision into the lumen. Suction is used to minimize spillage of cyst contents into the abdominal cavity. From Vet Surg 1997;26:202-207.

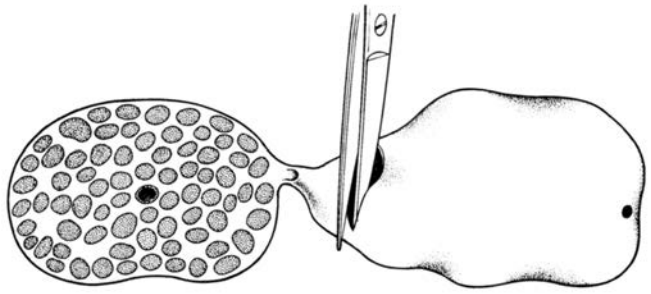

Figure 32-9. After drainage, the cyst wall is partially resected. Extensive dissection about the bladder neck and prostate is avoided.

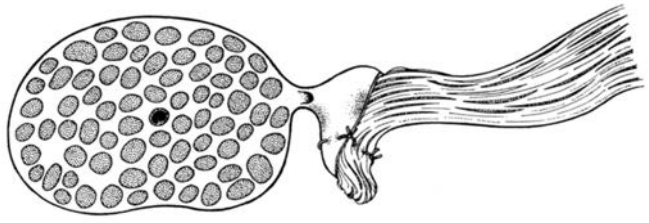

Figure 32-10. After partial resection of the cyst wall, an omental pedicle is created to fill the residual prostatic cavity. The omentum is anchored in place with stay sutures. From Vet Surg 1997;26:202-207.

Abscesses may recur if insufficient omentum is packed into the abscess cavity. The surgeon should ensure that adequate lateral capsulectomy resections—normally sufficient to accommodate the easy entry of the forefinger into the abscess cavity—are performed to avoid this complication.

Urinary incontinence is a frequent presenting sign in patients with prostatic retention cysts, and this problem may persist even after successful omentalized drainage of the cyst. Therapy with phenylpropanolamine (1 mg/kg every 24 hours orally) to increase urethral sphincter tone may be appropriate in some of these patients. Urinary retention is less common, and the patient's urinary function should be monitored carefully during the first 24 hours after the surgical procedure.

Prognosis

Omentalized drainage has proved successful for the management of both prostatic abscesses and retention cysts. Compared with other drainage techniques, the level of surgical expertise required for successful omentalization is modest, hospitalization stays are brief, and postoperative complication rates are low.

Chapter 33

Uterus

Prepubertal Ovariohysterectomy

Lisa M. Howe

Introduction

Prepubertal gonadectomy is not a new procedure. Veterinarians in the U.S. have often recommended that female dogs and cats be neutered prior to the first estrus (i.e., prepubertal) to eliminate unwanted pregnancies and reduce the risk of mammary neoplasia. Traditionally, female dogs and cats not intended for breeding purposes have undergone ovariohysterectomy at approximately six months of age. However, in an attempt to help alleviate the pet overpopulation problem, veterinarians began to investigate whether it was also safe to alter puppies and kittens at a younger age.[1] Currently, the literature suggests that prepubertal gonadectomy in female cats is safe as young as 6 to 8 weeks of age, particularly in the shelter environment. In female puppies, however, it is best to delay ovariohysterectomy until at least 3 to 4 months of age to prevent an increased risk of estrogen responsive urinary incontinence.[2] However, for shelters with an over supply of puppies, the advantages of ovariohysterectomy of puppies before adoption may outweigh the risk of urinary incontinence.

Surgical Anatomy

The surgical anatomy of the pediatric puppy or kitten is identical to that of the adult dog or cat; however, pediatric reproductive tract tissues are extremely small, friable, and susceptible to tearing if not handled with finesse. Additionally, there is minimal fat associated with the broad ligament or ovarian bursa in pediatric puppies and kittens.

Surgical Procedures and Techniques

When performing surgery in the pediatric patient, it is important to remember certain anesthetic and surgical considerations that may differ from the adult animal. Anesthetic and surgical considerations for the pediatric patient include the increased potential for hypoglycemia, hypothermia, a relatively small blood volume, and the delicate nature of pediatric tissues. Since hepatic glycogen stores are minimal in neonates, prolonged fasting may result in hypoglycemia. Food should be withheld no longer than 8 hours, with 3-4 hours recommended for the youngest patients (6-8 weeks).[3,4] Hypothermia can be lessened by using warm water or warm circulating air blankets and by the use of warm intravenous fluids (if used). Minimizing the period under general anesthesia and operative time will also help lessen the severity of hypothermia. Excessive wetting of the pediatric patient during preparation of the surgical site should be avoided, and the use of warmed scrub solution (chlorhexidine) and avoidance of alcohol will be beneficial in helping preserve body heat.[3,4] Pediatric tissues are very friable and should be handled carefully. The

relatively small blood volume of pediatric patients makes meticulous hemostasis very important. Fortunately, the small size of blood vessels and the presence of minimal abdominal and ovarian bursal fat allow for excellent visualization of the vasculature, and makes precise hemostasis simple to achieve.

Pediatric ovariohysterectomy may be performed similarly to adult ovariohysterectomy with some slight modifications.[3,5,6] Incisions in puppies are started more caudal to the umbilicus than in adult dogs. Generally, the uterus is more easily exposed in puppies if the incision is started at least 2 to 3 cm caudal to the umbilicus. This results in the incision positioned at, or near, the middle third of the distance from the umbilicus to the cranial brim of the pelvis, similar to an incision made for the adult cat. In kittens, the incision is placed in a similar location as in the adult cat. Upon entrance into the abdomen, it is common to encounter substantial amounts of serous fluid in both puppies and kittens. It may be necessary to remove some of the fluid using gauze sponges to improve visualization. In contrast to adult dogs and cats, it is recommended that the use of a Snook ovariohysterectomy hook be avoided in pediatric patients due to the delicate nature of the uterine tissues. Because of incision location in both puppies and kittens, the uterus is easy to locate by retracting the bladder laterally and looking between the urinary bladder and colon. If necessary, and if incision length will allow, the urinary bladder may be elevated from the abdomen and reflected caudally to permit easier visualization of the uterus. If this technique is used, once the uterus has been identified and secured, the bladder should be returned to the abdomen so as to preserve body heat. Uterine tissues are extremely small and friable in young puppies and kittens, therefore care must be taken to avoid excess traction and tearing of tissues. After the uterus has been located, the suspensory ligament may be carefully broken down to improve exposure and visualization of the ovary. A window is made through the broad ligament adjacent to the ovarian vasculature. A hemostatic clamp is then placed just proximal (medial) to the ovary across the ovarian vessels using a mosquito hemostat on kittens and small puppies and a Kelly, Crile, or Carmalt forceps on larger puppies. Although the triple clamp method may be used in pediatric OHE, it is often cumbersome and difficult to place multiple clamps proximal to the ovary without tearing tissues. The ovarian vessels are doubly ligated using 3-0 to 4-0 absorbable suture material or stainless-steel hemostatic clips. A single ligature may be sufficient to prevent hemorrhaging in very small pedicles, and transfixation ligatures are usually avoided. After ligation and transection of the ovarian vessels on both sides, the remaining broad ligament should be broken down (if it has not already torn) and the uterine pedicle ligated at the junction of the uterine body and cervix with two fully encompassing uterine body ligatures or hemostatic clips. After the reproductive tract has been removed, it should be examined to ensure complete removal (of ovaries and uterine body), and the abdomen should be examined for evidence of hemorrhage. As abdominal wall closure is performed, it is important to carefully identify the ventral fascia (external rectus sheath) and differentiate it from the overlying subcutaneous tissues since they can occasionally be difficult to tell apart (particularly in puppies). The ventral fascia can be closed using either a simple continuous or simple interrupted suture pattern using 3-0 (or possibly 2-0 on large puppies) absorbable (polydioxanone, polyglyconate, or polyglactin 910) suture. The subcuticular layer may be closed with an absorbable suture material (3-0 to 4-0, poliglecaprone 25 preferred) in a continuous intradermal pattern to avoid the use of skin sutures. Alternatively, skin sutures may be loosely placed following closure of the subcutaneous tissues. Although some veterinarians avoid using skin sutures in pediatric patients to prevent premature removal by the patient, we routinely use *loosely* placed skin sutures without complication or premature removal.

To prevent unnecessary abdominal exploratory surgery in the future, all animals undergoing early age ovariohysterectomy should be tattooed to identify their neutered status. The recommended tattoo site is the prepubic area in females. The female gender symbol along with an encircled "X" is used to denote the neutered status. Tattooing may be performed after the surgical site has been clipped but prior to the surgical prep of the area.

Postoperative Care

Postoperatively, pediatric patients should be monitored for hypoglycemia, hypothermia, pain, or dysphoria. Supplemental heat, glucose containing agents, or additional analgesics or sedatives may be used to ensure smooth recovery from anesthesia. These patients may be fed a small meal one to two hours after recovery since they tend to recover much more quickly from anesthesia and surgery than adults. Unlike traditional age patients undergoing ovariohysterectomy, pediatric puppies and kittens are typically hungry at this time and are often ready to eat and resume normal activity.

Postoperative Complications

Although the anesthetic and surgical procedures for early-age gonadectomy have generally been reported as safe, veterinarians have been concerned about long-term health risks. Veterinarians have questioned whether the immune system of puppies and kittens would be adversely affected by the stress of anesthesia and surgery at early ages and during a time when animals are being immunized against potentially fatal infectious diseases. Veterinarians have also been concerned about the risk of urinary incontinence and neoplasia in female dogs, abnormal long bone growth patterns, and obesity in dogs and cats neutered at an early age. Since the 1990's, several studies have been published that critically evaluate these concerns among dogs and cats altered at different ages prior to, and following, puberty. These studies, as well as more recent studies, have begun to clarify the long term health risks and benefits of early age ovariohysterectomy as compared to traditional age gonadectomy.

Infectious Diseases and Long-Term Immune Suppression

In some short-term studies conducted at animal shelters, puppies and kittens neutered at early ages had no higher risk of infectious diseases than older animals. One study involved dogs and cats from two animal shelters undergoing gonadectomy surgeries in association with the fourth-year student surgical

teaching program of a university teaching hospital.[5] Twelve of 1988 (0.6%) animals died or were euthanized because of severe infections of the respiratory tract or as the result of parvovirus infection during the 7-day postoperative period, and the deaths (or euthanasias) included similar numbers of animals from all age groups.

In long term studies of 263 cats[7] (36 month median follow up) and 269 dogs[8] (48 month median follow up), prepubertal gonadectomy did not result in an increased incidence of infectious diseases after adoption in cats, compared with traditional age gonadectomy. In dogs, however, gonadectomy before 5.5 months of age was associated with increased incidence of parvoviral enteritis. In more recent studies of 1660 cats9 (47 month median follow up) and 1842 dogs[2] (54 month median follow up), those gonadectomized before 5.5 months of age were no more likely than those gonadectomized after 5.5 months of age to have any conditions that might be presumably associated with long term immune suppression. Further, in cats, the study showed that early age gonadectomized cats had a lower incidence of gingivitis, a condition that may be associated with immune suppression. On a short-term basis, however, dogs from the study that were gonadectomized at an early age had an increased incidence of parvoviral enteritis that often occurred soon after adoption. In both of the long-term dog studies[8,2] (269 dogs and 1842 dogs), the increased incidence of parvoviral enteritis on a short-term basis probably represented an increased susceptibility of the younger puppies during the periadoption period, rather than long-term immune suppression.

Body and Long Bone Growth

At one time veterinarians believed that puppies and kittens neutered at an early age might be "stunted" in growth. Several research studies have now defined and dismissed these concerns. In a 15-month study, the effects of prepubertal gonadectomy on skeletal growth, weight gain, food intake, body fat, and secondary sex characteristics were investigated in 32 mixed-breed dogs neutered at seven weeks or seven months or left intact.[10] Growth rates were unaffected by gonadectomy, but the growth period and final radial/ulnar length was extended in bitches neutered at seven weeks of age. Thus, animals were not stunted in growth, but were actually slightly (as determined by radiographs) taller. In a similar study,[11] thirty-one cats were neutered at seven weeks or seven months or left intact. Distal radial physeal closure was delayed in gonadectomized cats when compared to intact cats. However, no differences were detected between cats neutered at seven weeks or seven months for mature radius length or time of distal radial physeal closure. Similar findings in cats were reported in another study.[12] In males and females, distal radial physeal closure was delayed in both groups of gonadectomized cats (neutered at seven weeks or seven months of age) compared to intact animals. In female cats, proximal radial physeal closure was also significantly delayed in cats neutered at 7 weeks of age.

The clinical significance of delayed closure of growth plates is not clear, but it does not appear to render the growth plates more susceptible to injury. In the long term studies of 263 cats[7] and 269 dogs[8] examining outcome of gonadectomy performed at an early age or traditional age, no differences in the incidence of musculoskeletal problems were seen between groups. Further, in the long term studies of 1660 cats[9] and 1842 dogs,[2] age at gonadectomy was not associated with the frequency of long bone fractures. In all these studies, long bone fractures were rare overall, suggesting that physeal fractures are not a common problem in gonadectomized dogs and cats in general.

Long-term studies have examined the incidence of hip dysplasia in dogs and the association with age at gonadectomy. Although one study of 269 dogs[8] found no association between age at gonadectomy and hip dysplasia, another study of 1842 dogs[2] found that early age gonadectomy was associated with a significant increased incidence of hip dysplasia. Puppies that underwent gonadectomy before 5.5 months of age had a 6.7% incidence of hip dysplasia, while those that underwent gonadectomy at the more traditional age had an incidence of 4.7%. However, those that were gonadectomized at the traditional age were three times more likely to be euthanized for the condition as compared to the early age group, suggesting that early age gonadectomy may be associated with a less severe form of hip dysplasia. A recent study showed that in the Golden Retriever breed, cranial cruciate ligament rupture was seen more frequently in dogs neutered before 1 year of age (early neutered) than those neutered after a year of age or remaining intact.[17] Although the incidence of hip dysplasia was higher in males of the early neutered group as compared to the intact group, this was not the case in the female dogs.

Obesity

Although obesity can occur in both neutered and intact animals, and is influenced by a number of factors such as diet and activity level, there are data to suggest that neutered cats may gain significantly more than those remaining intact. Clinically, spayed females seem likely to gain weight however objective data concerning whether dogs are more likely to experience weight gain following ovariohysterectomy is less clear. When comparing gonadectomized cats to sexually intact cats, intact cats were found to weigh less than cats altered at seven months, but there was no difference between intact cats and those neutered at seven weeks.[11] Another study,[12] 13 of 34 cats assessed obesity by body mass index at 24 months of age. Body condition scores and body mass index values were higher in animals gonadectomized at seven weeks or seven months than in intact animals, indicating that animals gonadectomized at either age were more likely to be obese than intact cats. Heat coefficient, a measure of resting metabolic rate, was higher in intact cats than in gonadectomized cats. Based on these data, the author suggested that neutered female cats require an intake of 33% fewer calories than intact female cats.[13] Another study[14] confirmed these findings, and demonstrated that the maintenance energy requirement is substantially lower for spayed female cats than for sexually intact cats. It was noted that sexually intact cats appeared to self regulate food intake, whereas spayed cats tended to eat all food available.

Information on body condition was gathered on over 8000 dogs

from 11 veterinary practices in the United Kingdom during a six month survey.[15] In this retrospective study, spayed dogs were about twice as likely to be obese as intact female dogs. However, another study[10] found no differences in food intake, weight gains, or back-fat depth among neutered (seven weeks or seven months) and intact animals during a 15-month prospective study. Interestingly, a long-term study of 1842 dogs[2] actually found that the proportion of overweight dogs was *lowest* in the early age gonadectomized dogs, as compared to the traditional age dogs.

Estrogen Responsive Urinary Incontinence

The incidence of estrogen-responsive urinary incontinence is increased among neutered female dogs and there is concern that gonadectomizing puppies at an earlier age might further increase the risk for spayed bitches. Urinary incontinence in dogs neutered at traditional ages can develop within days of the surgery or not until several years later. Estrogen-responsive urinary incontinence was reported in 34 of 791 (4%) bitches neutered at traditional ages, and seven of 2,434 (0.3%) sexually intact bitches.[16] A long term study that evaluated 269 dogs[8] adopted from shelters and neutered before 5.5 months of age, or $\geq$ 5.5 months of age, found only three cases where owners reported urinary incontinence. One dog was neutered at an early age and two dogs were neutered at the traditional age. In contrast, however, the long term study of 1842 dogs[2] demonstrated that decreasing age at the time of ovariohysterectomy was associated with increasing incidence of urinary incontinence that required medical treatment. Puppies that underwent ovariohysterectomy before three months of age appeared to be at the greatest risk. Based upon this study, female puppies should not undergo ovariohysterectomy until at least three to four months of age. The authors note, however, that in certain shelter environments, the need for gonadectomy prior to adoption may outweigh the risk of urinary incontinence.

Perivulvar Dermatitis

The vulvas of puppies neutered prior to puberty appear smaller when compared to intact bitches. Vulvar size may also appear small in intact bitches during anestrus or in some bitches spayed later in life. Perivulvar dermatitis can result in bitches with recessed or small vulvas, especially if the bitch has excessive skin and adipose tissue that cause skin folds that partially cover the vulva. Although perivulvar dermatitis has been associated with weight gains and recessed vulvas following ovariohysterectomy, there is no data to suggest that the occurrence is higher in bitches spayed at early ages over those neutered at conventional ages.

Neoplasia

Compared to intact dogs, gonadectomized dogs have been reported to have a higher risk of osteosarcoma, despite the fact that the neutered dogs actually lived longer than the intact dogs.[18,19]

Additionally, it has been suggested that ovariectomized females may be at an increased risk of hemangiosarcoma when compared to intact females,[20,21] although this was not confirmed in a later study.[17] Although rare, transitional cell carcinoma of the bladder may be seen more frequently in neutered dogs than in intact dogs.[22]

Ovariohysterectomy

Roger B. Fingland and Don R. Waldron

Indications

The most common indication for ovariohysterectomy (OVH) is elective sterilization. Ovariohysterectomy is the treatment of choice for most uterine diseases including pyometra, uterine torsion, localized or diffuse cystic endometrial hyperplasia, uterine rupture, and uterine neoplasia.[1] In a study of 1712 ovariohysterectomies in dogs, 82% were performed for elective sterilization, 18% for reproductive tract disease, and 7% as adjunctive therapy for mammary neoplasia.[2] Ovariohysterectomy is indicated for diabetic and epileptic animals to prevent hormonal changes that alter the effectiveness of medications.

Endogenous estrogen production plays a role in the etiology of spontaneous mammary tumors.[3] Ovariohysterectomy before the first estrus provides a definitive protective factor, reducing the incidence of mammary neoplasia to 0.5%.[1,3] The risk factor is 8% when ovariohysterectomy is delayed until after one estrus, and after two or more estrus cycles, the risk rises to 26%.[1,3]

Ovariohysterectomy may be a justifiable adjuvant therapy for mammary neoplasia. Controversy exists, however OVH may inhibit the recurrence of benign or malignant tumors that have estrogen receptors. Proponents of OVH also note that remaining mammary tissue atrophies permitting easier surgery on any mammary tumors that subsequently develop.

Surgical Anatomy

The ovaries, oviducts, and uterus are attached to the dorsolateral walls of the abdominal cavity and the lateral wall of the pelvic cavity by paired double folds of peritoneum called the right and left broad ligaments. Cranially, the broad ligament is attached by means of the suspensory ligament of the ovary (Figure 33-1). The broad ligament is divided into three regions: the mesovarium, the mesosalpinx, and the mesometrium. The suspensory ligament runs from the ventral aspect of the ovary and mesosalpinx cranially and dorsally to the middle and ventral thirds of the last two ribs.[3] The proper ligament is the caudal continuation of the suspensory ligament. The proper ligament attaches to the cranial end of the uterine horn. The round ligament of the uterus attaches to the cranial tip of the uterine horn and is a caudal continuation of the proper ligament. The round ligament extends caudally and ventrally in the broad ligament, and, in most bitches, it passes through the inguinal canal and terminates subcutaneously near the vulva.[4]

The ovarian arteriovenous (AV) complex lies on the medial side of the broad ligament and extends from the aorta to the ovary. The distal two-thirds of the ovarian AV complex is convoluted, similar to the pampiniform plexus in males.[2] The ovarian artery is less convoluted in cats.[5] The ovarian artery supplies the ovary and the cranial portion of the uterine tube in the dog and cat. The arterial supply to the uterus in the nonpregnant dog and cat is relatively independent of the supply to the ovary. Small anastomoses in the broad ligament are present between branches of the ovarian artery and branches of the uterine artery.[5]

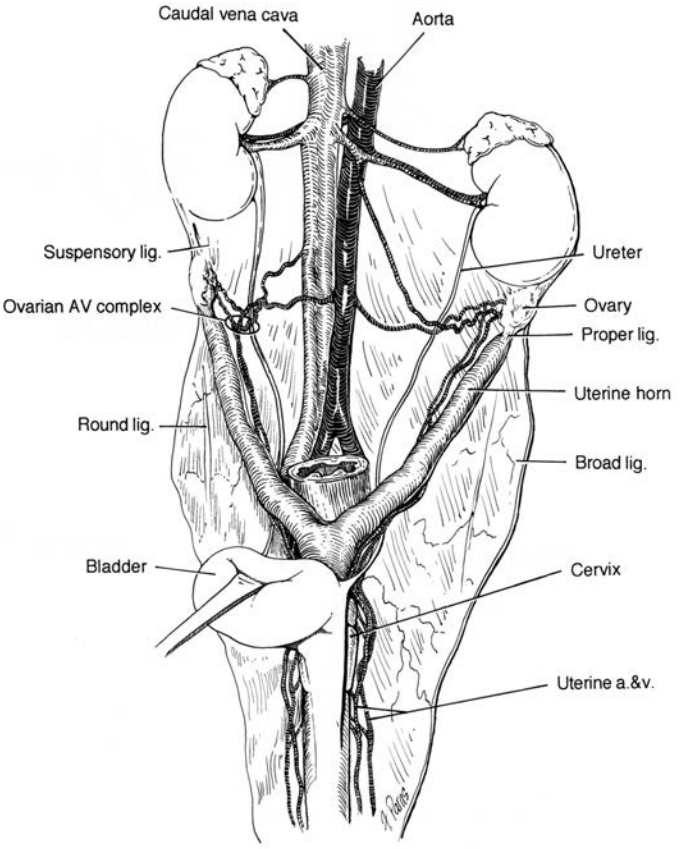

Figure 33-1. The female canine reproductive tract.

The left ovarian vein drains into the left renal vein, and the right ovarian vein drains into the caudal vena cava. The uterine veins run in close association with the uterine arteries and terminate caudally into the internal iliac veins.

Surgical Technique

The urinary bladder should be manually expressed before ovariohysterectomy. A midline abdominal incision is made extending from the umbilicus to a point halfway between the umbilicus and the brim of the pubis in the dog. The incision begins approximately 1cm caudal to the umbilicus in the cat and extends approximately 3 to 5 cm caudally. The abdominal incision must be carried further caudally in the cat to provide adequate exposure of the uterine body. A longer abdominal incision is recommended if the uterus is enlarged. The left or right uterine horn is located by using either an ovariohysterectomy (Snook) hook or the surgeon's index finger. A small hemostat may be placed on the proper ligament to aid in retraction of the ovary. The suspensory ligament is stretched or broken using the index finger (Figure 33-2A). Tension must be directed caudally along the dorsal body wall rather than perpendicular to the incision to avoid tearing the ovarian AV complex. Separate ligation of the suspensory ligament is seldom necessary. The ovarian AV complex is located, and a "window" is made in the mesovarium immediately caudal to the complex (Figure 33-2B). The ovarian AV complex is double clamped using Rochester-Carmalt hemostatic forceps in the canine or mosquito hemostats in the feline (Figure 33-3). The surgeon should maintain constant digital contact with the ovary when applying the first clamp to ensure that the entire ovary is removed. A third clamp is

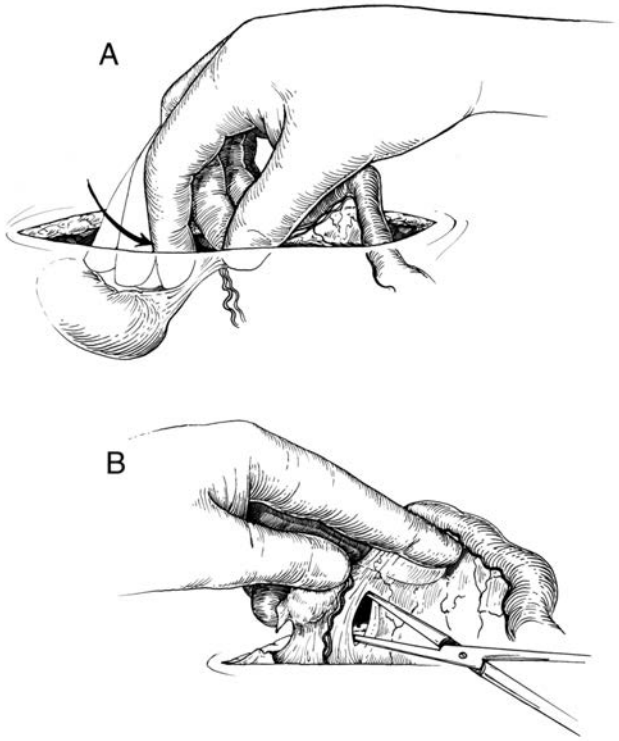

Figure 33-2. Isolation of the left ovary. **A.** The ovary is grasped between the thumb and middle finger, and the suspensory ligament is stretched or broken with the index finger. Tension must be directed caudally along the dorsal body wall. **B.** A window is made in the mesovarium caudal to the ovarian arteriovenous complex.

placed over the proper ligament between the ovary and uterine horn (Figure 33-4). The pedicle is severed between the middle clamp and the ovary (Figure 33-4). When this technique is used, the pedicle is severed between the middle clamp and the clamp closest to the ovary (See Figure 33-4, inset). Clamps should be placed on the ovarian pedicle as close to the ovary as possible to prevent accidental inclusion of the ureter.

Absorbable suture (e.g., chromic catgut, polydioxanone, or polyglyconate) is preferred for all ligatures. A circumferential

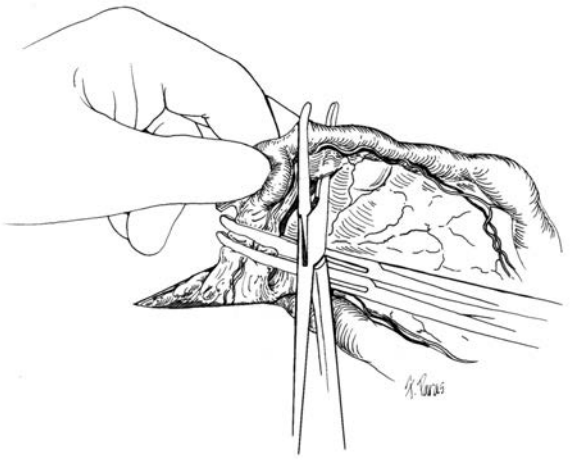

Figure 33-3. Two clamps are placed on the ovarian arteriovenous complex proximal to the ovary, and a third clamp is placed over the proper ligament.

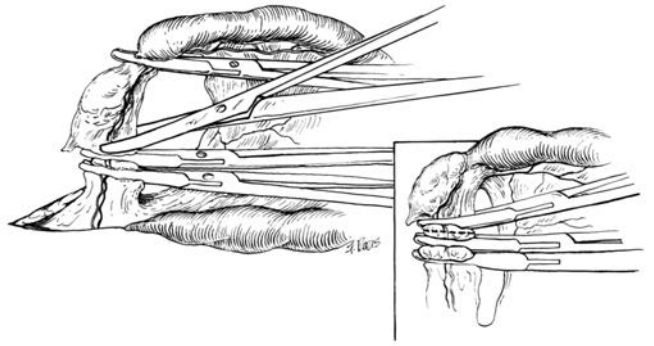

Figure 33-4. The ovarian arteriovenous complex is transected between the ovary and the middle clamp. When all three clamps are placed proximal to the ovary (inset), the ovarian arteriovenous complex is transected between the middle clamp and the clamp closest to the ovary.

suture is loosely placed around the proximal clamp (Figure 33-5). The clamp is removed while the circumferential suture is tightened so the circumferential suture lies in the groove of crushed tissue created by the clamp (Figure 33-5, inset). As the suture is tightened the second hemostatic clamp is "flashed" or temporarily opened which allows the tissue pedicle to return to its circumferential configuration and allows complete tightening of the first ligature. The benefits of clamp "flashing" are more noticeable in larger tissue pedicles. A second circumferential or transfixation suture is placed between the first circumferential suture and the cut end of the pedicle (Figure 33-6). The pedicle is grasped (without grasping the ligature) with thumb forceps, the final clamp is released, and the pedicle is inspected for bleeding. If no bleeding occurs, the pedicle is replaced into the abdomen.

The ipsilateral uterine horn is isolated by following the first side uterine horn distally to the bifurcation. The ligation procedure is repeated on the right ovarian pedicle. A window is made in the broad ligament adjacent to the uterine artery and vein (Figure 33-7A). The broad ligament is grasped and torn (Figure 33-7B and C). Mass ligation of the broad and round ligament is seldom necessary; however, large vessels in the broad ligament should be ligated especially in larger mature dogs.

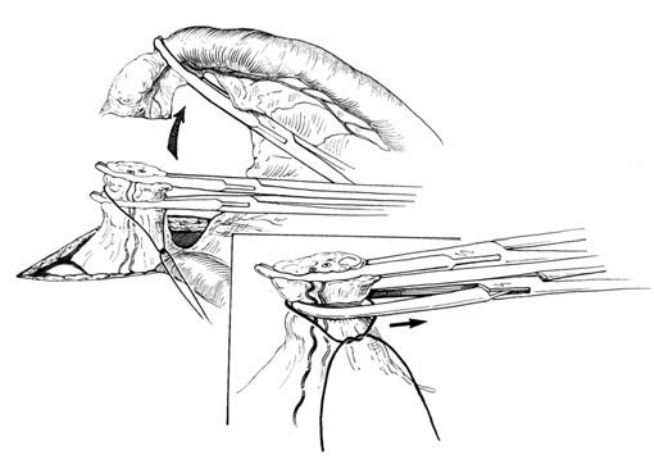

Figure 33-5. A circumferential ligature is loosely placed around the most proximal clamp. The clamp is removed, and the ligature is tightened in the groove of crushed tissue created by the clamp (inset).

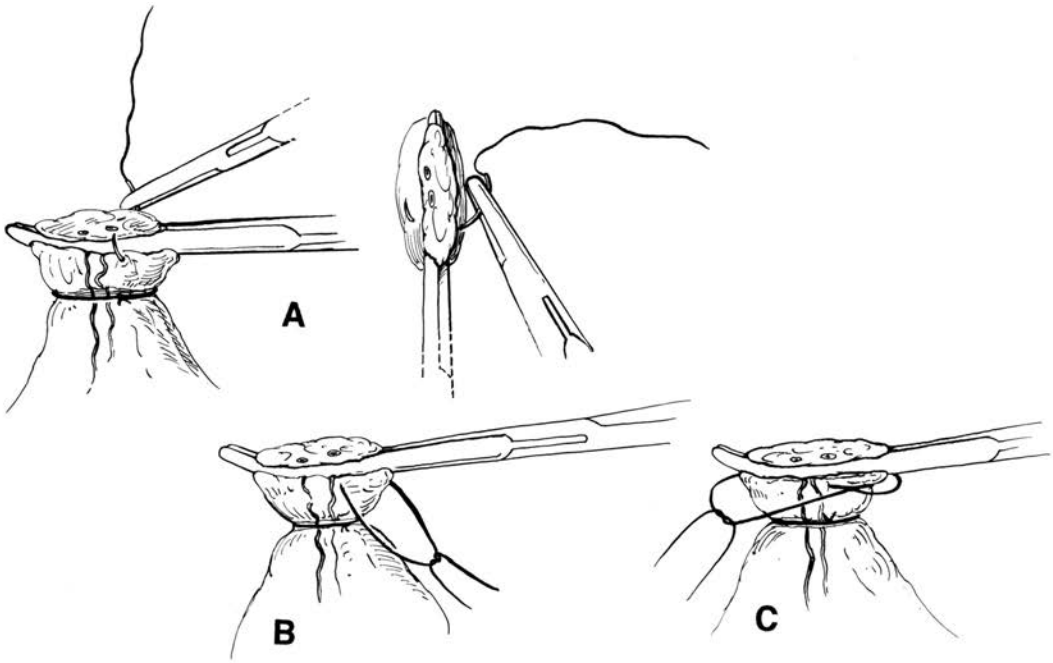

Figure 33-6. A transfixation suture is placed between the circumferential suture and the cut edge of the ovarian arteriovenous complex. **A.** Approximately one-third of the width of the ovarian arteriovenous complex is included in the initial suture. **B.** The initial suture is tied. **C.** The ends of the suture are directed around the ovarian arteriovenous complex and are tied.

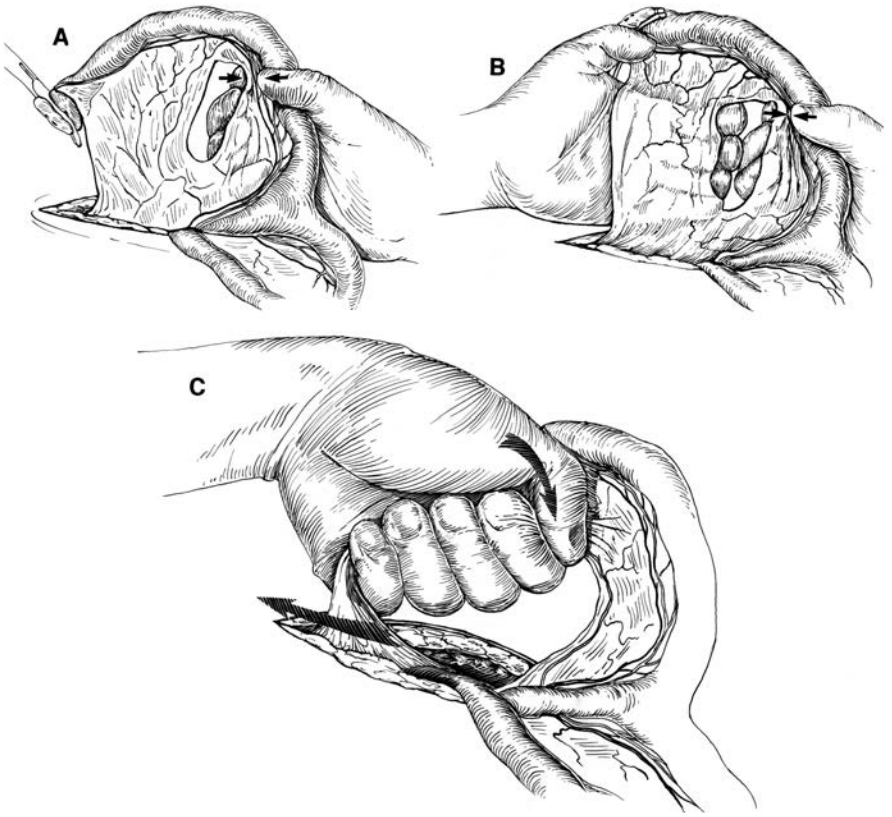

Figure 33-7. Separation of the broad ligament. **A.** The uterine artery and vein are protected with the thumb and index finger, and a window is made in the broad ligament. **B.** The broad ligament is grasped. **C.** The broad ligament is torn. Large vessels should be individually ligated.

The uterine body is exteriorized, and the cervix is located. Various techniques may be used to ligate and divide the uterine body, depending on the size of the uterus and the surgeon's preference. The triple-clamp technique may be used when the uterine body is small, such as in cats and small dogs. Three clamps are placed immediately proximal to the cervix. Care must be taken when applying clamps to the uterine body particularly in the cat because the clamps may cut rather than crush the tissue. Some surgeons prefer to not use crushing clamps on the feline uterine body. The uterine body is severed between the middle clamp and the proximal clamp. The uterine arteries and veins are individually ligated between the distal clamp and the cervix. A circumferential suture is loosely placed around the distal clamp, the clamp is removed, and the suture is tightened in the groove of crushed tissue. A transfixation suture is placed between the circumferential suture and the remaining clamp. The remaining clamp is removed, and the uterine stump is evaluated for bleeding and replaced into the abdomen.

A second technique for ligation of the uterine body involves placement of bilateral individual ligatures on each uterine artery. The uterine body is exteriorized and retroflexed. Sutures that initially incorporate the uterine artery and vein and a small bite of uterine serosa are placed on either side of the uterine body (Figure 33-8A and B). A clamp may be loosely placed proximal to the sutures to prevent backflow of blood after transection. The uterine body is severed between the clamp and the proximal sutures (Figure 33-8C). The uterine stump is evaluated for bleeding and is replaced into the abdomen. This technique is advantageous because clamps are not placed on the section of the uterine body that is ligated; therefore, the potential for cutting the tissue with the clamp is eliminated. Depending on the size of the uterine body and vessels, either mass ligatures, transfixation, or individual ligatures may be used to safely ligate the uterine vasculature.

A Parker-Kerr suture pattern has been used for ligation when the uterine body is greatly enlarged (i.e.-pyometra) but is seldom if ever indicated. A Parker-Kerr pattern has the potential for creating a closed cavity of tissue thus preventing drainage of infected material. The uterine arteries and veins should be ligated separately distal to the Parker-Kerr suture pattern.

The ovarian pedicles and uterine stump should be evaluated for bleeding before abdominal closure. The left ovarian pedicle is located by retracting the descending colon medially to expose the left paralumbar fossa. Retraction of the descending duodenum medially exposes the right paralumbar fossa and the right ovarian pedicle. The ovarian pedicles lie immediately caudal to the caudal pole of the kidneys. The uterine stump lies between the bladder and colon and is located by retroflexing the bladder. Sutures should not be grasped when evaluating the ovarian pedicles and uterine stump because excessive traction on the suture may cause it to loosen.

The abdominal incision is closed with either a simple interrupted or simple continuous suture pattern using appropriately sized polydioxanone suture. Sutures should be placed in the external rectus sheath.[6] It is not necessary to suture the internal rectus sheath or the peritoneum.[6] The subcutaneous tissue and skin are closed routinely.

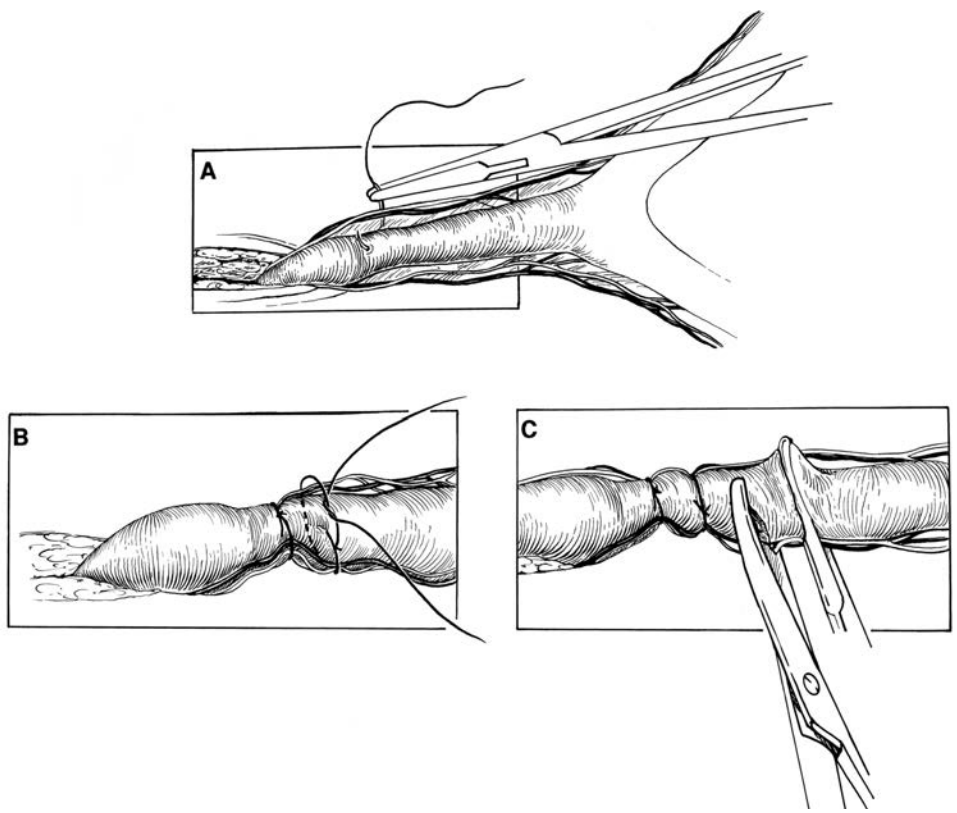

Figure 33-8. Ligation of the uterine body. **A.** A transfixion suture is placed to include the left uterine artery and vein. **B.** A similar transfixion suture is placed to include the right uterine artery and vein. **C.** A clamp is placed across the uterine body proximal to the transfixion sutures, and the uterine body is transected.

A flank approach for feline ovariohysterectomy is used widely in Europe, but it is not recommended. Recovery of a dropped ovarian pedicle is problematic, and it may be difficult to expose the opposite ovary and the uterine bifurcation through this approach.[7]

Complications and Sequelae

Hemorrhage

Intra-operative hemorrhage has been reported as the most common complication of ovariohysterectomy in dogs over 25 kg.[8] Hemorrhage during ovariohysterectomy may result from tearing of the ovarian AV complex while strumming the suspensory ligament. This complication may be avoided by carefully strumming the ligament as previously described. Intra-operative hemorrhage also may result from tearing of large vessels in the broad ligament, tearing of the uterine vessels by excessive traction on the uterine body, or accidental releasing of a clamp before placement of ligatures. Large vessels in the broad ligament should be individually ligated, and excessive traction on the uterine body should be avoided by lengthening the abdominal incision.[1] Improperly placed sutures may result in intra-operative or post-operative hemorrhage. The ovarian pedicles and uterine stump should be double ligated and evaluated for bleeding before abdominal closure. Other potential sources of hemorrhage that may be noted intra-operatively include the abdominal musculature, (rectus abdominis muscle), subcutaneous tissue and skin.

Uterine Stump Pyometra

Uterine stump pyometra can occur if the animal has elevated blood progesaterone levels. The source of progesterone may be endogenous, from residual ovarian tissue (incomplete removal), or exogenous, from progestational compounds used to treat dermatitis.[1,9] Uterine stump pyometra can be prevented by ensuring complete removal of the ovaries during OVH.

Recurrent Estrus (Ovarian Remnant Syndrome)

Recurrent estrus usually results from functional residual ovarian tissue after incomplete ovariohysterectomy. Clinical signs associated with estrus and ovarian hormonal activity may be present.[10] The hormonal effects may be delayed, depending on whether or not vascularity to the ovarian remnant has been maintained. Collateral circulation to the ovarian tissue may develop even though the ovarian AV complex has been ligated and transected.[11] Treatment of recurrent estrus after ovariohysterectomy is surgical exploration and excision of residual ovarian tissue. Surgical exploration during estrus is preferable. Identification of an ovarian remnant on one side should not preclude inspection of the other ovarian site.[10] Functional residual ovarian tissue is more commonly found on the right side.[12] Residual ovarian tissue occasionally cannot be identified or palpated, and its presence is often made manifest by increased vascularity of the ovarian pedicle. All excised tissue should be submitted for histopathologic examination. A disproportionate number of cats that develop the ovarian remnant syndrome have been operated through a flank incision.[10] Incomplete ovariectomy may be prevented by maintaining constant digital contact with the ovary during application of hemostatic clamps to the ovarian AV complex.

Ligation of Ureter

Accidental ligation of a ureter may occur during ligation of the uterine body or an ovarian AV complex.[12] Ligation of a ureter results in hydronephrosis and may predispose to pyelonephritis. The ureter may be accidentally crushed or ligated if the ovarian AV complex is dropped and indiscriminate clamping of tissue occurs in the lumber gutter. A ureter is more likely to be included in a uterine body ligature if the bladder is full because the trigone and vesicoureteral junction are cranially displaced, resulting in more slack on the ureters. Accidental ligation or crushing of a ureter may be prevented by ligating the ovarian AV complex as close to the ovary as possible, by evacuating the patient's urinary bladder preoperatively, and by isolating and ligating the uterine vessels carefully.

Urinary Incontinence

Urinary incontinence after ovariohysterectomy can be caused by a low systemic estrogen level, by adhesions or granulomas of the uterine stump that interfere with urinary bladder sphincter function, or by vaginoureteral fistulation from common ligation of the vagina and ureter.[13] Estrogen-responsive urinary incontinence may occur in any spayed bitch and is a poorly understood sequela of ovariohysterectomy.[14] The onset of estrogen responsive incontinence postoperatively is variable and may take several years.[14] The mean reported age of onset is 8.3 years and bitches spayed before 12 weeks of age appear to be at increased risk for developing incontinence.[14] The recommended therapy for estrogen-responsive urinary incontinence is oral administration of phenylpropanolamine (1.5-2.0 mg/kg PO, bid to tid) or diethylstilbestrol at 0.1 to 1.0 mg per day for 3 to 5 days, followed by a maintenance does of 1.0 mg per week.[14]

Fistulous Tracts and Granulomas

The most common cause of sublumbar fistulous tracts in spayed bitches is adverse tissue reaction to implanted nonabsorbable multifilament suture material (e.g., polymerized caprolactam, Braunamid, B. Braun Melsurgen AG, Germany) used for ovarian or uterine ligature.[12,15-17] The high bacterial adherence and capillarity of multifilament suture may contribute to persistent and progressive infection when the suture is contaminated with bacterial organisms and is buried in tissue.[18] No ovarian or uterine stump granulomas or fistulous tracts were reported in 377 bitches that had ovariohysterectomies using 2-0 chromic catgut suture.[8]

The interval between ovariohysterectomy and appearance of fistulous tracts is often several months and may be several years.[12] Fistulous tracts can occur anywhere on the trunk, although they most commonly occur in the flank when associated with ovarian pedicle ligatures and in the inguinal or thigh region when associated with a uterine ligature.[18] Ovarian pedicle granulomas caused by adverse tissue reaction to suture material may involve the kidney or proximal ureter, resulting in hydronephrosis and pyelonephritis. Uterine stump granulomas may involve the urinary bladder, distal ureters, or colon, leading to cystitis, pollakiuria, urinary incontinence, or bowel obstruction.[18] Exploratory celiotomy with excision of the offending ligature and of associated granulation tissue is the treatment of choice. All ovarian and uterine ligatures should be removed even though

some appear uninvolved because they may subsequently provoke an adverse tissue response.[12] Local exploration of fistulous tracts is seldom successful and is indicated only if exploratory celiotomy fails to identify the offending tissue.[1] The use of absorbable suture material for ovarian and uterine ligatures during ovariohysterectomy reduces or removes the incidence of this complication.[18]

Body Weight Gain

Body weight gain was the most common long-term sequela reported in one study, occurring in 26.2% of bitches undergoing elective ovariohysterectomy.[19]

The cause of excessive weight gain after ovariohysterectomy is poorly understood. One theory suggests that the fat deposits of the body possess receptors for specific steroid hormones so deposition is blocked or facilitated in a regional manner in response to testosterone, estradiol, progesterone, and cortisol. Estradiol inhibits lipoprotein lipase in adipocytes of fat deposits, so circulating fatty acides cannot be esterified and deposited.[20] A low systemic estradiol level after ovariohysterectomy may lead to excessive fat deposition and weight gain.

Eunuchoid Syndromes

The eunuchoid syndrome is occasionally observed in working dogs after ovariohysterectomy. Affected dogs have decreases in aggression, interest in work, and stamina.[20] Autotransplantation of an ovary to the subserosa of the stomach wall, which is drained exclusively by the portal vein, may prevent this complication.[20] The graft produces estradiol and progesterone, which are partially metabolized by the liver. Circulating estradiol levels are inadequate to initiate estrus, but they are sufficient to prevent the eunuchoid syndrome.[20]

Complications of Celiotomy

Accidental incision of the spleen or urinary bladder, failure to remove all gauze sponges from the abdominal cavity before closure, dehiscence, seroma formation, and self-mutilation may occur with any abdominal procedure. Self-inflicted trauma of the abdominal wound is the most commonly reported complication of ovariohysterectomy of dogs less than 25 kg.[8] Most of these complications can be prevented by gentle tissue handling, close attention to surgical detail and by adhering to the basic principles of aseptic surgical technique.

Early Prepubertal Gonadectomy

Minimal scientific evidence exists to support the widely accepted practice of delaying elective sterilization until an animal is 5 to 8 months old. Veterinarians are comfortable with this practice because untoward effects occur infrequently. Early prepubertal gonadectomy (i.e., at 8 to 12 weeks of age) has been investigated because the efficacy of sterilization programs could be enhanced if all animals were neutered before adoption. Much has been learned about the effects of early prepubertal gonadectomy on skeletal growth, obesity, behavior, secondary sex characteristics, anesthetic risk, and immunology.[21] The current body of knowledge supports the notion that early prepubertal gonadectomy is not deleterious[21] (See Chapter 35).

Harmonic Scalpel Assisted Laparoscopic Ovariohysterectomy (HALO)

Robert Hancock

Introduction

Ovariohysterectomy (OVH) is the most common elective surgical procedure performed for small animal sterilization in the United States.[1] Ovariohysterectomy provides canine and feline population control and decreases the incidence of life threatening diseases such as pyometra and mammary cancer. It is well documented that traditional OVH procedures performed by celiotomy inflict pain and morbidity in veterinary patients as a result of tissue trauma, organ manipulation, and inflammation.[2,3] With an increasing concern for postoperative morbidity from owners and increased public awareness of minimally invasive techniques, the frequency of minimally invasive veterinary procedures has increased recently.

Preoperative Considerations

Advantages and Disadvantages

Laparoscopic ovariohysterectomy and hysterectomy procedures in human and veterinary patients have been shown to have numerous advantages over traditional celiotomy techniques including decreased postoperative stress and pain, faster recovery periods, decreased hospital stays, improved cosmesis, and improved visualization of abdominal organs.[4] Two recent veterinary studies documented decreased postoperative pain and less incisional erythema in laparoscopic ovariohysterectomy patients.[5,6] Disadvantages of laparoscopic ovariohysterectomy include the inherent limitations of minimally invasive surgery, cost of equipment, procedural learning curve, and increased time of the operative procedure compared to traditional surgical techniques.

Anesthesia

The anesthetist should be prepared for changes in the cardiovascular and pulmonary systems during surgery. After induction of general anesthesia and aseptic preparation of the abdomen for surgery the animal is placed in a modified Trendelenburg position which requires a 20 to 30° tilt in the surgical table, placing the pelvic limbs above the level of the head.[7] This positioning provides the surgeon with better visualization of the caudal abdominal organs. However, this patient position can lead to increased pressure on the diaphragm from viscera leading to cardiopulmonary dysfunction. In addition, laparoscopic surgery requires insufflation of the abdomen with gas which increases abdominal pressure. Intra-abdominal pressures above 15 mm Hg can lead to decreased venous return and cardiac output, vasovagal reflexes, decreased compliance of the diaphragm, and ventilation-perfusion mismatch.[4,8,9] Finally, although the risk of gas embolus is low, due to carbon dioxide's high blood solubility, fluctuation in cardiopulmonary system function should be monitored carefully.

Harmonic Scalpel

The harmonic scalpel consists of an electrical generator, handpiece, an active and inactive blade system, and a foot pedal. Electrical energy is produced through an external generator and converted to ultrasonic energy by means of a piezoelectric, ceramic transducer located within the handpiece. The piezoelectric crystal vibrates at approximately 55,000 hertz, causing longitudinal movement against the inactive part of the blade. Mechanical energy from the oscillating blades results in energy transfer to tissue proteins, leading to protein denaturization and the formation of a sticky protein coagulum. This protein coagulum is capable of sealing vessels as large as 5 mm in size.[11,12]

The harmonic scalpel has been used for safe hemostasis in hysterectomy and other abdominal procedures for humans and ovariohysterectomy procedures in horses and dogs. The harmonic scalpel was designed to be used through laparoscopic and thorascopic instrument portals. This scalpel is able to cut, coagulate, and seal vessels simultaneously at much lower temperatures (50 to 100°C) than electrosurgery or laser surgical devices (150 to 400°C).[5,10] The ability to seal vessels at low temperatures with a protein coagulum is referred to as coaptive coagulation. Because of the lower temperatures, less collateral tissue damage occurs with the harmonic scalpel when compared to monopolar and bipolar cautery. In addition, the risk of stray electricity and electrical burn is eliminated with the harmonic scalpel. Lasers and cautery units vaporize cells via rapid heating and cellular explosion, resulting in eschar and smoke formation. Smoke from these devices can accumulate and decrease visualization in a hollow cavity and slow operative time. The harmonic scalpel produces no smoke, thus allowing rapid coagulation with excellent visualization of the surgical field.

Surgical Procedure

The ventral abdomen is prepared for surgery by wide clipping from the xiphoid to the pubis. Following routine preparation of the abdomen for surgery four quarter drapes are placed approximately 2 cm lateral to each row of mammary teats, at the level of the xiphoid cranially, and at the level of the pubis caudally. The dog is then placed in a Trendelenburg position to facilitate craniad displacement of the visceral contents. A 1 cm skin incision is made at the level of the umbilicus to expose the linea alba.

The abdomen is entered through the linea alba with a surgical trocar (Endopath® 355S Surgical Trocar Ethicon Endo-Surgery, Cincinnati OH) using the Hasson technique. Pneumoperitoneum is established with an insufflator (Electronic Insufflator Model 26012, Karl Storz,) to a pressure of 10mmHg using carbon dioxide gas. A 30° forward-oblique, 5 mm telescope (Hopkins II, Karl Storz, Charleston, MA) is placed through the umbilical port and used to identify the epigastric blood vessels in the abdominal wall to facilitate placement of the paramedian instrument ports under direct camera supervision (5X Hunt Trocar / 5 mm Pyramidal Tip, Apple Medical Corp, Bolton, MA). Each port is introduced 1cm lateral to the 4th mammary teat in the caudal abdomen, using care to avoid the caudal superficial epigastric artery and vein. (Figure 33-9) Babcock forceps (Endopath—5 mm Babcock Forceps, Ethicon Endo-Surgery Inc, Cincinnati, OH) are then placed

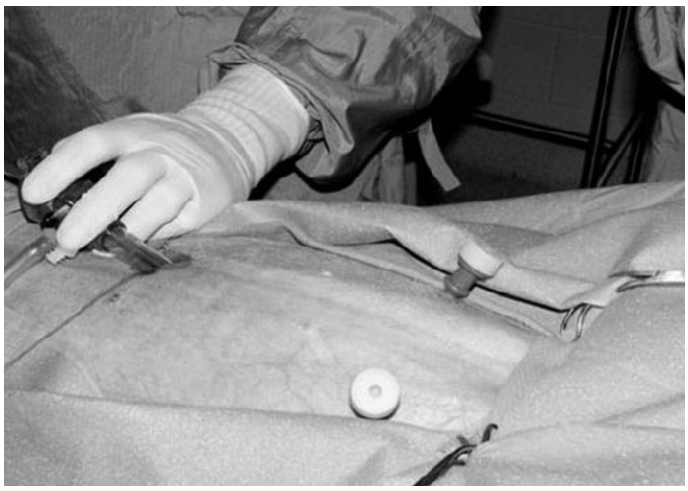

Figure 33-9. Ports are introduced 1 cm lateral to the 4th mammary teat in the caudal abdomen. Babcock forceps are then placed through the right paramedian portal and clamped to the proper ligament of the right ovary.

through the right paramedian portal and clamped to the proper ligament of the right ovary. Caudo-ventral tension is maintained on the ovarian vascular pedicle and suspensory ligament using the Babcock forceps. The harmonic scalpel (Ultracision LCSC5, Ethicon Endo-Surgery Inc, Cincinnati, OH) should then be placed through the left paramedian port and the suspensory ligament, ovarian vascular pedicle, and broad ligament of the uterus are transected and coagulated from cranial to caudal to the level of the uterine body. The uterine artery and vein are transected just proximal to the cervix, followed by the body of the uterus. The procedure is then repeated in reverse order on the left side transecting the broad ligament of the uterus first, followed by the left suspensory ligament, and finally the ovarian pedicle.

All of the transected areas are inspected for hemorrhage after completion of the procedure. The camera is then removed from the umbilical port and placed into the instrument port. Babcock forceps are then introduced through the umbilical port, clamped to the uterine body, and the entire reproductive tract is withdrawn through the umbilical port under direct camera visualization.

Pressure is applied to each side of the abdominal wall to facilitate the escape of carbon dioxide gas from the abdominal cavity prior to closure. The umbilical port can be closed with one, simple interrupted, absorbable suture. The subcutaneous tissue of the umbilical port is apposed with one, simple interrupted, absorbable, cruciate suture, followed by a single simple interrupted cruciate, nonabsorbable, skin suture. The paramedian ports are apposed similarly.

Alternative to Use of the Harmonic Scalpel

If a harmonic scalpel is not available or not used; other extracorporeal or intracorporeal knot tying techniques including Endoloop and Endoknot sutures can be placed on the ovarian and uterine pedicles for hemostasis. The Endoloop sutures consist of a pretied Westin Knot. These loops are placed through the ipsilateral cannula to the level of the intended tissue to be ligated and the loop is slowly closed with a knot pusher. The major disadvantage of using intracoporeal and extracorporeal sutures are the increased operative time and learning curve associated with their use, as well as, the risk of continued hemorrhage at the ovarian and uterine pedicles.[6,13]

Bipolar and monopolar laparoscopic cautery units can also be used for coagulation of ovarian and uterine pedicles. However, visualization during laparoscopy can be impaired by smoke when using bipolar cautery units within the abdomen. These affects are more profound in smaller sized animals. Also, when using any cautery unit there is a risk of collateral thermal damage, due to much higher coagulation temperatures and stray electricity to surrounding organs. One study evaluated laparoscopic ovariectomy using monopolar and bipolar cautery techniques. There was mesovarial arterial bleeding in 8% of dogs treated with bipolar cautery and 13% of dogs where monopolar cautery was used. Additional Endoloop ligatures were required to prevent recurrent hemorrhage in 20 of 103 of the reported cases.[14] The harmonic scalpel produces no smoke and minimal vapor. No additional hemostasis was required in any dog in one study where the harmonic scalpel was used.[5]

The use of the harmonic scalpel technique could be used for ovariectomy, as well as ovariohysterectomy procedures. Surgical times for ovariohysterectomy procedures with HALO are consistently less than 1 hour in duration and have been shown to decrease postoperative pain when compared to traditional OVH celiotomy techniques. With experience and proper training the HALO procedure provides a safe, efficient, minimally invasive technique for a commonly performed elective surgery. Laparoscopic OVH will likely become more common as owners and veterinarians seek less invasive surgical procedures for animals.

Editor's Note: The use of the harmonic scalpel and energy vessel sealing devices are well established in minimally invasive surgery (MIS). Several techniques of performing MIS ovariectomy or ovariohysterectomy are successfully used in the bitch.

Cesarean Section: Traditional Technique

Curtis W. Probst and Trevor N. Bebchuk

Introduction

Cesarean section in the dog and cat usually is an emergency procedure because prolonged dystocia risks the life of the mother and neonate. Cesarean section can be planned and performed before the onset of active parturition when dystocia is predicted owing to preexisting injuries or abnormalities that compromise the birth canal. Cesarean section is indicated when dystocia results from primary uterine inertia, when secondary uterine inertia has occurred in protracted dystocia of over 24 hours' duration, when obstructive dystocia (e.g., grossly oversized fetus or abnormally small pelvic canal) is present, or when removal of the obstructive fetus is not likely to alter the ultimate outcome of the dystocia.

Surgical Anatomy

The gravid uterus lies on the abdominal floor during the last half of pregnancy. The heavily gravid uterine horns are parallel and in contact with each other, unlike the divergent uterine horns in the non-pregnant animal. As the horns enlarge, they also flex and bend the uterus cranially and ventrally on itself. When making the abdominal incision during cesarean section, the surgeon must be aware that the uterus is close to the thin, distended abdominal wall.

The uterus is composed of three layers: tunica serosa (perimetrium), tunica muscularis (myometrium), and mucosa (endometrium). The tunica serosa is a layer of peritoneum that covers the entire uterus and is continuous with the mesometrium (broad ligaments). The muscular layer consists of a thin longitudinal outer layer and thick inner layer. The deeper myometrium contains blood vessels, nerves, and circular and oblique muscle fibers. The tunica muscularis is the layer of greatest tensile strength. The tunica mucosa is the thickest of the three layers.

The uterus is well supplied with arterial blood from the ovarian and uterine arteries (See Figure 33-1). The uterine vessels greatly enlarge during gestation and potentially complicate an ovariohysterectomy performed in conjunction with a cesarean section. Lymphatic drainage of the uterus is through the internal iliac and lumbar lymph nodes. Autonomic nervous innervation is through the hypogastric and pelvic plexuses.

Preoperative Preparations

Animals considered for cesarean section are often in poor physiologic condition at the time of presentation and should be carefully examined. Abdominal radiographs are useful in documenting the presence and number of fetuses, thus helping the surgeon to avoid inadvertently leaving a fetus in the uterus or pelvic canal. Laboratory tests are often limited to measurement of the animal's hematocrit, total plasma protein, serum urea nitrogen, or urine specific gravity. These tests assist in evaluating the need for corrective fluid therapy or cross matching of potential blood donors. Most pregnant animals are mildly anemic because of an increase in plasma volume during gestation without a concomitant increase in red blood cells. The surgeon should consider this physiologic anemia when deciding whether the dam requires a whole-blood transfusion.

An intravenous fluid infusion should be established before any anesthesia is given. The preferred fluid is a balanced electrolyte solution such as lactated Ringer's solution. A solution of 2.5% dextrose and half-strength lactated Ringer's may be more appropriate if the animal has not eaten for some time and hypoglycemia is suspected. A baseline administration rate of 10 mL/kg/hr may be increased as indicated by physiologic parameters. All volume deficits should be corrected before the surgical procedure is begun, if possible. If the fetuses are known to be dead and decomposing or if uterine infection is established, intravenous antibiotic therapy (cephalothin sodium, 40 mg/kg IV, or cefazolin sodium 22 mg/kg IV) should be instituted at this time.

The surgeon and the client should discuss, before surgery, the nature of the surgical procedure, its potential complications, and the issue of simultaneous ovariohysterectomy. The length of the surgical procedure may be important, depending on the condition of the dam. The advisability of an additional operation for ovariohysterectomy should be carefully considered. Ovariohysterectomy may be better postponed until the litter is weaned and the uterine vasculature has returned to normal size.

Surgical Technique

The dam is clipped from the xiphoid to the pubis, and the ventral abdomen is initially prepared by surgical scrubbing before induction of anesthesia to reduce total anesthesia time. Anesthesia induction and intubation are performed on the operating table. Usually, the dam has not been fasted before anesthesia; therefore, the patient should be intubated rapidly to minimize the risk of aspiration should vomiting occur during induction of anesthesia.

Operative speed is important in cesarean sections because prolonged "incision-to-delivery" time is associated with

increased fetal asphyxia and depression. A 10 to 20° left or right lateral tilt from dorsal recumbency is frequently used in women to prevent supine hypotension syndrome, which is thought to result from compression of the gravid uterus on the posterior vena cava, thus reducing venous return. Supine hypotension syndrome does not occur in the full-term pregnant bitch due to the bicornuate uterus and its position during pregnancy. Maternal posture has no effect on systemic blood pressure, therefore dorsal recumbency is an acceptable position for cesarean sections in dogs and cats.

After induction of anesthesia, the patient's limbs are tied down, and the final surgical preparation of the ventral abdomen is rapidly completed. The ventral abdomen is four-quadrant toweled and is draped from the xiphoid to the pelvic brim, to allow room for extension of the abdominal incision if necessary.

A ventral midline incision is made commencing at the umbilicus. The length of the incision is determined by the estimated size of the uterus. The mammary glands often are hypertrophied, and the surgeon should not invade mammary tissue when making the skin incision. The surgeon should also remember that the uterus is enlarged and should not be lacerated when the abdominal cavity is entered. I prefer using thumb forceps and a scalpel to open the abdominal cavity; however, Mayo scissors also are acceptable.

After the abdominal incision is completed, the wound edges are protected with laparotomy pads moistened with sterile saline. The first uterine horn and then the second are exteriorized by careful lifting through the incision. The surrounding and underlying viscera are packed off with additional moistened laparotomy pads to prevent abdominal contamination with fetal fluids. A small incision with a scalpel is then made in a relatively avascular area on the dorsal or ventral aspect of the uterine body; one must be careful not to lacerate a fetus inadvertently with the scalpel. The uterine incision is then extended with scissors to a length sufficient for easy removal of the fetuses (Figure 33-10).

In dystocia, the fetus present in the uterine body should be removed first. Each fetus is brought to the incision by gently "milking it down" the uterine horn. This is done by squeezing the uterine horn proximal to the enlargement. Once the fetus is near the incision, it may be grasped, and gentle traction may be applied to facilitate rapid removal from the uterus (Figure 33-11).

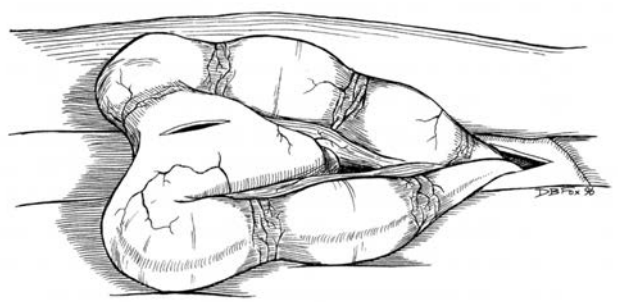

Figure 33-10. The gravid uterus has been exteriorized and surrounded with moistened laparotomy pads. An incision has been made in the dorsal aspect of the uterine body.

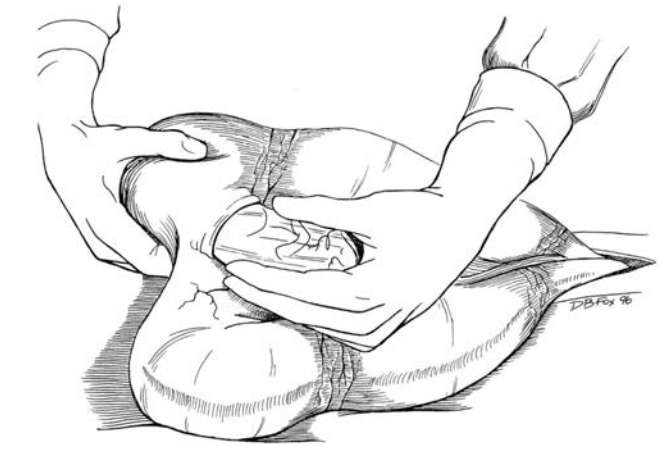

Figure 33-11. Each fetus is brought to the incision by squeezing the uterine horn proximal to the enlargement; it may be grasped and gentle traction applied to remove it from the uterus.

As each fetus is removed, the amniotic sac is broken to allow breathing to begin (Figure 33-12). Fetal fluids should be removed from the operative field by suction to minimize contamination. The umbilical vessels are then clamped and are severed approximately 2 to 3 cm from the fetal abdominal wall (Figure 33-13). The neonate is placed on a sterile towel and is passed to an attendant. The associated placenta is then slowly removed from the endometrium by gentle traction to minimize hemorrhage. This procedure is repeated until all fetuses and placentas have been removed. If considerable difficulty is encountered in mobilizing the fetuses down the uterine horns, additional incisions can be made in the horns. Before closure, the uterus is palpated from the pelvic canal to each ovary to be certain that all fetuses and placentas have been removed.

Another method of delivery is to remove the neonate and placenta with the umbilical cord and fetal membranes still intact. The amniotic sac is broken, and the cord is clamped when the neonate has been handed to an attendant. More maternal hemorrhage may be noted with this method.

Once all fetuses have been removed, the uterus rapidly begins to contract; this contraction is important in arresting hemorrhage. If the uterus has not begun to contract at the time of closure, oxytocin (5 to 20 units intramuscularly) can be administered.

I prefer absorbable suture material such as polydioxanone or polyglyconate with swaged-on noncutting needles for uterine closure. The edges of the uterine incision are carefully apposed with an inverting, continuous Cushing pattern followed by a continuous Lembert oversew (Figure 33-14). Before the uterus is returned to the abdomen, the closure should be inspected and the uterus should be cleansed with warmed sterile saline solution. If abdominal contamination has occurred during the surgical manipulations, the abdomen should be liberally lavaged with warmed sterile saline solution. The omentum is replaced over the uterus and other abdominal viscera before abdominal closure; the linea alba is closed with simple interrupted sutures of appropriate-sized absorbable suture material. Nonabsorbable suture material, such as polypropylene, nylon, or stainless steel

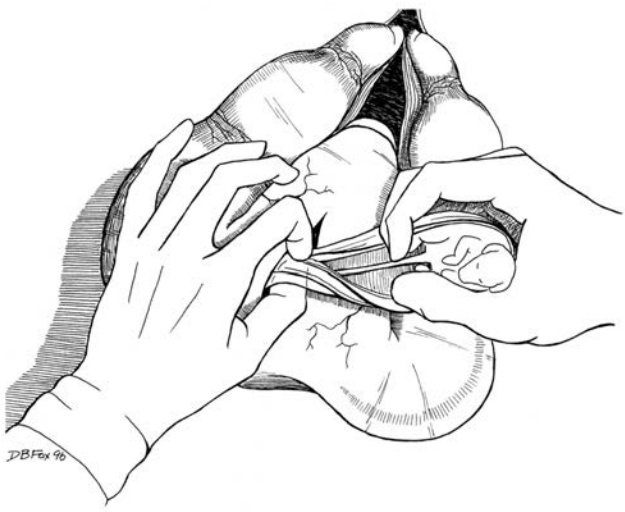

Figure 33-12. As the fetus is removed from the uterus, the amniotic sac is broken to allow breathing to begin.

Figure 33-13. The umbilical vessels are clamped and severed approximately 2 to 3 cm from the fetal abdominal wall.

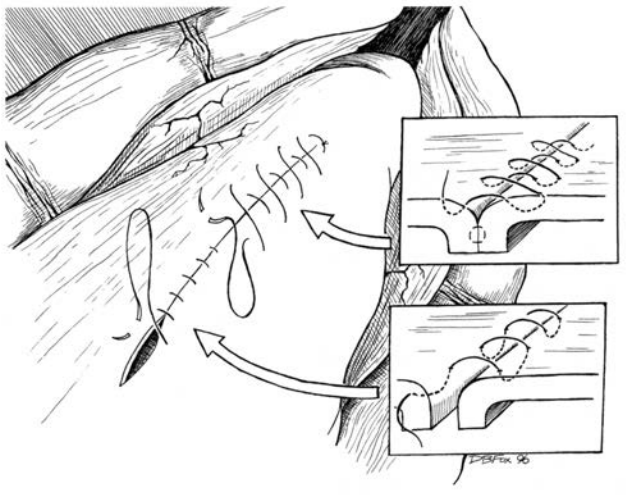

Figure 33-14. Double-layer closure of the uterus. *A.* A continuous Cushing pattern is used for the first layer. *B.* The first-layer closure is oversewn with a continuous Lembert pattern.

wire, may also be used to close the linea alba. The subcutaneous tissue is closed with 3-0 or 2-0 absorbable suture, and the skin is closed with nonabsorbable suture.

Before the conclusion of the surgical procedure, all inhalation anesthetic agents are discontinued, and the dam is weaned from assisted ventilation by progressively decreasing the respiratory rate. The dam should then be given several maximal inspirations to reopen any atelectatic areas of lung before a return to breathing room air.

Extubation should not be too hasty because patients that undergo cesarean section may have full stomachs and may vomit during induction or recovery. Vomiting during recovery is a major problem in parturient women, but it is less important in the dog and cat.

Resuscitation of the Neonates

After the neonate has been handed to the assistant, its umbilical cord should be temporarily clamped, the fetal membranes should be removed (if this has not yet been done), and its viability should be ascertained. If a heartbeat can be palpated, the nasopharynx should be cleared of fluid and mucus by gentle suction or cotton swabs. If a suction apparatus is not available, a bulb syringe can be used for suction. A gentle, controlled, downward swing of the neonate may help to clear fluid from the upper airways by centrifugal force. The neonate is then vigorously dried because skin stimulation stimulates respiratory drive in a reflex manner.

The neonate should be breathing and crying by this stage. Other encouraging signs are pink mucous membranes and a strong pulse. More active resuscitative measures include narcotic antagonists such as naloxone (0.01 mg/kg IM or IV) and the respiratory stimulant doxapram (1 to 2 drops sublingual or 0.1 ml IV in the umbilical vein). In the event of cardiorespiratory collapse, an emergency endotracheal intubation may be attempted with a plastic intravenous catheter (18 to 20 gauge).

Postoperative Care of the Dam and Neonates

When the puppies or kittens have been resuscitated and dried, they should be kept in a warm environment to avoid chilling. The clamp is removed from the umbilical cord, which is checked for hemorrhage. If hemorrhage occurs, the cord should be ligated with 3-0 chromic gut.

While the mother is recovering from anesthesia, her mammary glands should be cleaned with warm water to remove any residual surgical preparation solutions, blood, or fetal fluids. The dam should be returned to her litter as soon as she has recovered. The dam should continue to be carefully watched by the veterinarian or the owner in the first hours after the operation because sudden lapses into shock can occur if uterine bleeding recommences.

Colostrum is important to the neonates. Although some transplacental acquisition of passive immunity occurs before birth, most antibodies are transferred through the colostrum after birth. Nursing also stimulates the release of oxytocin to mediate

uterine contraction. Although drugs can be transferred to the neonate in the milk, this is not important unless drugs are administered to the mother on a continuing basis. Drugs that are weak bases and become ionized at a low pH usually accumulate in the milk at a higher concentration than in the dam's blood.

Before the litter is discharged, puppies or kittens should be inspected for obvious congenital abnormalities, such as deformed limbs, cleft palate, and imperforate anus. This check, together with advice to the owners on neonatal care, ensures good veterinarian-client relations. The dam and her litter can be discharged as soon as she is able to stand and appropriate behavior patterns toward the litter are confirmed. Owners should be instructed to monitor the dam carefully for the next 24 to 48 hours. They should look for evidence of continued uterine hemorrhage, anorexia, or signs of infection or dehiscence of the abdominal incision. The dam should be returned in 7 to 10 days for suture removal.

Postoperative Complications

Certain complications are associated with both emergency and elective cesarean section. Perioperative maternal mortality rates of over 4% have been reported, perhaps owing to the emergency nature of the operation and the patient's stressed condition at the time of surgery. Hypovolemia and hypotension are the most common complications and are treated with vigorous fluid therapy or blood replacement. Hemorrhage of uterine origin should be controlled with oxytocin (5 to 20 units IM or IV). In severe hemorrhage, the dosage may be repeated after 2 to 4 hours, and whole blood transfusion may be started. Persistent hemorrhage may require an emergency ovariohysterectomy. If an infected uterus is encountered during the surgical procedure, ovariohysterectomy or packing of the uterus with antibiotic boluses and systemic antibiotics should be considered.

Postoperative peritonitis should not be a problem unless a break in surgical technique or abdominal contamination with septic uterine contents has occurred. Infection can be controlled with careful surgical technique, intraoperative abdominal lavage, and antibiotic therapy in most cases. Agalactia may occur in the queen or bitch after cesarean section, but normal milk flow usually occurs within 24 hours. Oxytocin (0.5 units/kg intramuscularly) may be administered to stimulate milk production if necessary. Excessive depression of either the mother or the offspring after anesthesia indicates that one should critically review the anesthetic protocol for reduction in doses of analgesics or barbiturate depressants.

Cesarean Section by Ovariohysterectomy

Holly S. Mullen

Indications

Traditional cesarean section (hysterotomy) has been the treatment of choice for canine and feline dystocia that is not responsive to medical management. Hysterotomy is a well described and widely accepted technique. Most references advise against ovariohysterectomy at the time of hysterotomy, citing additional stress to the female, increased blood loss, longer anesthetic time, and problems with neonatal survival.[1,3] Sometimes, no reason is specified.[4] Many practicing veterinarians have performed ovariohysterectomy for dystocia in the dog and cat with excellent results. The technique of "en bloc" cesarean section (ovariohysterectomy) followed by rapid removal of neonates from the gravid uterus) has been shown to be safe and effective for both cats and dogs.[5] Future reproduction is impossible after this technique, a fact that pleases most owners. The technique described is easier, quicker, and has less chance for intra-operative contamination than traditional cesarean section.

Surgical Technique

Preoperative considerations and anesthetic techniques are identical to those for routine cesarean section. A caudal ventral midline incision is made through the skin, subcutaneous tissue, and linea alba of the abdomen. Care is taken as the linea is incised to not lacerate the large gravid uterus which may be in contact with the ventral abdomainl wall. The incision is packed off with sterile, saline moistened laparotomy sponges. The gravid uterus is exteriorized, and the uterine horns are laid out laterally to the incision (Figure 33-15). Next, the suspensory ligaments are cut or broken to allow mobilization of the ovaries by their vascular pedicles. No clamps are applied at this time. The broad ligament is broken down manually or incised on both sides of the uterus from the ovarian pedicle to the cervix. This leaves the blood supply to the uterus and fetuses intact while freeing up all attachments except the ovarian pedicles and the uterine body (Figure 33-16).

Ovariohysterectomy can now be performed rapidly and safely, with a maximum of no more than 45 to 60 seconds elapsed between clamping of the ovarian pedicles and uterine body and delivery of the neonates by assistants. The surgeon palpates the patient's cervix and vagina to check for a fetus. If one is present, it is manipulated gently back into the uterine body. Two hemostatic clamps are placed across each ovarian pedicle, and three clamps are placed across the uterine body just distal to the

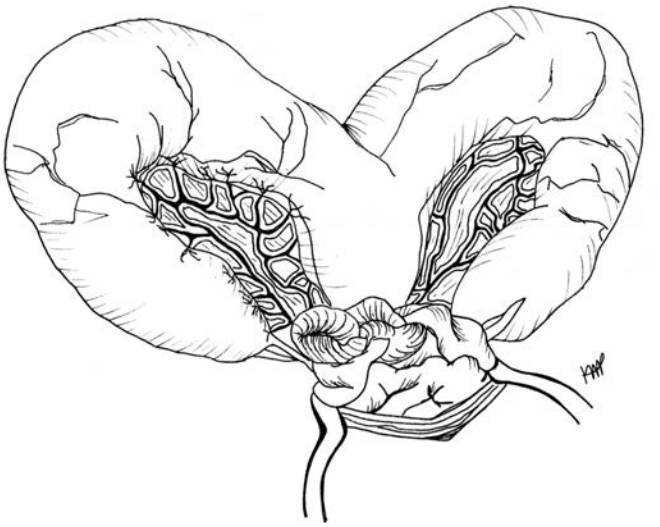

Figure 33-15. The gravid uterus is exteriorized, and both horns are laid out laterally to the abdominal incision.

Figure 33-16. The suspensory ligaments are broken down to exteriorize the ovaries, and the broad ligament is torn on both sides of the uterine horns. The ovarian pedicles and the uterine body provide blood supply to the uterus and are the only structures remaining that need to be transected and ligated to remove the gravid uterus.

cervix. A moistened laparotomy pad is placed to minimize any abdominal contamination from the uterine incision. The gravid uterus and ovaries are removed by dividing between the clamps (Figure 33-17). The surgeon hands the gravid uterus to a team of assistants, who immediately open the uterus and resuscitate the neonates. The ovarian pedicles and uterine stump are ligated with chromic gut or other absorbable suture sized according to the surgeon's preference. The abdomen is closed routinely. Subcuticular sutures are preferred over skin sutures to prevent irritation of the suture line by the nursing pups. Appropriate postoperative pain relievers, such as oxymorphonc (0.03 to 0.1 mg/kg) intravenously, intramuscularly, or subcutaneously, morphine sulfate (.1 to .5 mg/kg) subcutaneously or intramuscularly, or buprenorphine (5 to 10 ug/kg intravenously, intramuscularly, or subcutaneously), are given after the uterus has been removed.

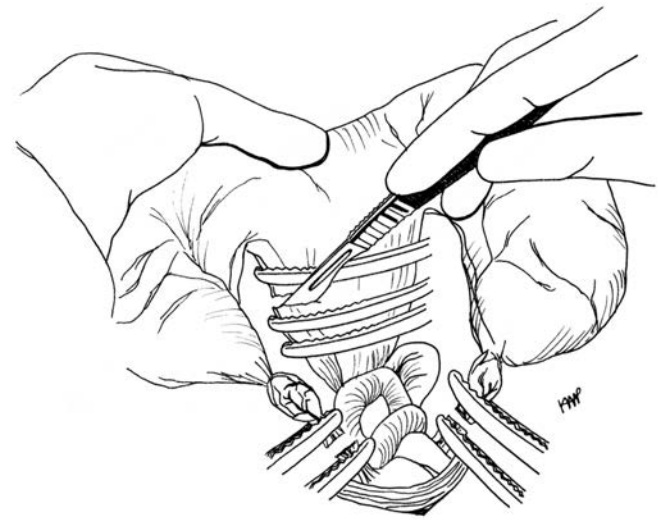

Figure 33-17. The gravid uterus can be removed in 45 to 60 seconds by first placing two hemostats on each ovarian pedicle and then three clamps on the uterine body and transecting between them as shown.

Resuscitation of the Neonates

The gravid uterus is handed to an assistant after removal, who takes it from the sterile operating room to a location previously prepared for neonatal resuscitation. The uterus is opened with scissors or a scalpel blade (Figure 33-18), taking care not to cut a fetus. The neonates are rapidly removed and resuscitated by the assistants. Ideally, one assistant should be available to treat each neonate, although one person can care for two or three neonates at a time if they are healthy. Hypoxia is thought to be one of the primary reason for neonatal mortality.[6] The mortality rate of puppies and kittens delivered by ovariohysterectomy is reportedly lower than the mortality rates by either traditional cesarean section or natural parturition.[5] This finding suggests that ovariohysterectomy for the treatment of dystocia has no adverse effect on neonatal survival.

Contraindications for Ovariohysterectomy

No important complications or contraindications for this technique have been described.[5] Some limitations include the

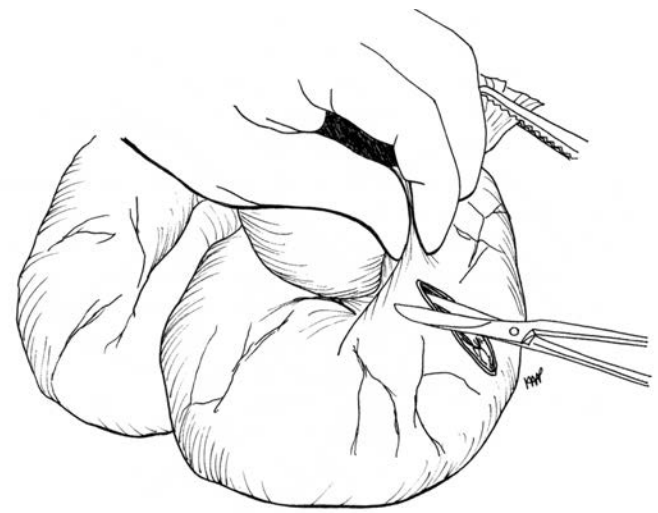

Figure 33-18. An assistant opens the uterus with scissors or a scalpel blade and removes and resuscitates the neonates.

need for multiple assistants for simultaneous neonatal resuscitation of a large litter and the loss of future reproductive capability (although this is usually considered an asset). Anemia is not a complication with this technique, because no significant decrease in packed cell volume was reported in either dogs or cats undergoing cesarean section by ovariohysterectomy.[5] In a small, significantly anemic female with a markedly engorged uterus, however, hysterotomy followed by rapid involution of the uterus will allow return of some of the uterine blood to the peripheral circulation before removal of the nongravid uterus.

Advantages of Ovariohysterectomy

Ovariohysterectomy for dystocia is rapid and safe for both the bitch and the neonate. Use of this technique minimizes anesthetic time and reduces intraoperative peritoneal contamination by uterine contents, which may occur during hysterotomy. Both dogs and cats continue to lactate normally as long as the babies continue to nurse. There is scant to no pos-toperative lochial discharge, as is common for several days after birth because the uterus has been removed. Ovariohysterectomy also provides an opportunity for future population control in pets that are unable to reproduce naturally or whose owners may not be able to afford a second operation for sterilization of the animal in the future. The health of the mother and of the neonates is not compromised when cesarean section by ovariohysterectomy is used as the surgical treatment for dystocia.

Chapter 34

Vagina and Vulva

Surgical Treatment of Vaginal and Vulvar Masses

Ghery D. Pettit

In the bitch, physiologic enlargement of the vulvar labia during proestrus and estrus is a normal estrogenic response. It may be mimicked or exaggerated by masses within the vestibule of the vulva or the vagina that cause the labia to protrude. Such masses include hyperplasia of the vaginal floor, vaginal prolapse, vestibular or vaginal tumors, and clitoral enlargement. Subtle perineal bulges may be detected, but the masses usually become apparent to an animal's owner when they protrude through the vulva, cause irritation and licking, or interfere with mating. They may cause dysuria. Prolonged estrogenic stimulation from follicular cysts or granulosa cell tumors can cause persistent hyperplasia of the labial and vaginal mucosa, making the labia larger, firm, pigmented, and hairless.

Inspection, digital vaginal or rectal palpation, and vaginoscopy provide preliminary identification of most vaginal lesions. In at least one instance, an intraluminal vaginal tumor was diagnosed by pneumovaginography. Surgical treatment of these lesions is facilitated by episiotomy. Excised neoplasms should be identified histologically.

Hyperplasia of the Vaginal Floor

During proestrus and estrus, the vestibular and vaginal mucosae normally become swollen, thickened, and turgid. Exaggeration of this estrogenic response occasionally leads to the development of a transverse mucosal fold on the floor of the vagina just cranial to the external urethral orifice. Although "hyperplasia" is the accepted term for this condition, histologically the swelling is mostly edema with some fibroplasia. If the redundant fold becomes large enough, it protrudes between the labia of the vulva as a red, fleshy mass (Figure 34-1A). The disorder occurs most often during a bitch's first, second, or third estrus. Spontaneous regression occurs during metestrus, but recurrence is common at the next estrus. The condition has been reported in more than 20 breeds of dogs, with frequent mention of brachycephalic breeds, such as boxers and English bulldogs.

Because the protrusion is vulnerable to trauma, inflammation, and ulceration, tends to recur, and is aesthetically objectionable, amputation is frequently the treatment of choice. Recurrence after surgical excision is uncommon, and natural mating is possible at subsequent estrous periods. With or without surgical excision, ovariectomy provides permanent relief.

Alternatively, one can manage the condition conservatively until it regresses spontaneously by lubricating the mass with an antibiotic ointment and applying an Elizabethan collar to prevent

self-abuse. If breeding during the same estrus is important, artificial insemination can be performed. Simultaneous excision of the mass and artificial insemination are technically possible but seldom indicated.

A third option is to try to shorten the duration of estrogenic stimulation of the vaginal tissue by inducing ovulation at the onset of clinical signs. A single dose of gonadotropin-releasing hormone or human chorionic gonadotropin has been used for this purpose. Regression of the prolapse occurs about 1 week after induction of ovulation.

Surgical Treatment

The animal is positioned in ventral recumbency with the hindquarters elevated, and the perineum is prepared aseptically. The vestibule and vagina are cleansed with a mild antiseptic solution (1:10 povidone-iodine [Betadine] or 1:5000 benzalkonium chloride [Zephiran chloride] solution). A median episiotomy incision is begun with a scalpel or an electrosurgery unit and is completed with scissors. Doyen intestinal forceps can be positioned on each side of the incision to serve as a guide and to reduce bleeding. Hemorrhage is controlled with hemostatic forceps, ligation, or electrocoagulation. Retracting the margins of the episiotomy incision exposes the vaginal lumen. The mass must be elevated for catheterization of the urethra, to identify and protect that structure (Figure 34-1B and C). The superfluous tissue is amputated by making connecting, curved, transverse incisions through its base. One incision is made on the dorsal surface of the mass (the cranial aspect of its base), and the other is made on its ventral surface (the caudal surface of the base of the mass). The incisions should be no deeper than necessary to excise the mass. The mucosal opening is closed with absorbable suture material in a transverse, simple continuous pattern (Figure 34-1D). The catheter is removed, and the episiotomy incision is closed (Figure 34-1E). The mucosa is apposed with simple interrupted absorbable sutures. In obese or heavily muscled animals, the musculature should be sutured separately with absorbable sutures. The skin incision is closed with simple interrupted nonabsorbable sutures. If bleeding persists, a vaginal tampon may be left in place for 12 hours.

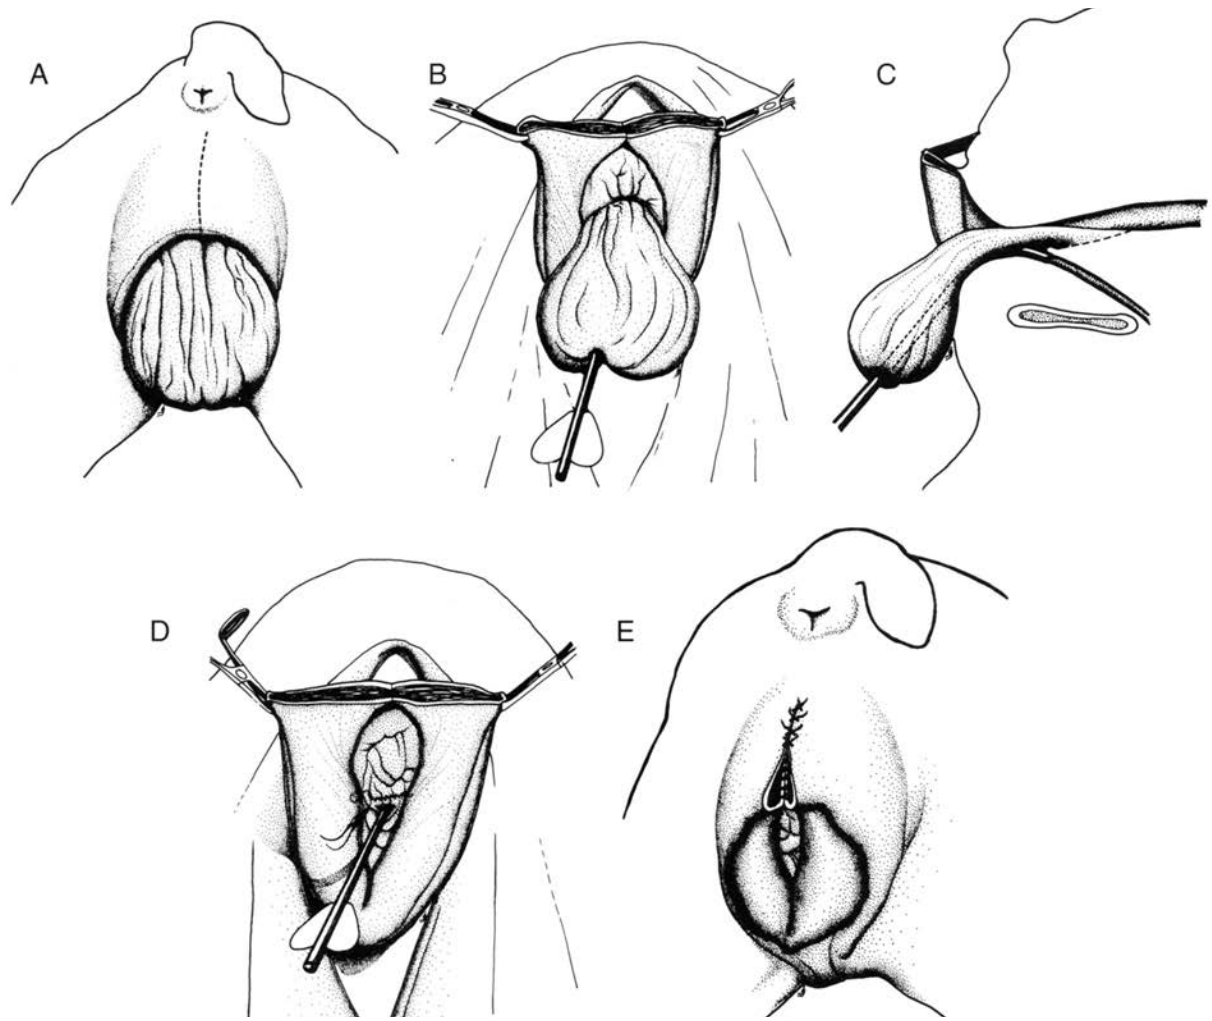

Figure 34-1. Hyperplasia of the vaginal floor. **A.** The broken line indicates the site of the episiotomy incision. **B.** The vestibule has been opened by performing an episiotomy, and a urethral catheter has been inserted. **C.** Lateral view. Episiotomy and urethral catheterization have been performed. The broken line on the floor of the vagina indicates the incision site for amputation of the redundant mucosal mass. **D.** The mass has been amputated, and the mucosal incision is closed with a simple continuous suture. **E.** Postoperative view. The catheter has been removed, and the episiotomy incision is being closed.

Vaginal Prolapse

Cylindric prolapse of the vaginal wall is much rarer than hyperplasia of the vaginal floor. In this condition, which also occurs during estrus, a donut-shaped eversion of the entire vaginal circumference protrudes from the vulva (Figure 34-2). Vaginal prolapse has been reported after forcible separation of the male and female during the genital tie. As in hyperplasia of the vaginal floor, the external urethral orifice is ventral to the entire mass, but access to the vaginal canal is through the center of the protrusion, rather than dorsal to it.

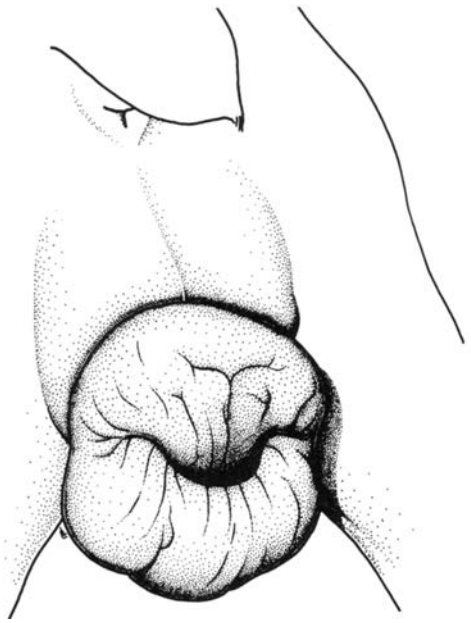

Figure 34-2. Vaginal prolapse. The entire circumference of the vaginal wall has everted.

Complete vaginal prolapse also occurs during parturition or advanced pregnancy, as a prelude to prolapse of the cervix, uterine body, and one or both uterine horns. It results from excessive straining while the supportive tissues are relaxed. The everted organs are usually discolored from venous congestion, soiled, and traumatized.

Some authors prefer to classify hyperplasia of the vaginal floor as a type of vaginal prolapse. According to that interpretation, hyperplasia of the vaginal floor that does not protrude through the vulva is called type I prolapse, and hyperplasia that protrudes completely is called type II. A true cylindric prolapse is called type III.

A recent "type III" vaginal prolapse can be reduced, but recurrence is likely. Recurrence, hemorrhage, infection, and necrosis make amputation necessary. Shock and dehydration are common complications that must be treated appropriately.

Surgical Treatment

With the animal under general anesthesia, the protruding structures are washed gently with warm saline solution or a mild detergent. Additional trauma is avoided. The mass is compressed manually to reduce edema before reduction is attempted. Sprinkling the mucosal surface with table sugar may further reduce the swelling, and episiotomy makes reduction easier. Once accomplished, reduction is maintained by placing heavy nonabsorbable sutures across the vulvar labia.

Reduction of a vaginal prolapse can be facilitated by traction on the uterus through a ventral abdominal incision. When this technique is used, suturing the uterine body or horns to the abdominal wall (hysteropexy) provides protection against recurrence.

If reduction is impossible or inadvisable, the protruding tissue must be amputated. Paying careful attention to the distorted anatomy minimizes errors. With a catheter in place to identify and protect the urethra, a circumferential incision is made in stages through the vaginal wall. The outer, everted mucosa is incised first. The incision is deepened to penetrate all layers of prolapsed vaginal tissue until the inner, noneverted mucosa is reached. Hemostasis is maintained by ligation or electrocoagulation, and the proximal mucosal margins are united with horizontal mattress sutures. The incision is extended for another short distance, the exposed segment is sutured, and the process is repeated until the amputation is complete.

Tumors of the Vulva and Vagina

Vulvar and vaginal neoplasms, which usually occur in older bitches, account for no more than 3% of all canine tumors; 70 to 80% of them are benign. The most common tumors of the vulva and vagina are leiomyoma, fibroma, and lipoma. Leiomyosarcoma is the most common malignant vaginal tumor. Mast cell tumors, sebaceous adenomas, and epidermoid carcinomas have been reported.

Leiomyomas and fibromas are often grossly indistinguishable. They form smooth, firm, spheric masses that are often pedunculated and protrude into the vestibular or vaginal lumen. They may protrude from the vulva and resemble an early hyperplasia of the vaginal floor. Lipomas occur as a gradually enlarging mass under the intact mucosa; they may protrude into the lumen, or they may become apparent under the perineal skin adjacent to the vulva. Surgical excision of benign vulvar and vaginal tumors combined with ovariohysterectomy is effective in preventing recurrence, but malignant tumors have been reported in spayed females.

The transmissible venereal tumor is an allogeneic cellular transplant that is transmitted by implantation of exfoliated cells into traumatized vaginal or penile epithelium. The condition is most prevalent and perhaps most severe when dogs are crowded and stressed. In females, the transmissible venereal tumor appears in the vagina as single or multiple projecting masses with roughened or reddened, ulcerated surfaces. Metastasis is rare. Spontaneous regression occurs after 2 to 6 months in about 60% of experimentally transplanted tumors, but reports of spontaneous regression in naturally occurring cases are inconsistent. Surgical excision is an appropriate initial treatment. If surgery is impossible or if recurrence or metastasis is noted, radiation therapy and chemotherapy are effective. Immunotherapy may be as effective as chemotherapy, but additional clinical trials are needed.

Surgical Treatment

Episiotomy is performed for better exposure. Pedunculated intraluminal tumors can be amputated, but encapsulated extraluminal tumors are removed by submucosal resection (Figure 34-3). An incision is made through the mucosa, and the tumor is bluntly peeled away. The mucosal incision is closed with absorbable sutures. Submucosal resection is especially useful for large or multiple tumors.

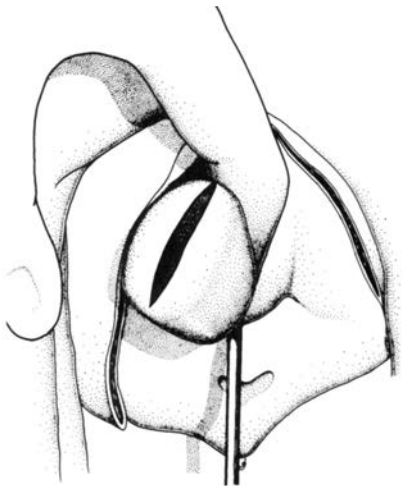

Figure 34-3. Vestibular leiomyoma. Episiotomy has been performed, and a mucosal incision has been made to facilitate submucosal resection of the tumor.

Clitoral Enlargement

Enlargement of the clitoris, sometimes with an os clitoridis, is an androgenic response. The condition has been caused by administration of exogenous androgens or anabolic steroids, and it has been reported in bitches with hyperadrenocorticism. Clitoral enlargement has occurred in puppies whose dams were treated with androgens during pregnancy. Friction between the protruding clitoris and the vulva may cause inflammation. Treatment includes topical antibiotic ointments, removal of the androgen source, or excision of the enlarged clitoris. If an os clitoridis is not present, the clitoris regresses to normal size when exogenous androgen is withdrawn.

Episioplasty

Dale E. Bjorling

Introduction

Episioplasty is a procedure performed most often to treat recessed or juvenile vulva in female dogs. This conformation results in deep perivulvar folds of tissue causing the vulva to be partially or totally hidden from view by overlapping perineal skin dorsal and lateral to the vulva. Older veterinary surgery texts indicate that ovariohysterectomy performed in dogs prior to the completion of puberty prevents normal development of secondary sex characteristics.[1] Although this association has never been proven, it has been postulated that this may result in recessed or juvenile vulva.[1,2] Particularly in obese female dogs, a recessed vulva in conjunction with redundant vulvar skin folds may prevent complete elimination of urine and vaginal secretions. However, this condition may be associated with clinical signs in young, relatively thin female dogs. Recessed or juvenile vulvar conformation can also be observed in female dogs in the absence of any associated clinical signs.

Retention of fluid within the vulva and perivulvar folds combined with frictional irritation predisposes the area to bacterial growth, infection, and ulceration.[3] In addition, urine dribbling has been reported in these dogs, possibly as a result of urovagina due to the conformation of the vulva and overlying skin folds that act as a dam to retain urine within the vagina.[4] Affected dogs may exhibit perivulvar dermatitis, pollakiuria, urinary incontinence, licking or other signs of irritation, chronic urinary tract infection (UTI), or vaginitis with or without discharge. In extreme cases, chronic perivulvar dermatitis leading to hyperpigmentation has been associated with neoplasia of the canine vulva.[2]

Recessed vulva is often accompanied by vaginal stricture located cranial to the urethral orifice. Vaginal stricture is usually diagnosed by positive contrast radiography (vaginourethrography) or by digital palpation. Although it has been suggested that vaginal stricture may contribute to persistent vaginitis or chronic urinary tract infection,[5] vaginal stricture is commonly observed in asymptomatic female dogs. It is my opinion that episioplasty should be performed prior to revision of vaginal stricture.

Many treatments have been used to palliate conditions that result from abnormal vulvar conformation, including weight reduction, regular cleaning of the affected perivulvar tissue, repeated vaginal flushes with antiseptics, and various topical or systemic medications to control dermatitis or urinary incontinence. Of the various techniques used, the most successful appears to

be removal of redundant tissue overlying the vulva (i.e., vulvar folds), a procedure referred to as episioplasty or vulvoplasty.[2] This procedure increases exposure of the external genitalia and eliminates redundant skin folds that overly the vulva, which appears to eliminate primary clinical signs such as dermatitis and urine dribbling, as well as secondary signs such as licking and self-induced trauma.[2]

Surgical Technique

The surgical procedure is relatively simple. The dog is placed in ventral recumbency with the hindquarters elevated. The skin dorsal and lateral to the vulva is compressed with the fingers to estimate the amount to be removed (Figure 34-4). Concentric crescent-shaped incisions are made between the vulva and the anus to remove redundant skin (Figure 34-5). These incisions extend laterally on either side of the vulva and meet at points lateral and ventral to the vulva. If insufficient skin is removed initially to satisfactorily improve the conformation of the vulva, additional skin is removed to achieve the desired effect. The crescent-shaped skin and associated subcutaneous fat are removed (Figure 34-6), taking care to avoid the dorsal wall of the vagina. The resultant wound is closed in 2 layers. Subcutaneous tissues are closed with synthetic absorbable suture (3-0 or 4-0) in an interrupted pattern, and the skin is closed with monofilament non-absorbable suture (3-0 or 4-0) in an interrupted pattern (Figure 34-7). Closure of the

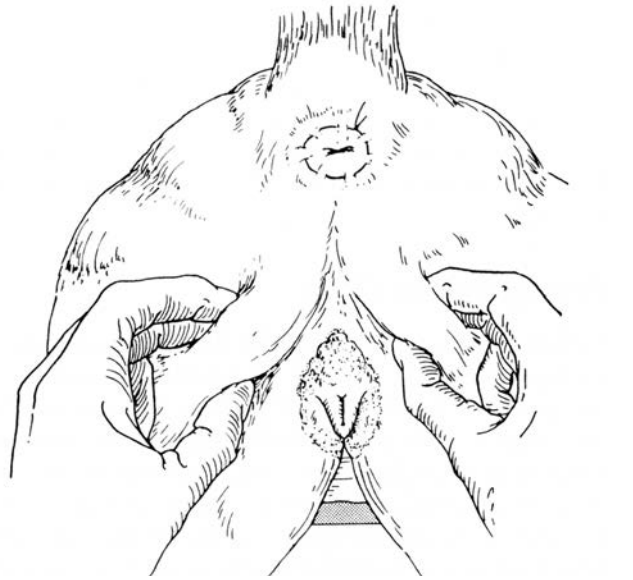

Figure 34-4. The extent of skin to be removed can be estimated by pinching the skin dorsal and lateral to the vulva between the thumb and index finger. It is often helpful to use a sterile marking pen to draw the lines of intended incision.

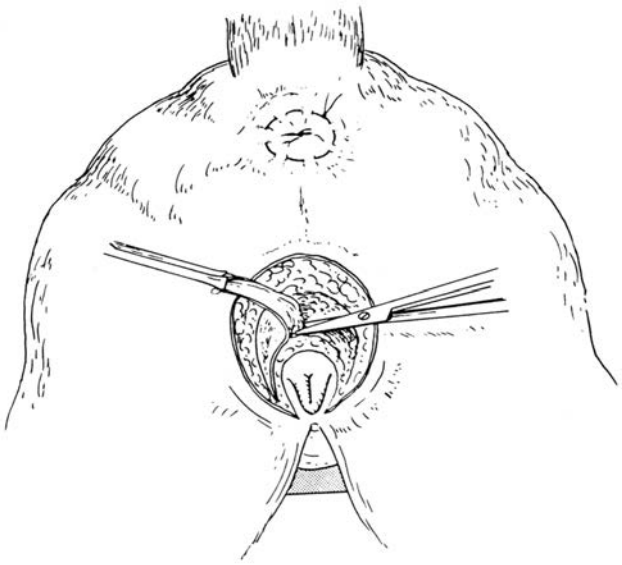

Figure 34-6. The isolated skin and associated subcutaneous fat are removed. The dorsal wall of the vagina should be avoided. Hemorrhage is primarily encountered from vessels dorsal to the vagina and lateral to the midline.

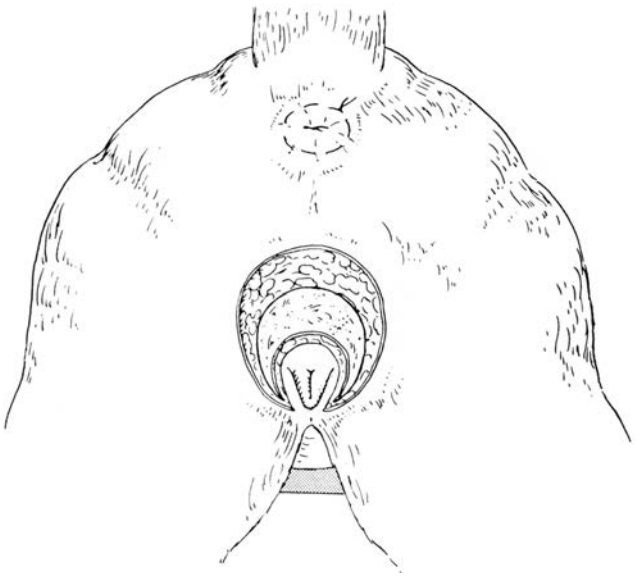

Figure 34-5. Two crescent-shaped incisions are made isolating the skin to be removed. Additional skin can be removed if the desired effect is not achieved.

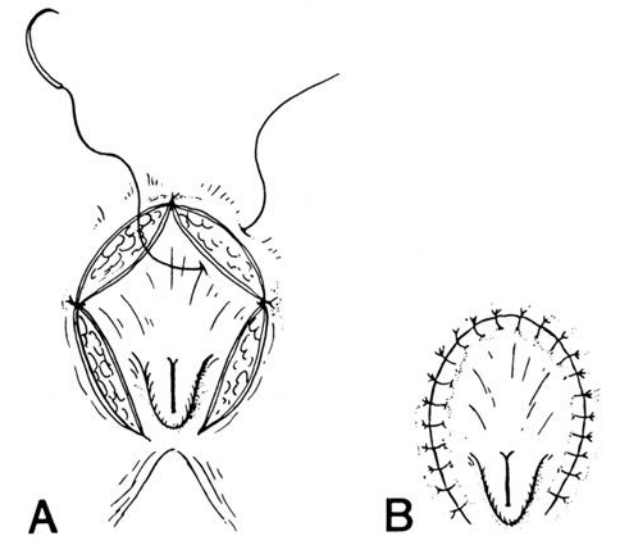

Figure 34-7. Placement of subcutaneous sutures facilitates wound closure. *A.* Skin sutures should be spaced to accommodate the differential length of the inner and outer incisions. *B.* Upon completion of the procedures, perivulvar skin folds should be eliminated, and the vulva should no longer appear recessed.

resultant skin defect eliminates the fold of skin that previously lay over the dorsal aspect of the vulva and also removes the depressions lateral to the vulva. Although removal of too much skin may complicate wound closure, failure to remove enough skin may result in persistence of the recessed conformation of the vulva. Closure of the defect is rarely a problem due to the large amount of redundant skin available in the area of the perineum and caudal aspects of the thighs. However, in heavily-muscled dogs, or dogs with a great deal of tension within the perineal skin, care should be taken to avoid removing too much skin.

Postoperative Care and Outcome

Wound infection rarely occurs. An Elizabethan collar should be used to prevent self-mutilation, if necessary.

In one study of the results of episioplasty in 34 dogs, the most common clinical signs at initial examination were perivulvar dermatitis 20/34 dogs (59%), and urinary incontinence and chronic urinary tract infection, each present in 19/34 dogs (56%).[6] Other common complaints included pollakiuria, irritation, and vaginitis. Most dogs developed clinical signs before 1 year of age. All dogs except one bichon frise were medium to giant breeds, suggesting that vulvar conformation may be related to growth rate or body conformation. Eighty-two percent of owners rated the outcome of the surgery as at least satisfactory. The incidence of urinary incontinence was reduced by vulvoplasty; however, it remained the most common residual sign after surgery, suggesting a multifactorial etiology. The incidences of urinary tract infection, vaginitis, and external irritation were greatly reduced after surgery. Wound dehiscence occurred in a Bull Mastiff, and multiple additional surgeries were performed to correct the resultant defect. This complication appeared to be due to removal of too much skin combined with a lack of mobility of skin in adjacent areas.

In another study of the outcome of episioplasty in 31 dogs, the primary complaint in 15 dogs was perivulvar dermatitis and repeated urinary tract infection in 16 dogs.[7] The mean weight of dogs with perivulvar dermatitis or chronic urinary tract infection was 26.7 $\pm$ 1.89 kg and 32.43 $\pm$ 4.02 kg, respectively, again suggesting that this condition predominantly affects medium and larger size dogs. Performance of episioplasty resulted in complete resolution of perivulvar dermatitis in 15/16 dogs, although 1 dog suffered recurrence of perivulvar dermatitis 2 years after surgery in association with a 9 kg weight gain. Episioplasty was followed by resolution of urinary tract infection in all 16 dogs in this study. Postoperative complications were limited to transient local swelling immediately after surgery.

Dogs with recessed or juvenile vulvas that are examined because of vaginitis, perivulvar dermatitis, or chronic urinary tract infection should be examined carefully for other abnormalities that may be contributing to these clinical problems. However, it is often difficult to control these disorders in the presence of conformational abnormalities of the vulva. Owners should be warned that failure to prevent weight gain may compromise the outcome of the surgery.

Episiotomy

Roy F. Barnes and Sandra Manfra Marretta

Introduction

Episiotomy is a surgical procedure that temporarily enlarges the vulvar cleft. This procedure provides exposure of the caudal female urogenital tract which cannot be reached with a conventional laparotomy or ventral pubic osteotomy. Indications for an episiotomy in the dog include vaginal and vestibular masses, vaginal prolapse, vaginal and vestibular trauma, congenital vaginal strictures, and dystocia from an inadequate vulvar cleft.

Preoperative Care

Depending on the stability of the patient and the underlying clinical disorder, episiotomies may be performed under local, epidural and general anesthesia. The patient is placed on a padded perineal stand in a manner to prevent neuropraxia, compromised circulation or exacerbate chronic osteoarthritis of the rear limbs. The rectum and anal sacs are emptied, and several gauze sponges are placed into the rectum. A purse string suture is placed in the anus to minimize contamination during surgery.

The hair from the perineal region is clipped and the vestibule and vagina are liberally flushed with a dilute antiseptic solution. Surgical scrub is avoided during lavage of the vestibule and vagina. The perineum is surgically prepared in a routine manner. A Foley catheter is aseptically placed through the urethral papilla into the urinary bladder to allow for exact identification and protection of the lower urinary tract throughout the procedure. Surgical draping includes the vulvar cleft and the perineal skin dorsal to the vulvar cleft with exclusion of the anus.

Surgical Technique

A digital examination precedes the surgical incision. During digital examination, the caudodorsal aspect of the horizontal vaginal canal is identified. To avoid incising the external anal sphincter, the episiotomy incision should not extend any further dorsally than the caudodorsal aspect of the horizontal vaginal canal.

A median skin incision is made from the level of the caudodorsal aspect of the horizontal vaginal canal, extending to the dorsal commissure of the vulvar cleft (Figure 34-8). A pair of thumb forceps or the handle of a scalpel blade can be inserted into the vaginal canal to aid in the stabilization of the incision site. The remaining layers of the episiotomy incision, including the thin musculature, subcutaneous tissue and mucosal layers are cut with Mayo scissors (Figure 34-9). Hemorrhage may be brisk. The

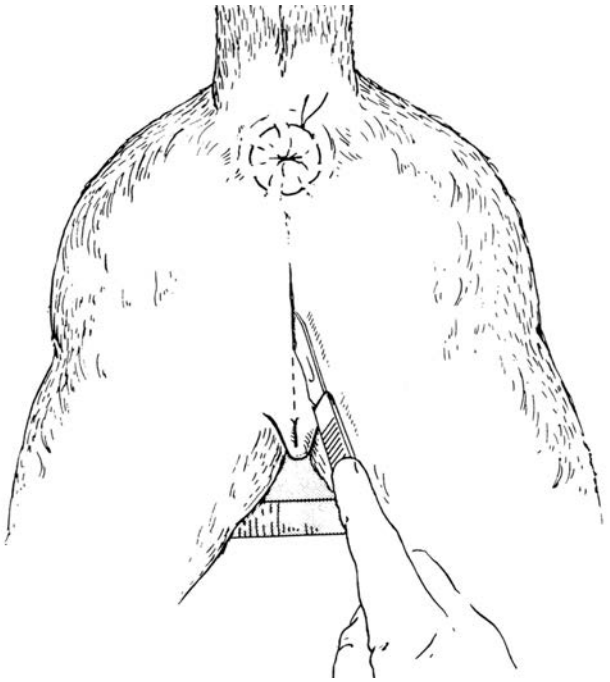

Figure 34-8. A median skin incision is made from the caudodorsal aspect of the horizontal vaginal canal to the dorsal commissure of the vulvar cleft.

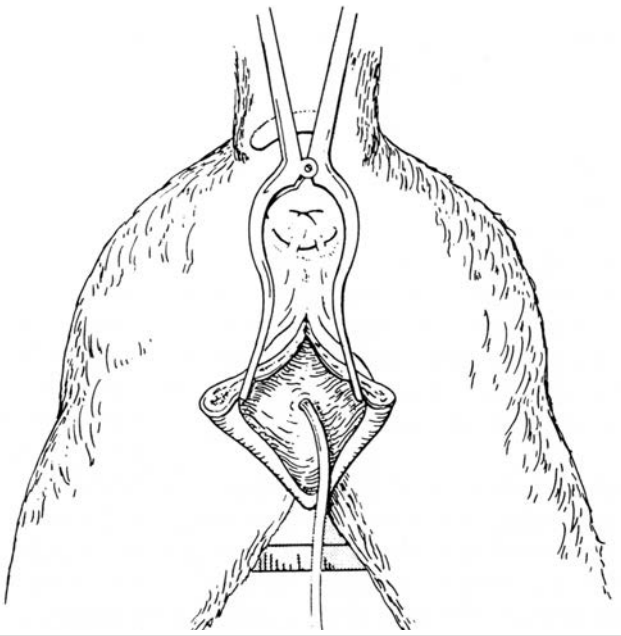

Figure 34-10. The episiotomy has been completed. A Foley catheter is in place in the urinary bladder to aid in the localization and protection of the urethral papilla and urethra during additional surgical procedures. A self-retaining retractor is in place to provide increased visibility of the vestibule and vagina.

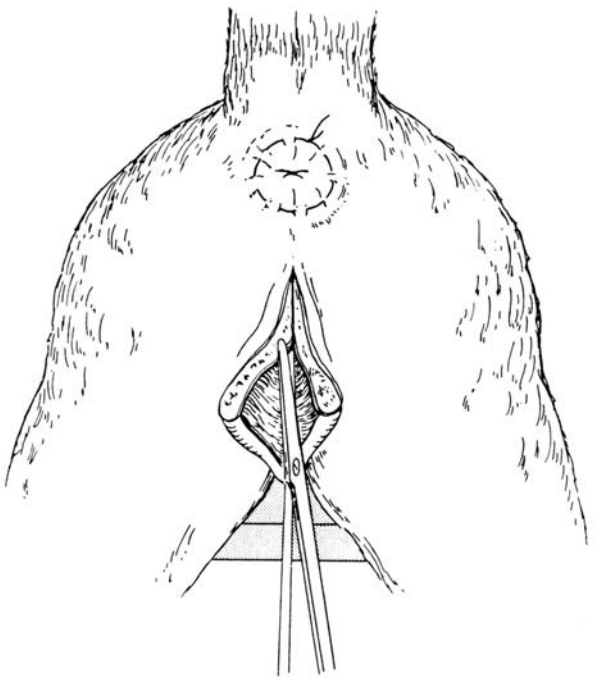

Figure 34-9. The musculature and mucosal layers are cut with Mayo scissors following the skin incision.

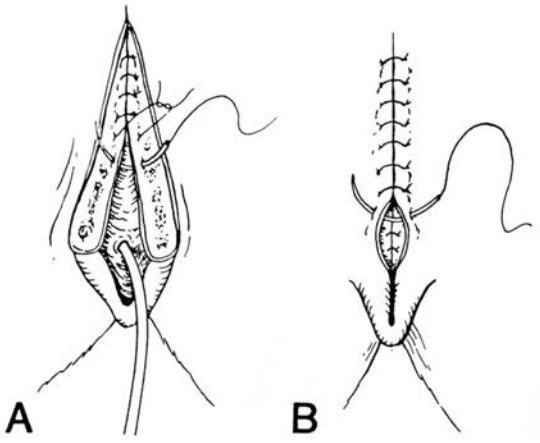

Figure 34-11. A. The mucosal layer of the episiotomy is closed with simple interrupted sutures. **B.** The skin edges are apposed with simple interrupted monofilament nonabsorbable sutures.

use of hemostats, ligatures and the judicious use of electrocautery will control hemorrhage and improve visualization of the surgical field. Alternatively, atraumatic intestinal forceps can be temporarily applied to the edges of the incision to achieve hemostasis.

The definitive surgical procedure that necessitated the episiotomy may be performed at this time. Self retaining retractors can be used to increase exposure at the surgical site. It is imperative that the position of the urethral papilla and the urethra should be visualized and protected at all times (Figure 34-10).

Closure of the episiotomy is completed in three to four layers, depending on the size of the dog. The mucosa is apposed using a simple interrupted suture pattern with 3-0 synthetic, monofilament, absorbable suture material (Figure 34-11A). If the vulvar cleft was congenitally shortened, the vestibular mucosa is directly sutured to the skin until the desired length is attained. The muscular and subcutaneous tissues are closed in one layer using a simple interrupted suture pattern of 3-0 or 4-0 synthetic, monofilament, absorbable suture material. In larger dogs, the muscular and subcutaneous tissues can be closed in separate layers. The skin is apposed with simple interrupted or cruciate mattress sutures of 3-0 synthetic, monofilament, nonabsorable material (Figure 34-11B). The purse string suture and gauze sponges are removed from the anus and rectum, respectively. The urinary catheter may be removed or left in place during the immediate postoperative period.

Postoperative Care

An Elizabethan collar is recommended to prevent self mutilation of the surgical site. Analgesia is a requirement. Full opioid agonists, such as oxymorphone or hydromorphone, should be administered for the first 24 hours. If medically appropriate, additional analgesia could be obtained using a non-steroidal anti-inflammatory agent. Cold compresses should be applied for the first 48 hours. Skin sutures should be removed in 10 to 14 days.

Complications

Postoperative complications associated with the performance of episiotomy are rare and are often associated with poor surgical technique or inappropriate postoperative care. Poor surgical technique during closure of the incision, including inaccurate suture placement, tight sutures or the use of through and through sutures, may result in unnecessary pain, self mutilation of the surgical site and inflammation. Urinary obstruction may occur if the urethral papilla and urethra were not identified during the initial incision, the definitive surgical procedure or during the closure of the episiotomy. Vestibular reconstruction for enlargement of the vulvar cleft may predispose to urinary tract infections by way of environmental exposure to gastrointestinal contents.

Chapter 35

Testicles

Prepubertal Castration

Lisa M. Howe

Introduction

Prepubertal castration of puppies and kittens (as early as six weeks of age) is slowly increasing in popularity in the United States, particularly in the shelter setting, as a result of mounting evidence of the safety of the procedure, on both a short and long-term basis. Puppies and kittens undergoing prepubertal castration have shorter recovery rates, lower morbidity, and similar mortality rates as compared to those neutered at a more traditional age (≥ six months of age). Although many safety concerns, including urethral obstruction in male cats, have been raised regarding early age castration, long-term outcome in cats and dogs undergoing early neutering is similar to those undergoing traditional age neutering. Early age castration in dogs and cats is a safe procedure when appropriate anesthetic and surgical principles and techniques are applied.

Surgical Procedures and Techniques

The surgical anatomy of the pediatric puppy or kitten reproductive tract is identical to that of the adult dog or cat; however, pediatric testes are extremely small, highly mobile, and the spermatic cords are susceptible to tearing if not handled gently.

Anesthetic and surgical considerations for the pediatric patient, differ somewhat from the adult patient, and include increased risk of hypoglycemia and hypothermia, a relatively small blood volume, and delicate tissues. Prolonged fasting may result in hypoglycemia because hepatic glycogen stores are minimal in neonates. Thus, food should be withheld no longer than 8 hours, with 3 to 4 hours recommended for the youngest patients (6 to 8 weeks).[1,2] Minimizing operative times and the use of warm water blankets can decrease hypothermia. The use of warmed scrub solution (chlorhexidine) and avoidance of alcohol or excessive wetting of the pediatric patient during the surgical site preparation will be beneficial in helping preserve body heat.[1,2] Because pediatric tissues are very friable, gentle tissue handling is mandatory. The relatively small blood volume of pediatric patients makes meticulous hemostasis very important. Fortunately, the small size of blood vessels in the spermatic cord makes precise and complete hemostasis easy to accomplish.

Pediatric castration is performed with modifications to the techniques used in adult dogs. Because puppy testes are mobile and can be difficult to identify, careful palpation is performed to determine whether both testicles have descended into the scrotal region before beginning surgery. If one or both testes have not descended, standard cryptorchidectomy techniques may be used for castration. The entire scrotal region is clipped and surgically prepared to permit the scrotum to be incorporated

in the surgical sterile field. Because of the mobility and small size of the puppy testes, including the scrotum in the surgical field can facilitate locating and manipulating the testes during surgery. Clipping and surgical preparation of the scrotum does not result in scrotal irritation in puppies as it does in adult dogs because the scrotal sac of puppies is not well developed as compared to adult male dogs. Puppies are positioned on the surgery table in a similar fashion as adult males, however, it is often useful to very *loosely* secure the hind legs to the table so as to facilitate testis identification and palpation after draping. Puppies may be castrated through a single midline (preferred) prescrotal or scrotal incision, or through two scrotal incisions positioned similarly to a feline castration. When a midline incision is used, the testicles must be securely held underneath the incision site to prevent iatrogenic penile or urethral trauma. Following exposure of the testicle and spermatic cord in a closed fashion, (testes remain enclosed in the parietal vaginal tunic during castration), the spermatic cord is doubly ligated with 3-0 absorbable suture material or stainless steel hemostatic clips. If the parietal vaginal tunic is inadvertently penetrated and the testis extruded, an open castration technique may be performed using standard adult canine castration techniques. Adequate hemostasis should be verified prior to return of the vascular pedicle to the inguinal region. The skin incision is closed using one or two buried interrupted sutures of absorbable suture in the subcuticular layer, or the incisions may be left open to heal by second intention healing. Closure of the incision is preferred and prevents postoperative wound contamination with urine or feces, and extrusion of subcutaneous fat from the incision.

Kitten castration is performed using identical techniques as in the adult cat. Two separate scrotal incisions are used to approach the testes. When preparing the surgical site of a kitten castration, it is often easier to shave the scrotal region than to pluck the scrotal region. Positioning and draping of the kitten is identical to positioning of the adult male cat prior to castration. As with the pediatric puppy, the testes of the pediatric cat are extremely small, highly mobile, and occasionally difficult to stabilize in the scrotal region in preparation for incision. The testis should be securely stabilized in the scrotal region and the incision made directly over the testis at the ventral most aspect of the scrotal "sac". After the incision, the testis is carefully exposed using *gentle* caudoventral traction. It is important to realize that the pediatric testis cannot be exteriorized to the same distance as in the adult cat without potential tearing of the spermatic cord. The closed castration technique is preferred, using a hemostat to place an overhand throw in the pedicle, or using suture or hemostatic clips for hemostasis. If the parietal vaginal tunic is inadvertently opened, an open technique using either a hemostat to place an overhand throw in the spermatic cord, or the use of spermatic cord tissues (vas deferens) for knot tying may be employed. Alternatively, sutures or hemostatic clips may be used to achieve hemostasis in an open castration. Care must be used when manipulating tissues to prevent rupture or tearing of the small and fragile spermatic cord. As with adult cat castrations, the scrotal skin incisions are left open to heal by second intention.

Postoperative Care

All animals undergoing early age castration should be tattooed to identify their neutered status so as to avoid unnecessary abdominal exploration in the future. The recommended tattoo site in males is the inguinal area. The male gender symbol along with an encircled "X" is used to denote the neutered status. Tattooing is best performed after the surgical site has been clipped but prior to the surgical prep of the area.

During recovery from anesthesia, pediatric patients should be monitored for hypoglycemia, hypothermia, pain, or dysphoria. Supplemental heat, glucose containing agents, or additional analgesics or sedatives may be used to ensure smooth recovery from anesthesia. These patients may be fed a small meal one to two hours after recovery since they tend to recover much more quickly from anesthesia and surgery.

Postoperative Complications

Veterinarians have long been concerned about the potential health risks of early age castration. These concerns have included increased risk of urethral obstruction in male cats, obesity, and abnormal long bone growth patterns in dogs and cats neutered at an early age. Concerns have also been expressed regarding the immune system of puppies and kittens and the effects of the stress of anesthesia and surgery at an early age. The development of neoplasia has also been a more recent concern. Recent studies have begun to clarify the long term health risks and benefits of early age castration as compared to traditional age castration.

Urethral, Penile, and Preputial Development in Male Cats

A major concern of veterinarians regarding performing early age neutering is that of feline lower urinary tract disease (FLUTD) and urethral obstruction in male cats. It was thought that early neutering of the male cat would result in a smaller diameter urethra thus predisposing the cat to urinary obstruction caused by FLUTD. Numerous experimental and clinical studies dating to the 1960's have studied this concern. Recently, two experimental studies examining cats castrated at seven weeks and seven months of age as compared to sexually intact cats have studied this concern.[3,4] The first study examined urethral development when cats were one year of age, and found that urethral diameters as determined by contrast retrograde urethrography were similar among both groups of neutered cats as compared to intact cats.[3] Additionally, no difference in urethral dynamic function as determined by urethral pressure profiles was seen among groups. In the second study, voiding cystograms were used to measure the diameter of the preprostatic and penile urethra when cats were 22 months of age.[4] As in the previous study, no differences were seen in urethral diameter of male cats neutered at seven weeks or seven months of age as compared to intact cats.

In addition to experimental studies, two recent long-term clinical studies have examined the effect of early age castration on the incidence of urinary tract disease. The first long-term (37 month

median follow-up) study examined 263 cats neutered at an early age (< 5.5 months) as compared to the traditional age ≥ 5.5 months.[5] There were 108 male cats which were divided into two groups based on age at the time of castration: early age (median age at castration = nine weeks; n = 70) and traditional age (median age at castration = 51 weeks; n = 38). In that study, *traditional age* neutered cats had significantly more overall urinary tract problems (17%) as compared to early age neutered cats (3%). "Cystitis" was the most common problem seen, and the incidence was significantly greater in cats neutered at an older age. There was no significant difference in the rate of urethral obstruction between groups although 2/38 (5%) traditional age neutered cats suffered urinary obstruction, while 0/70 (0%) early age neutered cats became obstructed. A second recent study examined 1660 cats neutered at an early age (< 5.5 months of age) as compared to the traditional age (≥ 5.5 months of age).[6] The median follow-up time for that study was 47 months, with follow-up available for as long as 11 years after surgery. That study found no association between the incidence of FLUTD or urethral obstruction and the age at gonadectomy.

Abnormal penile and preputial development in male cats castrated at an early age has also been a concern for many veterinarians. The balanopreputial fold is a fold of tissue (a continuous layer of epithelium) connecting the penis to the prepuce at birth. The balanopreputial fold separation process is androgen dependent and is complete at birth in some species, but not until after puberty in other species such as the cat. Concerns have been expressed that prepubertal castration in cats might delay or prevent dissolution of the membrane, and predispose to ascending urinary tract disease since these cats may not be able to fully extrude the penis for cleaning.[7] Recent studies examining separation of the balanopreputial fold have reported conflicting results. In one study of cats castrated at seven weeks and seven months of age, it was reported that at one year of age, the penis could be fully extruded in all males.[8] Penile spines were atrophied in those castrated at seven months, and were absent in those castrated at seven weeks of age. This is in contrast to another study reporting on penile extrusion in cats at 22 months of age.[4] In cats neutered at seven weeks of age, the penis could not be fully extruded in any cat, while in intact cats, the penis could be fully extruded in all cats. Of the cats neutered at seven months of age, the penis could be fully extruded in 60%. In those males incapable of complete penile extrusion, only 1/3 to 2/3 of the length of the penis could be visualized. It would appear, however, based upon the long-term clinical studies of 263 and 1660 cats,[5,6] that failure of separation of the balanopreputial fold (when present) does not cause a clinical problem in cats neutered early and does not lead to an increase in the incidence of FLUTD or urinary obstruction. Should cats neutered at an early age become obstructed however, penile manipulations for catheterization may be more challenging because of smaller penile size and the inability to fully extrude the penis.

All studies reported to date indicate that *urethral* development and diameter in male cats is not an androgen dependent process, even though *penile* size and development is androgen dependent. Therefore, it would appear that concerns about FLUTD, urinary obstruction, or potential failure of separation of the balanopreputial fold are not objective reasons to delay castration in male cats.

Obesity

Obesity is influenced by a number of factors, including neuter status, and studies suggest that gonadectomized cats may gain significantly more weight than intact cats. The literature regarding whether dogs are more likely to become obese after castration is less clear.

When comparing neutered cats to sexually intact cats, intact cats were found to weigh less than cats neutered at seven months, but there was no difference between intact cats and those neutered at seven weeks.[8] Another study[9,10] has assessed obesity by body mass index at 24 months of age in 34 cats. Body condition scores and body mass index values were higher in animals gonadectomized at seven weeks or seven months than in intact animals. This indicated that animals gonadectomized at either age were more likely to be obese than intact cats. Heat coefficient, a measure of resting metabolic rate, was higher in intact cats than in gonadectomized cats. Based on these data, the author suggested that neutered male cats require an intake of 28% fewer calories than intact males.[10]

In dogs, one study found no differences in food intake, weight gains, or back-fat depth among neutered (seven weeks or seven months) and intact animals during a 15-month prospective study.[11] A long-term study of 1842 dogs[12] actually found that the proportion of overweight dogs was *lowest* in the early age gonadectomized dogs, as compared to the traditional age neutered dogs.

Body and Long Bone Growth

Several research studies have refuted the concern that early neutering will "stunt" growth. In a 15-month study of 32 dogs, growth rates were unaffected by gonadectomy, but the growth period in final radial/ulnar length was extended in all neutered male dogs (neutered at seven weeks or seven months).[11] Thus, neutered animals were not stunted in growth but were actually slightly taller. In a similar study,[8] 31 cats were neutered at seven weeks or seven months or left intact. Distal radial physeal closure was delayed by approximately eight weeks in neutered cats as compared to intact cats, and no differences were detected between the two groups of neutered cats, for mature radius length or time of distal radial physeal closure. A third study in cats showed that male cats neutered at seven weeks or seven months of age reached the growth plateau on average 35% later, and achieved radial length of 13% longer than intact males.[13]

The clinical significance of delayed closure of growth plates is not clear, but it does not appear to render the growth plates more susceptible to injury. In the long term studies of 263 cats,[5] 269 dogs,[14] 1660 cats,[6] and 1842 dogs,[12] no differences in the incidence of musculoskeletal problems were seen between groups. Further, in the long term study of 1660 cats[6] and 1842 dogs,[12] age at gonadectomy was not associated with the frequency of long bone fractures. Based on the low incidence of long bone fractures in this study, it would seem that physeal

fractures are not a common problem in gonadectomized dogs and cats in general.

Long-term studies have examined the incidence of hip dysplasia and the association with age at gonadectomy. One study of 269 dogs[14] found no association between age at gonadectomy and hip dysplasia, however another study of 1842 dogs[12] found that early age gonadectomy was associated with a significant increased incidence of hip dysplasia. Puppies that underwent gonadectomy before 5.5 months of age had a 6.7% incidence of hip dysplasia, while those that underwent gonadectomy at, or after, 5.5 months of age had an incidence of 4.7%. However, those that were gonadectomized at the traditional age were three times more likely to be euthanized for the condition as compared to the early age group, suggesting that early age gonadectomy may be associated with a less severe form of hip dysplasia.

In the Golden Retriever breed, one study found that when dogs were neutered before 1 year of age (early neutered) the incidence of cranial cruciate ligament rupture was greater than in those neutered after 1 year of age or remaining intact.[16] When compared to intact dogs, the incidence of hip dysplasia was also increased in the male dogs of the early neutered group.

Infectious Diseases and Long-Term Immune Suppression

In the shelter environment, puppies and kittens neutered at early ages had no higher risk of infectious diseases than older animals according to one short-term (seven day) study. This study involved shelter source dogs and cats undergoing gonadectomy in association with the fourth-year student surgical teaching program at a university teaching hospital.[15] Twelve of 1988 (0.6%) animals died or were euthanized because of parvovirus infection or as a result of severe infections of the respiratory tract during the seven day postoperative period, and the deaths (or euthanasias) included similar numbers of animals from all age groups.

In long term studies of 263 cats[5] and 269 dogs,[14] prepubertal gonadectomy did not result in an increased incidence of infectious disease after adoption in cats, compared with traditional age gonadectomy. In dogs, however, gonadectomy before 5.5 months of age was associated with an increased incidence of parvoviral enteritis. In more recent studies of 1660 cats[6] and 1842 dogs,[12] those gonadectomized before 5.5 months of age were not significantly more likely than those gonadectomized after 5.5 months of age to have any conditions that might be presumably associated with long-term immune suppression. On a short-term basis, however, dogs from the study that were gonadectomized before 5.5 months had an increased incidence of parvoviral enteritis that often occurred soon after adoption. In both of the long-term dog studies[14,12] (269 dogs and 1842 dogs), the increased incidence of parvoviral enteritis on a short-term basis probably represented an increased susceptibility of the younger puppies during the periadoption period, rather than long-term immune suppression.

Orchiectomy of Descended and Retained Testes in the Dog and Cat

Stephen W. Crane

Introduction

Castration (orchiectomy) is performed frequently for reproductive neutering and for reducing or eliminating the behavior patterns characteristic of intact males. The procedure continues to be the first line of defense against the plague of animal overpopulation. Testicular neoplasia, severe traumatic injury, refractory orchitis, and epididymitis are primary medical indications for unilateral or bilateral orchiectomy. Removal of the primary endocrine sources of androgenic hormones are secondary reasons for castration in that androgens may be complicating mediators in benign prostatic hypertrophy, prostatitis, perianal adenoma, and perineal hernia. In addition, castration, coupled with scrotal ablation, is the initial surgical step in creating the perineal urethrostomy of the cat…a salvage procedure for a scar damaged urethra. Castration and scrotal ablation are the first steps in creating a permanent scrotal urethrostomy in dogs…a procedure to allow urolithic debris in urine to be discharged prior to the narrowing of the urethra within the os penis.

Surgical Anatomy

The spermatic cord must be exposed, exteriorized and transected in any castration. The cord originates at the vaginal ring as its individual components exit the abdominal cavity. In the center of the spermatic cord are the mesorchium, the testicular artery, the testicular vein and the associated pampiniform plexus. The lymphatic vessels, deferent duct and the testicular plexus of autonomic nerves complete the structure. Externally, the cord is wrapped in a double tunicae of the vaginal process which is covered by the spermatic fascia, an extension of the fascia of the abdominal wall. Between the visceral and parietal layers of the vaginal process the cavity is continuous with the peritoneal cavity. Two thin layers of spermatic muscle overlay the tunicae as flat extensions of the internal abdominal oblique muscle. The muscle runs along the external surface of the parietal tunica of the vaginal process to insert on the spermatic fascia and parietal vaginal tunic. Surgically, the cremaster is considered and handled as though it were part of the spermatic cord. Between the subcutaneous inguinal ring and the scrotum, the spermatic cords pass ventral and medial to the thigh adductor muscles in a subcutaneous position. When the spermatic cords are delivered into a surgical incision they are often covered with a thin layer of fat.

Surgical Preparation for Castration of the Dog

Canine orchiectomy is performed under general anesthesia with the dog positioned in dorsal recumbency and with tethering restraint of the pelvic limbs in a caudal direction. The hair of the prescrotal and medial thigh areas is clipped and these areas and the scrotum are washed with water and mild soap. The prescrotal area of the prepuce, but not the scrotum itself, is then further prepared for aseptic surgery with skin preparation soap and solution. (Should the scrotum be prepared with antiseptics there is a high incidence of contact dermatitis). Because the scrotum has not received aseptic preparation the fully prepared prescrotal operative field is quadrant toweled to cover the scrotum. A fenestrated drape is positioned over the prescrotal area and the remainder of the patient. All further manipulations of the testes and scrotum are performed through the sterile fabric layers of the towel and drape.

Surgical Procedure for Castration of the Dog

To begin the orchiectomy a skin and subcutaneous incision is made on the ventral midline of the prepuce at the cranial base of the scrotum (Figure 35-1). The length of the incision must allow for the outward expression of each testis (Figure 35-2A). Next, one testis is manipulated forward and into the incision by pressure on the scrotum through the drape and towel. The tissue that limits the outward extrusion of the testis at this point is the spermatic fascia which must be incised down to the parietal layer of the vaginal tunica. The latter structure is a white, dense glistening layer of fascia that closely surrounds the testis. Once the spermatic fascia has been divided, the tunica covered testis can be delivered ("popped") forward, outward and into the skin incision (Figure 35-2B). Shortly after the testis appears, however, its outward progress is again resisted this time by the additional attachment of the spermatic fascia which connects the tail of the epididymis to the scrotal wall. This ligament may be broken by traction but often requires isolation by blunt dissection and, then, sharp transection. Using a hemostatic forceps across the ligament to crush small vessels is good practice in younger dogs and is often sufficient for hemostasis. However, in the case of mature adults, testicular neoplasia or orchitis, the ligament should be ligated to preclude the potential complication of postoperative scrotal hematoma. After clamping or ligation of the ligament of the tail of the epididymis, the structure is divided to release the invagination of the scrotal skin and to allow further exteriorization of the testis (Figure 35-3). Steady caudal and outward traction is next applied to the testis to break down

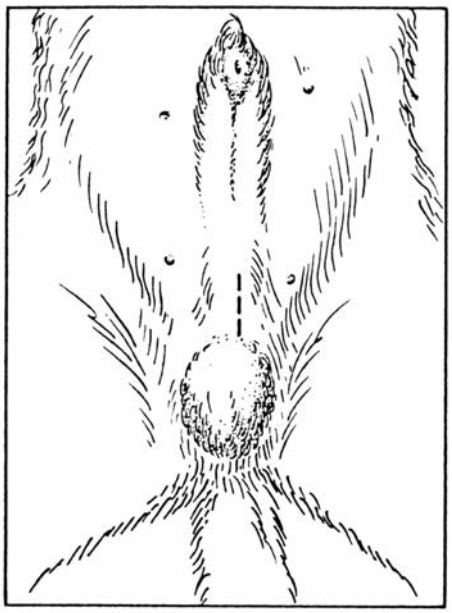

Figure 35-1. Location of the prescrotal incision for orchiectomy.

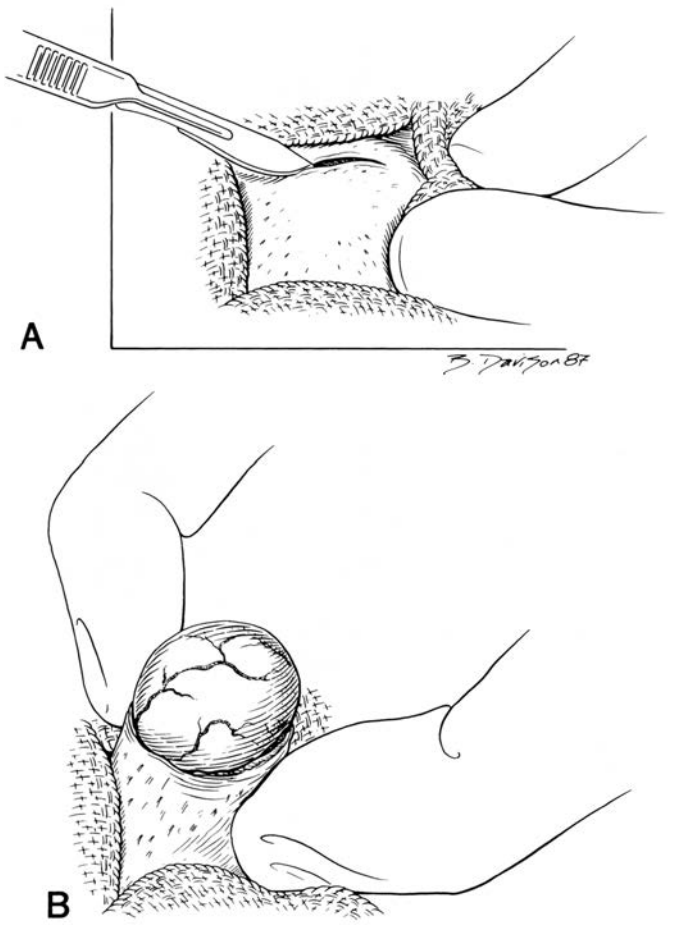

Figure 35-2. A. The skin, subcutaneous tissue, and the spermatic fascia are incised. The body of the penis is visible deep to the incision. **B.** Once the spermatic fascia has been completely divided, the testis, covered by the vaginal process, can be manipulated cranially into the incision. The scrotum is handled only through the sterile fabric of the towel and drape.

Figure 35-3. The spermatic fascia is fenestrated to identify and Isolate the ligament of the tail of the epididymis. This structure is clamped with hemostatic forceps before its sharp division. The clamp can be left in place until the incision is closed.

connective tissue attachments between the spermatic cord and the spermatic fascia. As the cord emerges into the operative field, any fat around the cord is removed by a proximal wiping and stripping action with a moist sponge. At this stage, the testis and a considerable portion of the spermatic cord have been exteriorized and the cremaster muscle is dearly seen on the external surface of the vaginal tunicae. The technique for cord transection depends on the patient's size.

Closed Castration

In patients under 20 kg, a "closed" castration technique is used. "Closed" means that the contents of the spermatic cord are triple clamped, ligated, and divided with the tunicae of the vaginal process intact around the cord (Figure 35-4). Additionally, the vaginal process is transfixed to the cremaster muscle to provide extra security in ligation. After triple hemostatic forceps are applied to the proximal portion of the exposed cord, the most proximal clamp is removed, and a slowly absorbable suture material, swaged to a taper needle, is passed through the

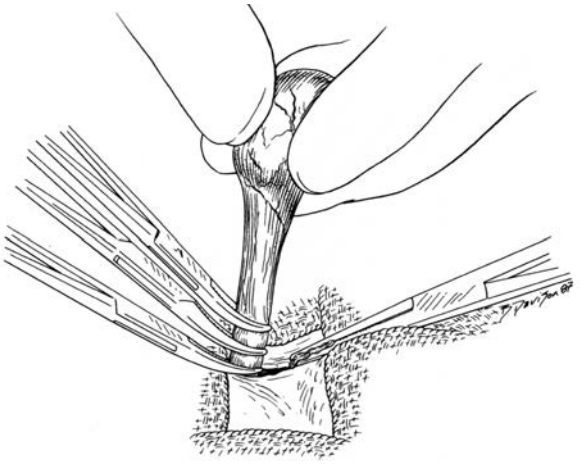

Figure 35-4. After exteriorization of the testis and most of the spermatic cord, any fat around the cord is removed. The initial step in closed castration is the application of triple hemostatic forceps across the unopened vaginal process and the cremaster muscle.

cremaster and tunica (Figure 35-5A). In placing this transfixation ligature, the surgeon must take care to miss the vascular structures of the spermatic cord. The ligature is tied over the cremaster and the ends of the suture are passed in opposite directions back around the spermatic cord to encircle it before forming a final knot (Figure 35-5B and Figure 35-6). The transfixation method of securing the hemostatic ligature prevents loosening or shifting of the ligature if the cremaster should contract. Ligature loosening could cause a retraction of the testicular artery away from ligature control. The middle clamp is removed and a second, non-transfixing ligature is placed in the clamp's crush mark. The spermatic cord is severed along the proximal edge of the distal clamp to prevent backfiow hemorrhage from the testis into the operative field (See Figure 35-6).

Open Castration

The "open" castration method is used for dogs over 30 kg. After each testis is exteriorized as described previously, the vaginal

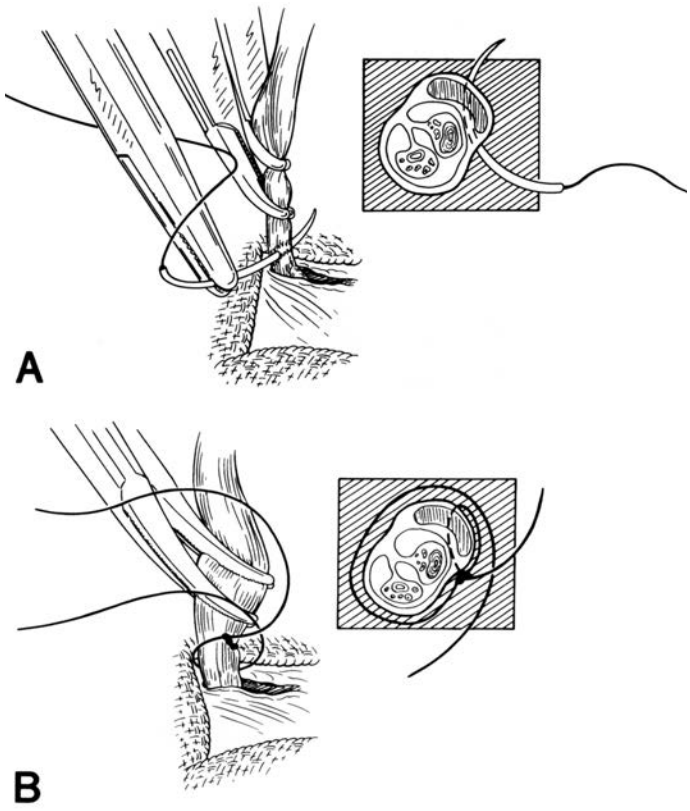

Figure 35-5. A. A transfixing ligature is applied between the cremaster muscle and spermatic cord in the closed castration. The needle passage incorporates the parietal tunica of the vaginal process and the cremaster. **B.** After the ligature transfixing the vaginal process and cremaster is tied, the entire cord is encircled with ligature before forming the final knot.

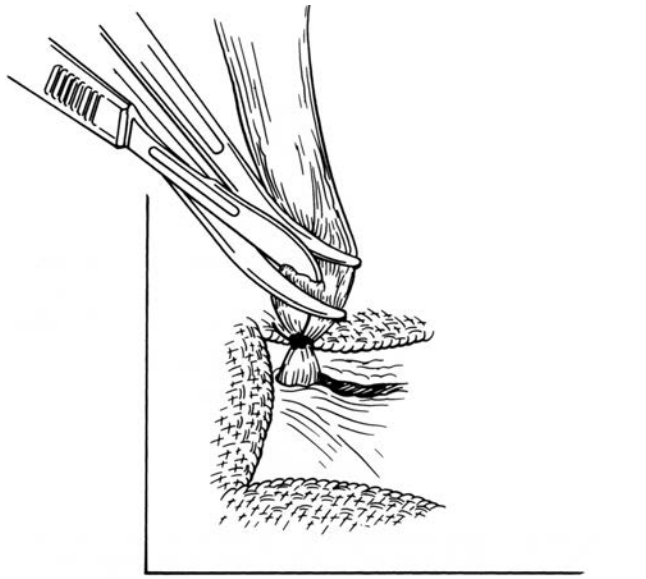

Figure 35-6. The spermatic cord is severed between the two most distal clamps to prevent backflow hemorrhage from the testis into the operative field and to retain control of the cord.

process is incised and opened longitudinally with scissors to expose the internal structures of the spermatic cord (Figure 35-7).

Proximally, most of the vaginal process and cremaster muscle are amputated; they are ligated only if large blood vessels are present. In returning to the spermatic cord itself, the testicular artery and vein and the deferent duct are ligated according to triple-damp technique with slowly absorbable suture material and are divided (Figure 35-8 and Figure 35-9). The advantages of the open method are that the vascular ligations are direct and, thus, more secure. The disadvantage is opening of an extension of the peritoneal cavity and a longer operative time.

After the spermatic cord is divided in either the open or closed castration technique, the remaining portion of the cord is released proximally into the subcutaneous tissue under direct

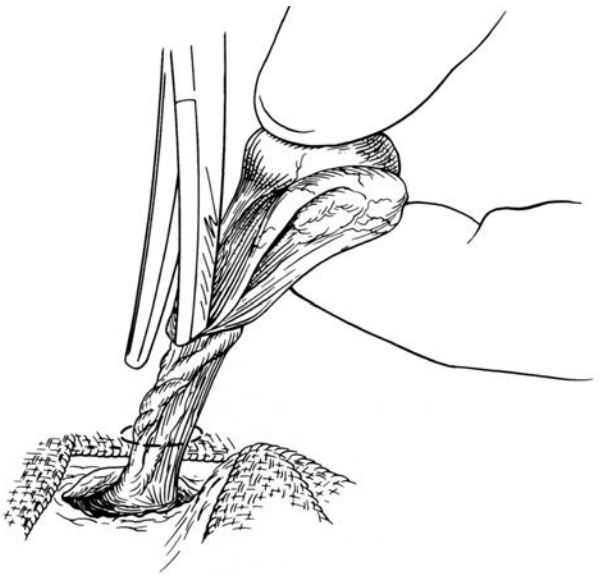

Figure 35-7. Open castration involves opening the parietal tunic of the vaginal process with scissors to directly reveal the internal vascular structures of the spermatic cord. The vaginal process and cremaster muscle are amputated proximally (*dotted line*). Ligation of the vaginal process and cremaster is not usually performed, but it may be required if larger blood vessels are present.

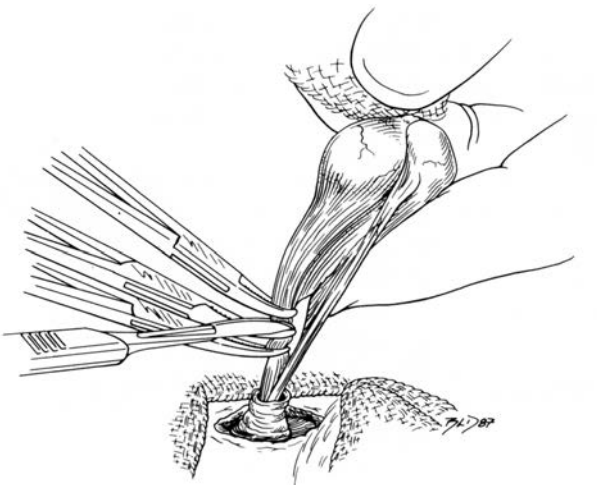

Figure 35-8. The testicular artery and vein and then the deferent duct are triple clamped. They are ligated just distal to the most proximal clamp.

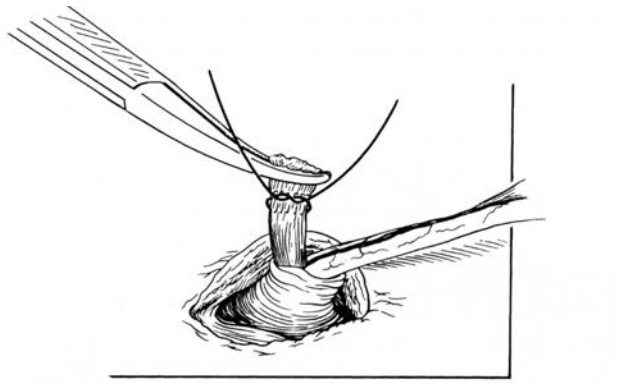

Figure 35-9. After division of the vessels, single or double ligations are securely placed directly on the testicular artery and vein, using slowly absorbable suture material. In this drawing, the arteriovenous complex is receiving its first ligature, and the ductus is yet to be clamped and ligated.

control of thumb forceps (Figure 35-10). Control during the release of the cord is important because the vessels shorten and dilate as tension on them is released. Any ligature slippage and hemorrhage will probably occur at this time. If bleeding occurs, the vessels or cord can be immediately retrieved for further attention if held by thumb forceps.

The remaining testis is produced by incising the contralateral spermatic fascia and the second gonad is removed in the same manner to complete the castration. At no time is invasion of the scrotal wall or scrotal septum necessary and any incision into the scrotum or the septum invites the complication of scrotal hematoma. After inspection for the complete arrest of bleeding, the deep and superficial subcutaneous layers and the subdermal skin are closed in one layer with an absorbable suture material. A simple interrupted or continuous pattern can be used but several of the suture bites should be placed laterally and deeply enough to "pick up" the connective tissue surrounding the retractor penis muscle to ablate potential dead space. Finally, the skin edges are gently and loosely apposed with a fine, nonabsorbable suture material in a simple interrupted pattern (Figure 35-11). Skin sutures that are placed too tightly often attract postoperative licking or self mutilation. In this case sutures will need to be removed if they are "cutting through" and can be replaced. New, looser skin sutures may also be complemented by the use of restraint devices such as a head collar or side bars, tranquilization, or topical preparations that are bitter to the taste. Skin edges can also be opposed with fine staples or surgical adhesive.

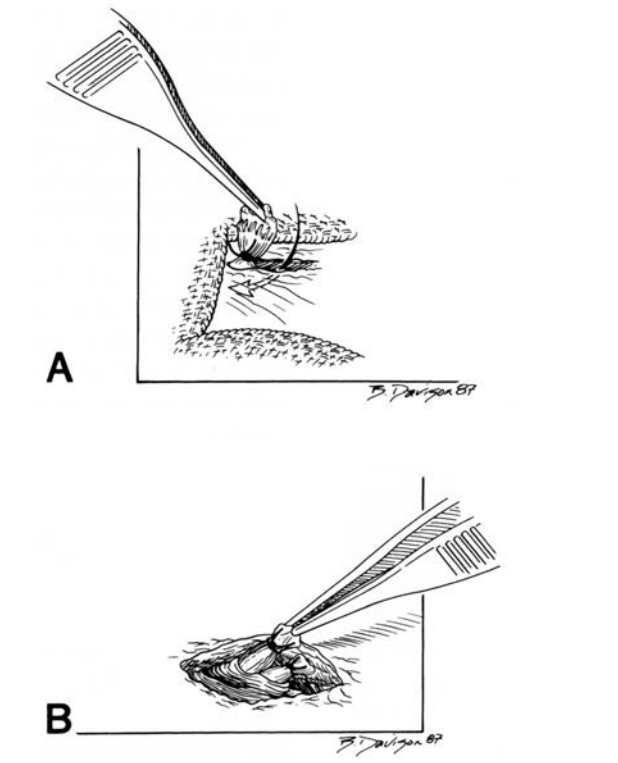

Figure 35-10. A. and **B.** In either the closed or open technique, the remaining portion of the amputated spermatic cord is released into the subcutaneous tissue under direct thumb forceps control. This allows retrieval of the vessels or cord if hemorrhage should begin when the stretched vessel is shortened.

Editor's Note: Intradermal closure of the skin is practiced by many surgeons instead of skin closure as it is believed that self-trauma of the incision by licking is less of a postoperative problem when skin sutures are omitted.

Ancillary Techniques to Orchiectomy

Scrotal Ablation

Veterinarians and clients may prefer scrotal ablation in the opinion that it cosmetically complements the orchiectomy. This is especially true in larger breed dogs with short hair coats. Preperation for surgery includes full antiseptic scrubbing of the scrotum and the inner thigh and perineal areas. Scrotal ablation is initiated by a circumfrential incision around the scrotum with the incision made slightly toward the scrotal side of the junction between the skin. Such an incision placement reduces skin tension and utilizes incision-induced spasms of the tunica dartos layer of the scrotum to help reduce intra-operative hemorrhage. The incision is extended through the entire subcutaneous tissue by sharp dissection where pinpoint electrocautery may be useful. After removal of the scrotum and following orchiectomy, attention to dead space ablation during the subcutaneous layer closure is important.

Implantation of Testicular Prostheses

Alternatively to scrotal ablation, veterinarians and clients may prefer preserving the appearance of a natural scrotal and testicular anatomy. In this case prosthetic testicular implants are available in various sizes, firmnesses and degrees of anatomic correctness. The implantation technique is a patented procedure and is described in literature supplied by the manufacturer of the implants. As with any implanted bioprosthesis strict adherence to aseptic technique is a critical facet of the procedure.

Orchiectomy Through a Caudal Approach

A caudal approach is a choice for canine orchiectomy when the patient is already positioned in sternal recumbency on a "head-down" elevated platform for perineal surgery (see pages 581-582). Before the other perineal procedure is performed a transverse incision is made dorsal to the scrotum at its junction

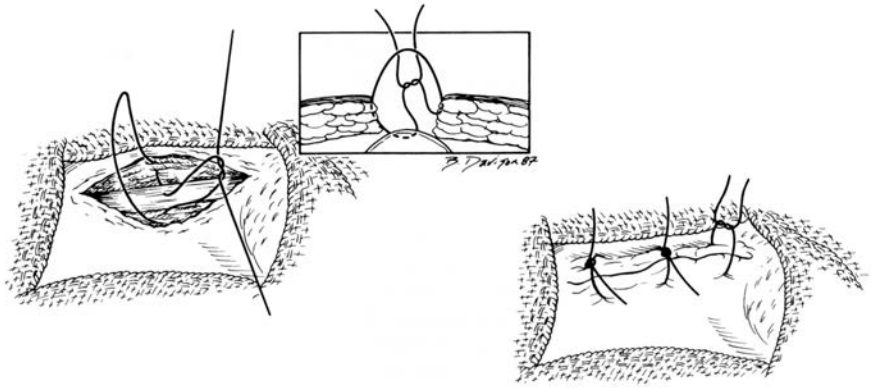

Figure 35-11. Simple interrupted intradermal sutures, with the knots buried, are used to ablate dead space and to appose wound edges. Each suture is just "catching" superficial portions of the retractor penis muscle. Ablation of dead space helps to prevent post operative hematoma or seroma. Skin suture should loosely approximate wound edges.

with the perineal skin. After the spermatic fascia is incised, the testes are delivered dorsocaudally into the operative field by upward pressure on the toweled scrotum. With outward traction applied the ligament of the tail of the epididymis is identified, isolated, clamped, and divided. The spermatic cord and testis are then delivered into the incision and the remainder of the operation is performed as previously described for a closed or open technique.

Castration of the Cat

Male cats are usually neutered at or before sexual maturity. The intact male cat is usually not well tolerated as an indoor companion animal because of marking and spraying with an odoriferous urine. Nocturnal fighting and roaming are other behavior patterns of male cats that are often successfully controlled by orchiectomy.

The only instruments needed for cat castration are two mosquito forceps, a pair of smaller, sharp sharp scissors, a No. 10 scalpel blade, absorbable ligature material, and a nonfenestrated paper drape. The cat is placed under ultrashort acting general anesthesia and positioned in dorsal, ventral, or lateral recumbency. While in dorsal recumbancy the cat's perineal area is conveniently exposed by bringing the hindquarters to the edge of a table and allowing the tail to fall toward the floor. The patient's pelvic limbs are secured in a laterally abducted position, and the hair covering the scrotum is either plucked with the fingers or clipped with a No. 40 clipper blade. The scrotal area is prepared with scrub soap and skin antiseptics. A drape is easily and economically made from paper drape material that is sterilized with the other instruments and a fenestration about the size of a dime is cut in the center of the drape. The prepared scrotum is expressed through the hole to create an acceptably draped surgical area without any exposure of hair.

The skin, tunica dartos and spermatic fascia over each testis are vertically incised with a No. 10 scalpel blade. The incision should extend amply from the dorsal to the ventral aspect of the scrotal compartments. With a pinching maneuver the testis, still enclosed in the vaginal process, is "popped" out of the incision. The testis is pulled caudoventrally until considerable exposure of the spermatic cord is obtained and resistance to further traction is met. Any fat investing the spermatic cord is stripped from the cord and, in a proximal position, two Halstead mosquito forceps are placed across the spermatic cord. As the proximal forceps is removed a ligature of absorbable suture material is tied tightly in the crush mark. The spermatic cord is then transected and released up into the scrotum under direct control of the remaining mosquito forceps. As an alternative to ligature placement, kittens and juveniles, but not adults, can have their spermatic cord looped with an overhand knot and cinched tight (Figure 35-12). After the testes are removed, both scrotal incisions are dilated by spreading the tips of mosquito forceps between the wound edges to preclude an early fibrin seal across the incision. The application of topical ointments or systemic antibiotics are unnecessary.

Cryptorchidism

Unilateral or bilateral cryptorchidism is encountered frequently in dogs and is transmitted as a hereditary disorder in a simple, autosomal recessive manner. The condition occurs most frequently in small purebred dogs, with a right to left ratio of 2.3:1. Unilaterally cryptorchid males are typically fertile and possess normal libido so the trait is widely disseminated.

Testicular descent should be complete shortly after birth and testes not located within the scrotum by 2 months of age should be considered permanently retained. Veterinarians should strongly recommend the castration of cryptorchid animals because testes retained in an inguinal or abdominal position are predisposed to the malignant changes of seminoma and Sertoli cell tumor. Orchiopexy or prosthetic testicular implantation is illegal and unethical for show purposes and can contribute to the perpetuation of cryptorchidism.

The palpable absence of one or both testes during several examinations confirms the diagnosis of cryptorchidism. Once a diagnosis of cryptorchidism has been established, the surgeon must determine at what point along the normal path of testicular descent migration became arrested. This point can be anywhere from just cranial to the scrotum in the subcutaneous tissue of the groin all the way up to the position of embryonic organogenesis

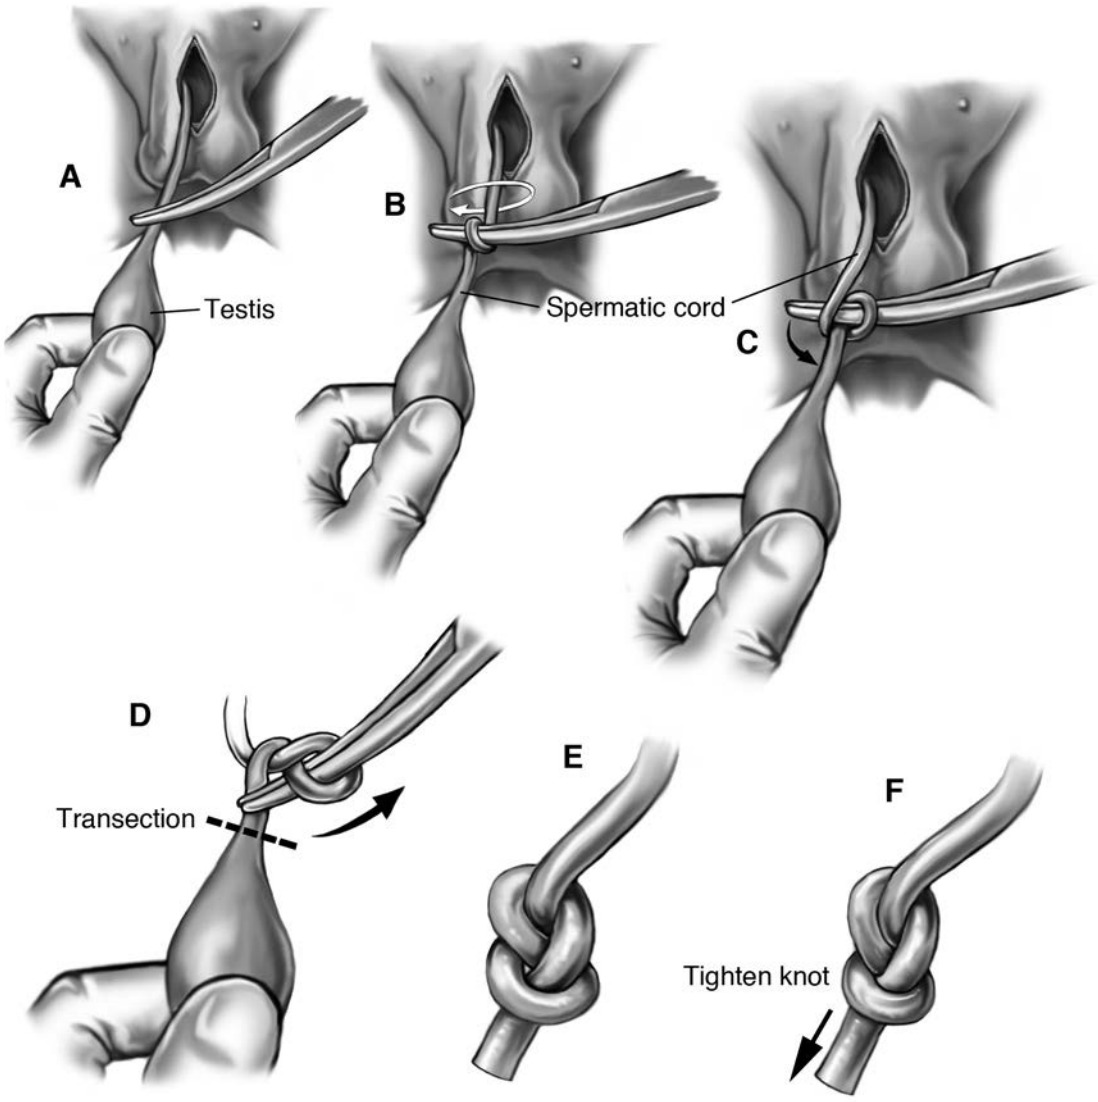

Figure 35-12. Feline Castration-Closed technique. This is a six step technique where the spermatic cord is tied on itself using a mosquito hemostat. This technique is applicable to a closed castration for kittens and juvenile aged males. The spermatic cord should be well exteriorized, free of tension and stripped of fat prior to forming the loop and pulling tissue with a curved mosquito hemostat.

just caudal to the kidney. Careful palpation usually enables the examiner to detect most gonads if they are distal to the superficial inguiinal ring in the subcutaneous tissue of the groin.

Many retained canine testes are located within the abdominal cavity and exploratory celiotomy or laparoscopy is required for their removal. With the patient under general anesthesia and the ventral abdominal wall prepared for aseptic surgery, a midline celiotomy is performed through the linea alba from the umbilicus to the prepuce. Frequently, the testis is located in the mid abdominal region as a highly movable organ smaller than the descended gonad. Arterial supply from the testicular artery, a direct branch of the aorta, and a small artery in the gubernacular remnant or the deferential fold of the peritoneum are typically visualized. Also, the ductus deferens courses toward the caudal aspect of the abdomen and can be a reliable primary landmark for tracing to the retained testis.

If the testis cannot be located initially in the mid abdominal area, the area of the inguinal ring is next examined. When testicular descent is arrested at this location, the testis can usually be palpated by moving a finger along the abdominal wall toward the ring. After the cryptorchid testis is located, the testicular vessels and ductus are isolated, triple clamped, and doubly ligated either collectively or individually with a slowly absorbable ligature material. After division of vascular structures, the abdominal cavity is checked carefully for bleeding, and the celiotomy is closed. True agenesis of the testis and vas deferens is reported, but it is rare. If the testis has descended through the inguinal canal and is located in the subcutaneous tissue of the groin, removal is by a standard prescrotal incision with manipulation of the testis into the incision by digital pressure.

Chapter 36

Penis and Prepuce

Surgical Procedures of the Penis

H. Phil Hobson

Amputation Techniques

Partial or "complete" amputation of the penis may be indicated in certain congenital, traumatic, or neoplastic conditions. The most common neoplasm of this area, transmissible venereal tumor, is generally responsive to chemotherapy or radiotherapy. Thus, amputation of the penis should be considered rarely, if ever, as a corrective measure for this condition. Cryotherapy has also been used successfully for removal of benign tumors of the penis.

Partial Amputation

The exact location of the amputation is determined by the site of the lesion. In most cases, the penis can be extruded (Figure 36-1A) and held in the extruded position by clamping the preputial orifice with a towel clamp just caudal to the bulbus glandis. The sheath can be opened full thickness on the ventral midline, when necessary, to expose the penis. The penis can be extruded through a ventral opening in the prepuce, or the entire length of the prepuce can be opened for better exposure. A Penrose drain tube works well as a tourniquet around the base of the penis.

Amputation of the tip of the penis may be necessary in patients with chronic or recurrent prolapse of the urethra (Figure 36-1). Placing a catheter in the urethra helps to identify the limits of the lumen. The surgeon should make the incision partway across the tip, place a stay suture to unite the mucosa of the urethra with the

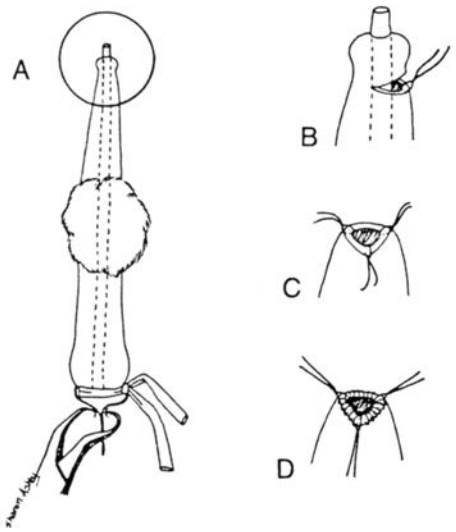

Figure 36-1. A. Amputation of the tip of the penis. **B.** Securing the urethral mucosa to the penile mucosa. **C.** Triangulating the urethral orifice with stay sutures. **D.** Placement of a simple continuous pattern between the stay sutures with the orifice in maximal dilatation.

mucosa of the penis, and then complete the excision of the tip of the penis (Figure 36-1B). The triangula-tion technique (Figure 36-1C and D) conserves a patent lumen to the tip of the urethra. Careful apposition of the cut mucosal edges to the penile tunica helps to avoid excessive scar tissue proliferation and stricture. A continuous suture pattern helps to control seepage from the cavernous erectile tissue. Synthetic absorbable suture is used for mucosal closure.

An Elizabethan collar or a side-bar restraint device should always be used to prevent the patient from licking the wound. Castration or careful hormone therapy may be indicated to help to prevent erection during healing.

Amputations of the main body of the penis require the severing of the os penis, as well as the salvaging of enough urethra distal to the severed os penis for a distance of 1 cm. The os penis and urethra are severed with bone-cutting forceps and a scalpel. The urethra is isolated subperiosteally from the groove of the os penis with a small dental chisel. The urethra is split, flared, trimmed, and sutured to the infolded tunica albuginea, as shown in Figure 36-2. Care should be taken to appose the mucosal surfaces. Although it is perhaps easier to achieve excellent apposition with fine, closely placed interrupted sutures, a continuous pattern is more likely to control bleeding. Some bleeding, especially at the end of urination, is common, even for several days after the operation. It is difficult to identify and to ligate individual vessels in this area. Releasing the tourniquet while the wound is open, in an effort to identify and to ligate the vessels within the corpus spongiosum penis, may prove unrewarding.

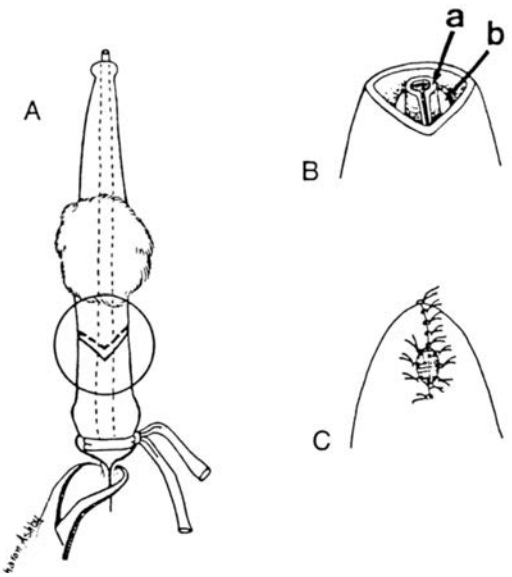

Figure 36-2. A. Amputation of the penis proximal to a lesion. The corpus spongiosum penis is incised at a 45° angle. The os penis and urethra are incised I cm further distal than the corpus spongiosum penis. **B.** The urethra (*a*) is elevated subperiosteally from the groove in the os penis. The os penis (*b*) is trimmed away with a rongeur to the level of the corpus spongiosum penis. **C.** The urethra is sutured to the penile mucosa, and the remainder of the penile stump is closed.

Preputial Amputation

When pooling of urine within the prepuce becomes a concern after partial amputation of the penis, shortening of the entire prepuce may be desirable. For the best cosmetic results, a full-thickness section of the prepuce can be removed (Figure 36-3). The length of prepuce to be removed should be the same as the length of the penile resection. In patients with congenital micro-penis, the tip of the prepuce should cover the tip of the penis by approximately 1 cm. The cranial transverse incision is made 2 cm caudal to the cranial junction of the prepuce and the body wall, to allow adequate circulation to the cranial end of the prepuce. The location of the caudal transverse incision is determined by the length of the penis. The two incisions are extended laterally in an elliptic fashion to facilitate a smooth closure of the skin.

Next, the dorsal aspect of the section of prepuce to be removed is dissected free from the body wall with scissors. With careful dissection, most of the preputial vessels, which lie immediately subcutaneously on both sides of the sheath, can be identified and preserved. To close the amputation, the preputial mucosa is apposed with 4-0 absorbable suture, using a submucosal pattern. If a continuous pattern is used around the circumference of the prepuce, care should be taken to avoid a pursestring effect, which limits the movement of the penis. The veterinarian may find it easier to close the dorsal mucosa if the penis is allowed to protrude through the incision site during this phase of closure.

Complete Amputation

The initial skin incision is made in an elliptic fashion around the entire external genitalia (Figure 36-4A). The preputial vessels are ligated, as are any additional branches of the caudal superficial epigastric vessels that cross the incision line. The spermatic cords are isolated, ligated, and severed. Care must be taken to place the ligatures tightly enough to prevent retraction of the severed spermatic artery if the tunicae are incorporated in the ligature. When the penis and the prepuce have been stripped from the body wall in a caudal direction, the dorsal penile vessels are identified and ligated just caudal to the level of the desired penile amputation site. The retractor penis muscle is reflected from the urethra, and, with a catheter in place, a midline incision is made into the urethral lumen at the desire urethrostomy site. A 1-0 absorbable, ligature, which circumscribes the penis, is placed just caudal to the amputation site and just cranial to the urethrostomy site (Figure 36-4B), to control seepage bleeding from the erectile tissue further, if necessary. The shaft of the penis is amputated in a wedge fashion, and the tunica albuginea is apposed over the amputation stump. The urethrostomy should be located in the scrotal area whenever possible. Careful apposition of penile urethra and skin edge, as the urethrostomy is completed, minimizes postoperative bleeding and scar tissue formation (Figure 36-4C). Although suture patterns and materials are a matter of choice, a continuous pattern aids in controlling hemorrhage from any incised erectile tissue. The use of synthetic absorbable suture eliminates the need for suture removal.

Particular care should be taken to obliterate dead space, especially cranial to the stump of the amputated penis, when closing the subcutaneous tissue. The use of a restraint device to prevent licking of the surgery site by the patient is imperative.

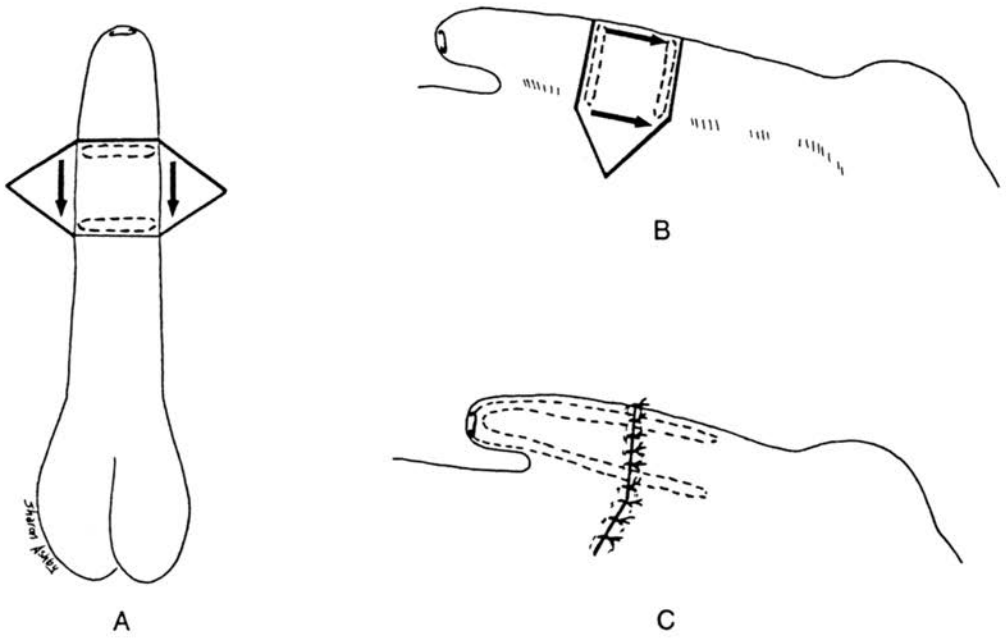

Figure 36-3. Shortening of the prepuce in cases of pooling of the urine within its lumen. **A.** Removal of a section of the entire prepuce. **B** and **C.** Reapposition of the mucosa and skin.

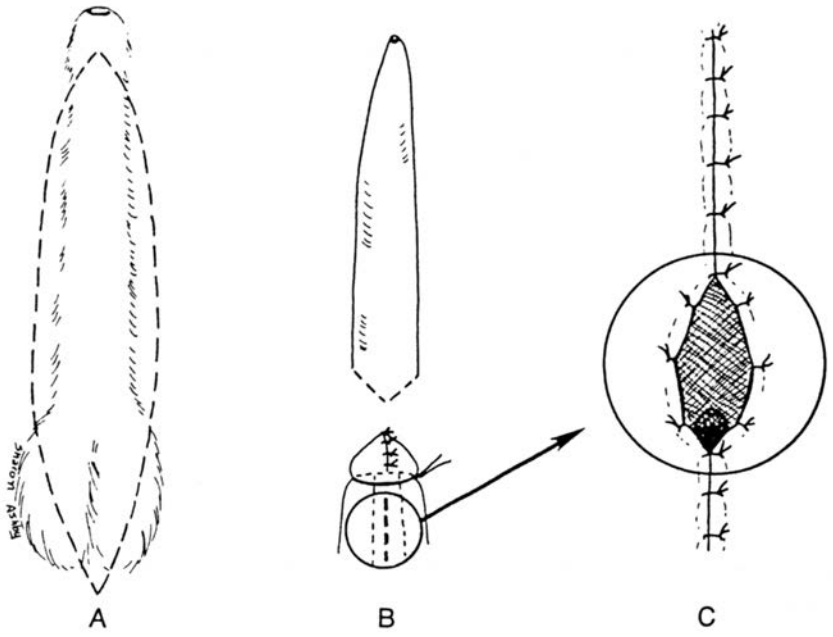

Figure 36-4. Ablation of the external male genitalia. **A.** The skin incision extends from cranial to the prepuce to caudal to the scrotum. **B.** Amputation of the shaft of the penis in the area of the scrotum. The penis is ligated, incised, and sutured. **C.** The urethrostomy is established by careful apposition of the urethral mucosa to the edge of the skin.

Correction of Hypospadias

Hypospadias is a congenital anomaly of the external genitalia in which the penile urethra terminates caudal to its normal opening. The urethra can terminate at any level from the perineum to the tip of the penis (Figure 36-5) because the urethral folds fail to fuse (See Figure 36-9). In severe cases, the two halves of the scrotum can fail to fuse, the penis fails to develop normally, and the urethra fails to close in the perineal area (Figure 36-6). Frequently, the analog of the urethra can be present as a fibrous cord that runs from the glans penis to the urethral opening and pulls the penis into a deforming ventral curvature (chordae) (See Figure 36-6).

Minimal defects usually require no urethral surgery. The constant extrusion of the tip of the glans penis can often be relieved by closing the prepuce to its normal extent (Figures 36-7 and 36-8) on its caudoventral aspect. Should the resulting orifice be too small to allow extrusion of the penis, the opening can be increased to the desired diameter by enlarging the lumen of the craniodorsal aspect. Simply leaving the orifice larger by not

closing the caudoventral defect to its fullest extent can cause the tip of the penis to continue to droop from the prepuce and may thus subject it to continual drying, licking, and trauma.

Caudoventral closure is accomplished by incising the mucocutaneous junction, separating the mucosa from the skin, and closing the two layers individually (Figure 36-8A). Sutures of 4-0 to 6-0 absorbable synthetic material are preferred. Should the orifice need to be enlarged dorsally, one scissor jaw is inserted into the lumen of the prepuce, and the orifice is cut to the needed extent. With a minimum of undermining, the cut mucosal and skin edge can be apposed (Figure 36-8B). Failure to appose the skin and mucosal edges adequately may result in closure by granulation, or, should the patient be allowed to lick out the sutures, stricture formation is likely to follow.

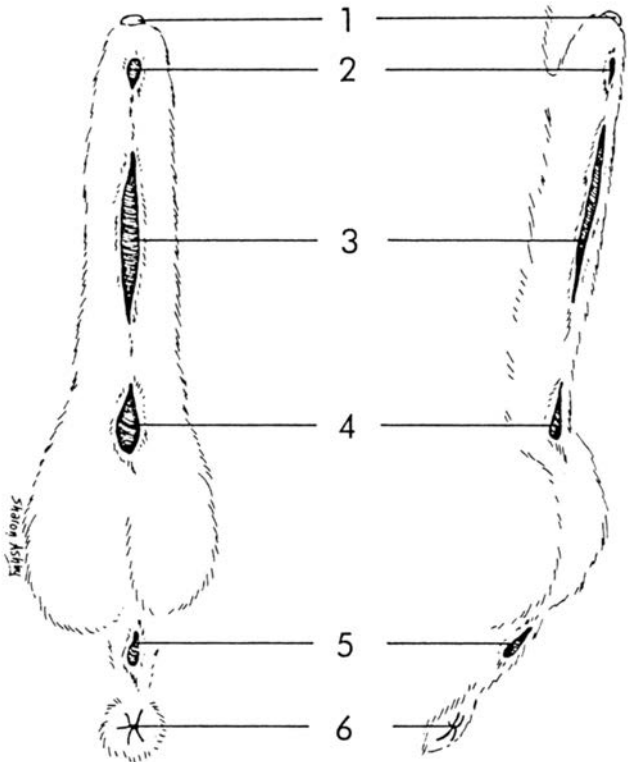

Figure 36-5. Normal urethral meatus *(1)* and types of hypospadias: glandular *(2)*; penile *(3)*; scrotal *(4)*; perineal *(5)*; and anal *(6)*.

Small urethral defects can be closed successfully with a two-layer closure (Figure 36-9). A catheter is inserted past the defect, and an incision is made at the open mucocutaneous junction around the perimeter. The mucosa is undermined and is closed, as is the skin. Care must be taken not to create a stricture. Skin can be invaginated to close the urethral defect, provided the hair follicles have been destroyed previously.

Rectangular full-thickness bladder wall sections, rolled into a tube, have been used to replace surgically sacrificed sections of urethra (i.e., urethral neoplasms). Oral mucosa has been used as well. After suturing of the grafts into the urethral defect (over a catheter), the skin is undermined as in Figure 36-9C and is closed over the urethral graft. The catheter is left in place for 7 to 10 days. If open-ended catheters are used as stents, the catheter need not be introduced all the way to the bladder. Catheters remain in place much better if they are cut flush with the urethral orifice and are sutured in place by passing one or two sutures through the catheter and the tip of the penis. For major urethral defects, excision of the external genitalia and urine diversion by urethrostomy are the treatments of choice (See Figure 36-4). An elliptic incision is made around the rudimentary penis, prepuce, and scrotum. Dissection from the body wall is carried out in a cranial-to-caudal direction; the surgeon should ligate preputial vessels as they are identified and isolated. Should penile tissue

The mucocutaneous junction is trimmed away, the skin is undermined, and the mucosa *(1)* and the skin edges *(2)* are closed as separate layers. **B.** Enlargement of the dorsocranial aspect of the preputial orifice. The prepuce is cut at full thickness. The mucosa *(1)* is sutured to the skin edge *(2)* along the margin of the incision.

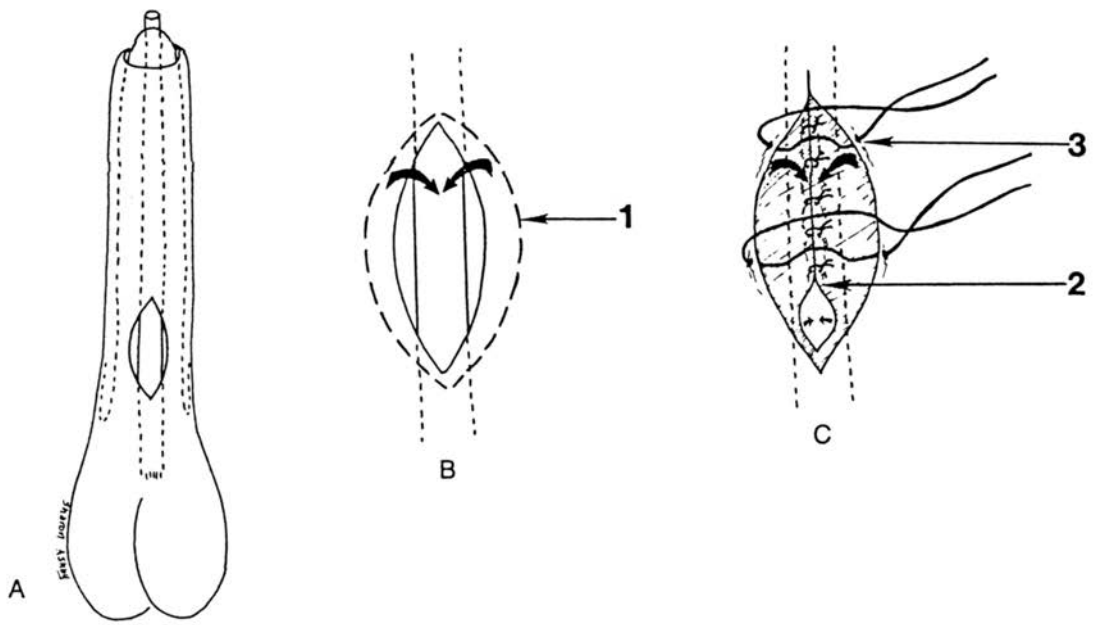

Figure 36-9. A. Penile hypospadias with a catheter in the urethra. **B.** Incisions are made lateral to the defect (*1*). Skin can be used to reconstruct the ventral wall of the urethra if mucosa is insufficient. Hair follicles need to be destroyed if skin is invaginated. **C.** The tissue is undermined sufficiently to allow the ventral urethral wall to be reconstructed (*1*) and the skin to be closed (*2*) without undue tension.

be present near the caudal end of the incision, it can be ligated in its entirety and excised. Ligation of the dorsal artery of penis is accomplished when necessary. The subcutaneous tissue and skin are closed in a routine fashion.

Correction of Phimosis

The inability to extrude the penis from the sheath (phimosis) is usually the result of too small a preputial orifice. Because surgical enlargement of the orifice with a ventrocaudal preputial incision can cause persistent extrusion of the glans, the orifice should be enlarged on the craniodorsal surface. A full-thickness incision is made to the desired length with heavy scissors. The severed preputial mucosa is then undermined sufficiently to allow apposition to the ipsilateral skin edge (See Figure 36-8B). The use of a restraint device to prevent licking or chewing is imperative.

Correction of Paraphimosis

The inability to return the penis to the sheath can result in severe trauma or circulatory compromise. The animal can develop necrosis or injury sufficient to require penile amputation. Persistent exposure of the glans can also result in chapping and excessive licking.

Many patients with acute paraphimosis can be managed by noninvasive methods to return the penis to the lumen of the sheath. The extruded and visually edematous penis should be cleansed, and the sheath should be thoroughly irrigated with nonirritating soaps. A combination of massage and locally applied hypertonic and hygroscopic agents, such as sugar, can help to reduce swelling. Once swelling is reduced, the constricting preputial orifice can usually be pulled over the lubricated penile shaft. Preputial enlargement can be accomplished by incision and primary repair of the mucosal and skin layers, to reduce refractory paraphimosis.

On occasion, the tip of the penis can remain exposed when no obvious orifice defects are present. Once the mucosa has been exposed for some time and has become dry and cornified, the skin of the prepuce rolls inwardly as attempts are made to return the penis to its sheath. After adequate cleansing and lubrication, the penis can be returned to its sheath. If the tip of the penis is well covered by the prepuce (at least 1 cm), narrowing of the preputial orifice will probably prevent recurrence (See Figure 36-8A). Should the prepuce not cover the tip of the penis well, cranial movement of the prepuce should be performed (Figure 36-10). This translocation can be accomplished by removing a crescent-shaped piece of skin from the ventral body wall just cranial to its juncture with the prepuce. Care should be taken to preserve the preputial vessels. The preputial muscles, which lie superficial to the rectus abdominis muscles, can then be shortened by either an overlapping technique (Figure 36-10A) or simple excision followed by reapposition (Figure 36-10B). The closure of the subcutaneous tissue and skin is routine.

Preputial Reconstruction

A hypoplastic prepuce can be lengthened in a two-step surgical procedure. The first step involves transplanting oral mucosa to a prepared graft site on the ventral body wall immediately cranial to the hypoplastic prepuce; in the second step, the lateral sides of the grafted mucosa are freed, are formed into a tube, and are anastomosed to the isolated mucosa of the cranial end of the prepuce. Single pedicle skin flaps are advanced to the ventral midline from both sides of the ventral body wall to cover the mucosal tube and to complete the cranial extension of the prepuce.

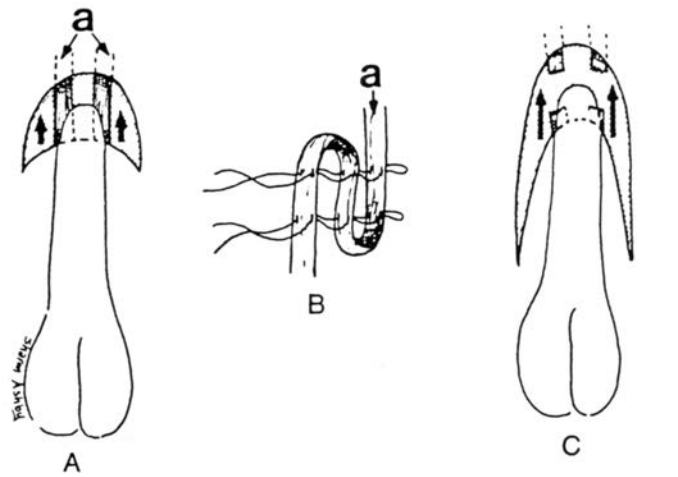

Figure 36-10. A and **B.** A crescent-shaped piece of skin is removed with subsequent cranial movement of the cranial aspect of the prepuce by folding the preputial muscles *(a)*. **C.** Excision of a segment of the preputial muscles.

Correction of Ventral Deviation of the Penis

Wedge osteotomies reportedly have been successfully performed to correct ventral penile deviation. The os penis is approached on the dorsal midline over its greatest curvature. The os penis is fractured with a bone cutter, and a small pie-shaped wedge of bone is excised to allow for straightening of the os penis. After wound closure, an open-ended catheter is sutured in place within the urethra and is left for a minimum of 3 weeks. One disadvantage of this procedure is possible damage to the penile urethra at the time of surgery or during healing. Rigid fixation of the os penis should definitely be maintained to help alleviate the likelihood of nonunion or malunion. Animals with congenital anomalies should not be used for reproductive purposes.

Removal of Penile Urethral Calculi

Most urethral calculi causing impairment of urine flow are lodged just proximal to the os penis. On rare occasion, particularly when the groove within the os penis is narrowed, calculi lodge within the penile urethra. This narrowing can be the result of a congenital deformity or injury, with or without fracture of the os penis. Whenever possible, these calculi should be hydropulsed into the bladder. Extraordinary efforts should not be used to relocate these stones, however, because debridement of the urethral mucosa is likely to result in stricture formation.

The penile urethra is approached from a ventral midline incision, after exposure of the penis as in Figure 36-1A or by splitting the prepuce. A catheter is advanced from the urethral orifice caudally to determine the exact location of the obstruction. Ideally, the incision is made exactly on the ventral midline of the penis, to avoid the erectile tissue. The incision is extended

caudally 1 to 2 cm, exposing the calculi. On rare occasion, the surgeon may need to rongeur away a part of the wall of the groove in the os penis after carefully elevating the soft tissue, including the urethra, from the bone.

The calculi are grasped with forceps and carefully are removed. The area is flushed with sterile saline, and the catheter is advanced to the bladder, while one checks for the presence of more calculi. A cystotomy is performed if indicated. The penile urethral incision is closed with fine absorbable suture over a catheter with a continuous suture pattern. The penile incision is then closed over the urethra in similar fashion.

Correction of Penile Urethral Strictures

Minimal stricturing of the penile urethra can often be managed by dilating the stricture and leaving an indwelling open-ended catheter in place for 7 to 10 days. More extensive strictures may be better managed with a prescrotal or scrotal urethrostomy, as discussed previously and in Chapter 31, because the urethra is immobile within the groove of the os penis and does not lend itself well to reconstruction.

Correction of Persistent Penile Frenulum

On rare occasions, the penile mucosa may fail to separate from the prepucial mucosa as the puppy matures, and it may serve as an irritant to the pup or may even impair breeding in the mature male. Rarely is this persistent attachment more than a narrow band of tissue that is easily severed.

Chapter 37

Endocrine System

Adrenalectomy

Stephen D. Gilson, Lillian Brady Rizzo and Akiko Mitsui

Introduction

Adrenalectomy is most often performed for treatment of primary adrenal tumors (adrenal cortical adenoma, carcinoma, and pheochromocytoma). Rarely, adrenal resection may be used for treatment of metastatic tumors, sex hormone imbalances, and treatment of pituitary-dependent hyperadrenocorticism refractory to medical therapy. Adrenal tumors are often biologically active resulting in adverse physiologic alterations, and may invade the adjacent great vessels (vena cava, aorta, renal vein or artery). Clinical management and resection can be challenging. Surgeons must have a thorough understanding of the pathophysiology associated with adrenal diseases, be suitably familiar with the regional anatomy and make appropriate perioperative preparations to minimize complications and maximize treatment success.

Preoperative Management

Routine diagnostic and staging tests recommended for adrenal masses include: complete blood count and serum biochemistry profile, thoracic radiographs, and abdominal ultrasound (including Doppler flow evaluation of great vessels for presence of tumor thrombus). For the majority of patients this collection of diagnostic tests is adequate for preoperative assessment. In selected patients, further imaging evaluation may be deemed necessary and abdominal CT (with contrast) and MR imaging provide excellent assessment of the adrenal glands and surrounding tissues.

Adrenal cortical tumors may produce excess cortisol and symptoms of Cushing's disease. Where indicated by clinical findings, patients are evaluated by low dose dexamethasone suppression test (or similar assessment) prior to surgery. Hyperadrenocorticism can predispose patients to complications resulting from hypertension, delayed wound healing, immune suppression, and thrombosis. If testing confirms hyperadrenocorticism, preoperative adrenal suppression may reduce the risk of complications. Ketoconazole therapy (10 mg/kg q 12hours) is a rapid and safe method for suppression. The optimal duration of preoperative therapy to reverse adverse effects remains unknown, and further study would be valuable. Empirically, the authors find a 10 day course of treatment is effective. When significant hypertension is present, concurrent use of vasodilator therapy is also indicated (Table 37-1).

Pheochromocytomas can produce excess catecholamines resulting in hypertension, tachycardia, arrhythmias, and chronic myocardial changes. Patients should have blood pressure measured, and where indicated by relevant clinical signs, echocardiographic evaluation. For cases where definitive diagnosis remains difficult, catecholamine by-products can be measured in the urine (vanillylmandelic acid, metanephrine and normetanephrine).[1] When hypercatecholaminemia is present preoperative treatment with phenoxybenzamine and atenolol or propranolol can reduce anesthetic complications (Table 37-1). The optimal duration of preoperative catecholamine suppression is also unknown, however empirically the authors have found a 10-day course of treatment to be effective. When significant hypertension is present concurrent use of vasodilator therapy is also indicated (Table 37-1).

Table 37-1. Pharmacologic agents used for preoperative preparation for catecholamine producing tumors.

Alpha-adrenergic Antagonism
Phenoxybenzamine: 0.25 mg/kg PO BID initially; (range 0.2-2.5 mg/kg BID) for 7-10 days before surgery.
Treatment of hypertension, hypovolemia associated with chronic vasoconstriction, and reduces cardiovascular events related to tumor manipulation induced acute catecholamine release.
Beta-adrenergic Antagonism
Atenolol: 0.2 -1 mg/kg PO q12-24 hours for 7-10 days before surgery.
Treatment of severe tachycardia/arrhythmia. Administer ONLY AFTER phenoxybenzamine has been initiated to prevent severe hypertension.
OR
Propranolol: 0.2 -1 mg/kg PO TID for 7-10 days before surgery.
Treatment of severe tachycardia/arrhythmia. Administer ONLY AFTER phenoxybenzamine has been initiated.
Chronic Vasodilator
Enalapril (ACE inhibitor): 0.5 mg/kg once to twice daily.
Treatment of refractory hypertension.
OR
Hydralazine (Direct acting vasodilator): 1-3 mg/kg twice daily.
Treatment of refractory hypertension.

Surgical Anatomy

The adrenal glands are located craniomedial to the pole of each kidney in the retroperitoneal space. The left adrenal gland lies in loose collagenous connective tissue, is generally well localized, and easily visualized with retraction of the mesocolon. The right adrenal is less well localized from the adjacent structures and the capsule is often continuous with the outer tunic of the vena cava. In some animals the gland lies dorsal to the vena cava. Deep chested animals require substantial retraction of the mesoduodenum for adequate visualization. The adrenals have a rich blood supply and it is often significantly enhanced by tumor neovascularization. The renal artery and vein run along the caudal boundary of each adrenal gland and these vessels can be encroached upon and invaded as tumors enlarge. The phrenicoabdominal veins course dorsoventrally across the center of each gland and are frequently invaded by a tumor thrombus. The right adrenal vein empties into the caudal vena cava, and the left adrenal vein enters the left renal vein. Clinically relevant arterial supply is by multiple short branches located on the dorsomedial side of the glands arising from the aorta, renal, lumbar, and phrenicoabdominal arteries. Innervation is by preganglionic sympathetic nerve fibers from the splanchnic supply, and medullary cells are the postganglionic neurons (Figure 37-1).[2]

Surgical Approach

Adrenalectomy is best performed via ventral midline laparotomy. Though a paracostal retroperitoneal approach is described, the field of view is small making resection of larger tumors difficult or impossible. The ventral approach allows exposure to both adrenal glands, permits complete exploration of the abdominal cavity for identification and biopsy of suspected metastatic lesions, and provides exposure for intravascular thrombus resection or nephrectomy if necessary. Disadvantages are minimal but include risk of iatrogenic pancreatic injury and more severe consequences of wound dehiscence. On rare occasions in deep chested dogs, a right paracostal extension is needed. The laparotomy incision is continued dorsolaterally from the xiphoid cartilage, following 1cm caudal to the last rib. The rectus abdominis, external and internal abdominal oblique, and transverses abdominis muscles are incised respectively. Care is taken to avoid inadvertent incision of the diaphragm and creation of a pneumothorax. The formed abdominal muscle flap is retracted caudodorsally, exposing the craniolateral abdomen. Closure is by approximation of the abdominal wall at the junction of the combined ventral and paracostal incisions near the xiphoid cartilage followed by routine closure of the linea alba and each muscle layer of the paracostal incision.[3]

Patient preparation for caudal median sternotomy and anesthesia provisions for ventilatory support are readied if a tumor thrombus extends cranial to the diaphragm and access to the thoracic vena cava is needed. The neck may also be prepared to harvest a jugular venograft if significant caval involvement is suspected.[4] Intraoperative complications should be anticipated and prepared for (Table 37-2).

Surgical Technique

Abdominal viscera are covered and padded with laparotomy sponges and retracted by hand or with malleable retractors. Retraction must be gentle in animals with hyperadrenocorticism as tissues are often friable and easily torn. The adrenal

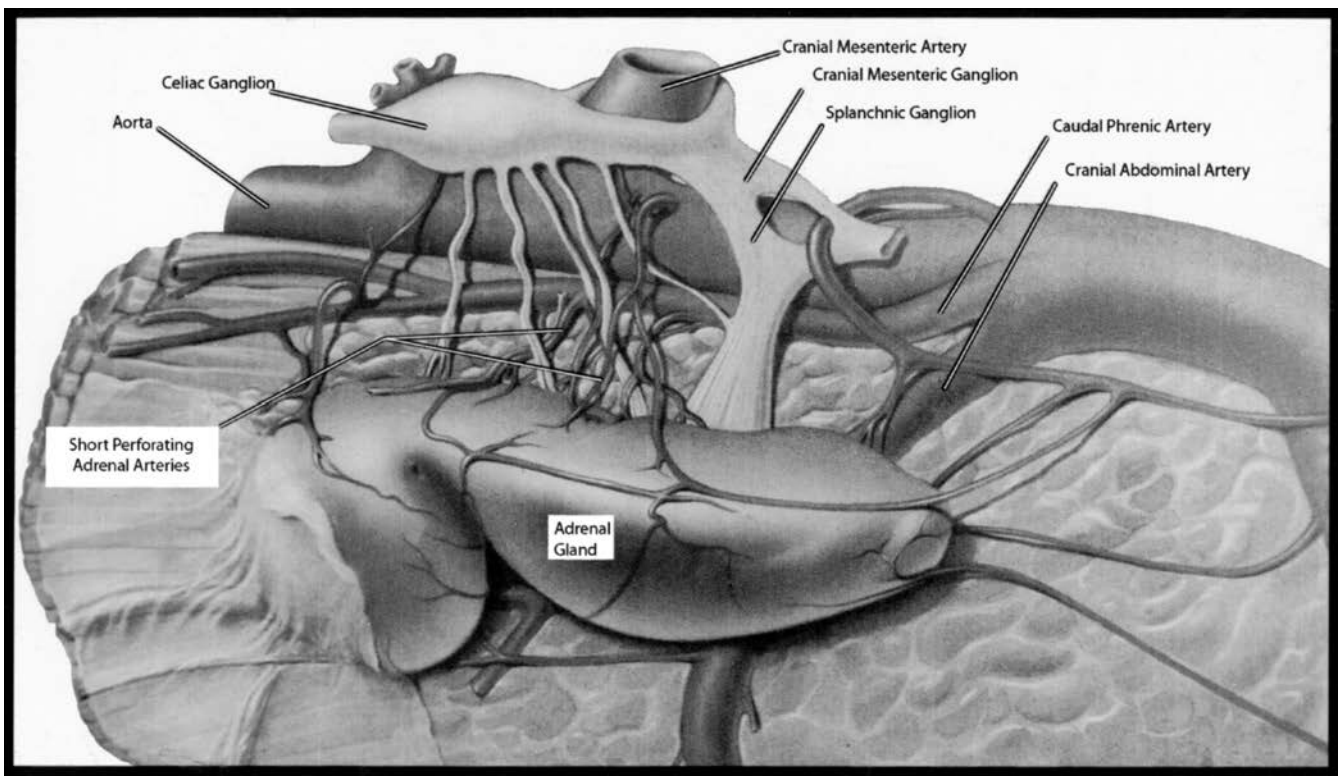

Figure 37-1. Surgical anatomy of the medial surface of the adrenal gland, depicting the neurovascular structures to be encountered during dissection. (Modified from Evans HE, Christensen GC. Miller's anatomy of the dog. Philadelphia: WB Saunders, 1993: 578.)

Table 37-2. Pharmacologic agents used for management of intraoperative complications for adrenal tumors.

Hypertension (systolic pressure > 200 mmHg)
Phentolamine (Alpha-adrenergic antagonist): 0.02-0.1 mg/kg IV PRN.
Sodium nitroprusside (Direct acting vasodilator): Dose to effect at 0.5-10 µg/kg/minute constant infusion.
Hypotension (systolic pressure < 70 mmHg)
Dobutamine (Positive inotrope): 2-10 µg/kg/minute IV.
Cardiac dysrhythmias
Esmolol (short acting Beta 1-adrenergic antagonist): slow bolus 0.5 mg/kg, then 50-200 µg/kg/minute infusion.
Propranolol (Beta-adrenergic antagonist): 0.02-0.1 mg/kg slow IV over 2-3 minutes.
Lidocaine (ventricular antiarrhythmic agent): 2 mg/kg bolus, up to 8 mg/kg; if responsive then CRI of 50-100 µg/kg/minute.

gland and retroperitoneal tissues are inspected for extent of local invasion, and the abdomen inspected for metastasis to the liver, regional lymph nodes, and along the sympathetic chain (pheochromocytoma). Biopsy specimens are procured from any suspected metastases.[5,6] The phrenicoabdominal vein, vena cava, ipsilateral renal artery and vein, and aorta are palpated for evidence of tumor thrombus. In the authors' experience thrombus formation is by far most common in the phrenicoabdominal vein and vena cava. Renal vein thrombi are uncommon and aortic or renal artery thrombus formation is rare. After surgical staging is complete a resection plan is made and initiated.

Wide incision is made in the peritoneum around the mass and a combination of blunt and sharp dissection of surrounding fatty tissue and ventral paralumbar muscle fascia are utilized to isolate the mass in an envelope of normal tissue (Figure 37-2). It is generally easiest to work from the periphery of the mass towards the great vessels. If a tumor thrombus is present the authors prefer to completely dissect the adrenal tumor first, and then perform venotomy while using the tumor to tether the thrombus for manipulation. Attention to hemostasis is paramount to visualize fine anatomy, and keeping the tissues under constant tension allows delicate layer-by-layer dissection. The phrenicoabdominal vein is ligated, and hemostatic clips and electrocautery are used for occlusion of smaller perforating arteries (Figure 37-3). Though difficult, an attempt is made to isolate and ligate tumor blood supply as much as possible prior to extensive tumor manipulation to minimize iatrogenic hormone release. Careful technique and barrier sponges/material are utilized to avoid seeding the abdominal cavity with neoplastic cells.

When a tumor thrombus is present, additional preparation is made. If the thrombus is confined to the phrenicoabdominal vein a standard adrenalectomy is performed and the thrombus removed by ligation and en bloc removal of the phrenicoabdominal vein. Intracaval or aortic thrombi are removed by isolating the affected segment of vessel (and renal vessels if

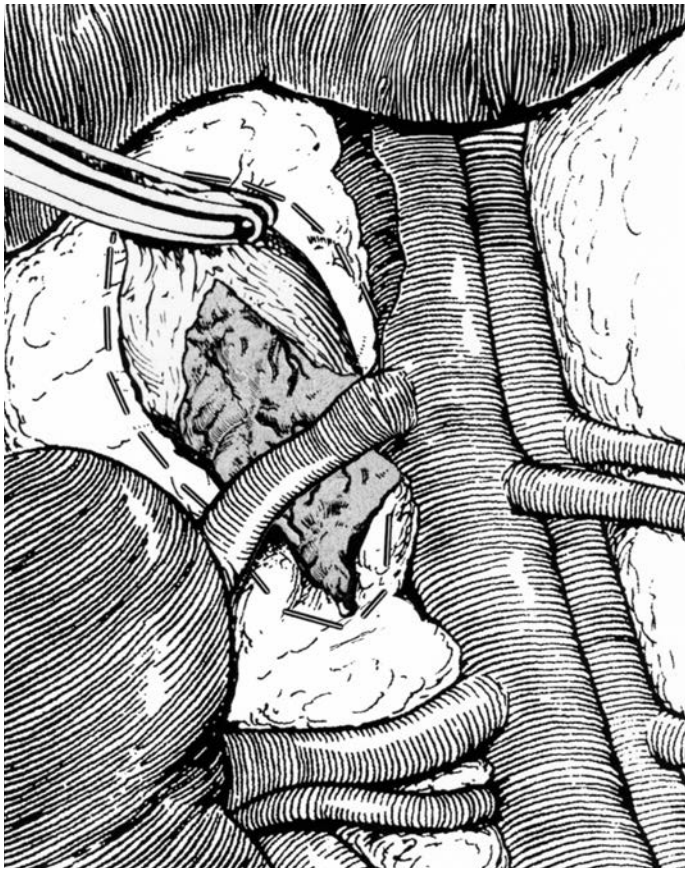

Figure 37-2. Surgical anatomy indicating the plane of dissection within the peritoneum necessary for isolation of the mass within an envelope of normal tissue. (Modified from Birchard SJ. Adrenalectomy. In: Slatter D. Textbook of Small Animal Surgery. 3rd ed. Philadelphia: WB Saunders, 2003:1697.)

thrombus proximity requires occlusion more caudally) with Rumel tourniquets (Figure 37-4). Following complete tumor dissection, occlusion of blood flow is quickly implemented and the vessel wall at the site of tumor penetration is circumferentially incised with a #11 scalpel blade. The thrombus is removed by exerting traction on the tumor base and tethered thrombus with one hand, while the other hand is used to "milk" the thrombus out by extramural manipulation.[5] The incision is extended as needed to allow thrombus removal without tearing the vessel wall. The lumen is lavaged and a partial occlusion clamp (Satinski or similar) is placed to permit vascular flow during suturing. The vessel wall is closed with a continuous suture pattern using 4-0 or 5-0 polypropylene. Air is displaced from the lumen by releasing the caudal Rumel tourniquet prior to tightening the final suture. The cranial tourniquet is released and the suture line checked for bleeding. Minor leakage is controlled with gentle pressure, and more significant leakage with placement of additional interrupted sutures. Vessel occlusion must be as brief as possible to avoid visceral injury.

Special Surgical Considerations

If the tumor thrombus extends cranial to the diaphragm, a caudal median sternotomy is performed to allow placement of a Rumel tourniquet cranial to the thrombus; removal is as described above.

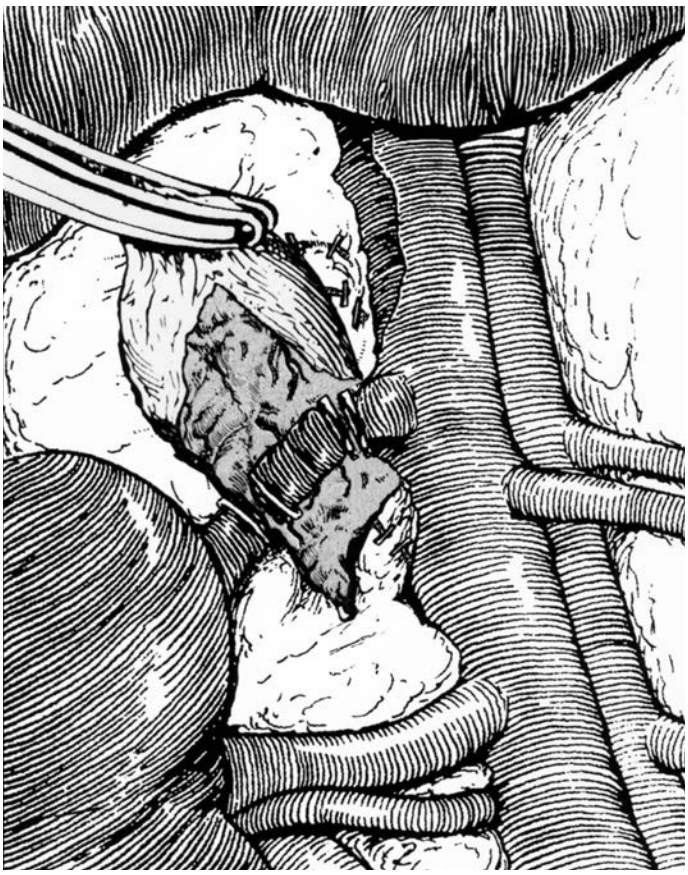

Figure 37-3. The surgical field during ligation of the phrenicoabdominal vein and smaller perforating arteries. Attention to hemostasis is paramount, therefore, use of hemostatic clips and electrocautery is recommended. (Modified from Birchard SJ. Adrenalectomy. In: Slatter D. Textbook of Small Animal Surgery. 3rd ed. Philadelphia: WB Saunders, 2003:1697.)

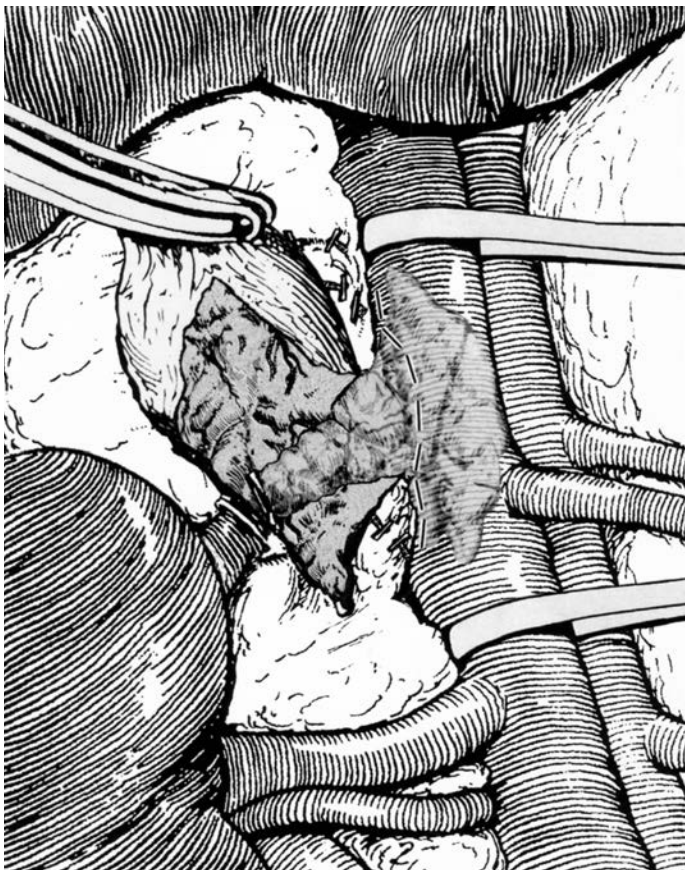

Figure 37-4. Thrombusectomy of an intracaval thrombus. Following complete tumor dissection the affected segment of vessel is isolated with Rumel tourniquets. Occlusion of blood flow is implemented. The dotted line indicates the site of circumferential incision of the vessel wall at the site of tumor penetration. The thrombus is removed by exerting traction on the tumor base with one hand, while the other hand is used to "milk" the thrombus out. The incision is extended as needed to prevent tearing the vessel wall. The vessel wall is closed as air is displaced from the lumen by releasing the caudal Rumel tourniquet prior to tightening the final suture. Finally, the cranial tourniquet is released. (Modified from Birchard SJ. Adrenalectomy. In: Slatter D. Textbook of Small Animal Surgery. 3rd ed. Philadelphia: WB Saunders, 2003:1697.)

En bloc nephrectomy is occasionally required because of tumor invasion into the renal vessels or parenchyma. The tumor and kidney are isolated en bloc before great vessel incision to minimize occlusion time and facilitate rapid thrombus removal.

When pheochromocytoma is suspected but tumor location is not evident, identification can be aided by a palpation induced increase in arterial blood pressure of a suspected mass, and subsequent decrease in pressure following removal (even if preoperative adrenergic blocking agents have been used). If blood pressure fails to decline, unidentified metastases are likely.

Nonresectable tumors are debulked if possible to decrease circulating cortisol or catecholamines and improve the efficacy of long-term medical management.[6]

Consider jejunostomy tube placement before closure when iatrogenic pancreatitis is of concern.

Complications and Postoperative Management

Adrenalectomy (particularly with thrombusectomy) is a demanding surgery. Minor complications are almost always expected, and provisions always made in preparation for major complications.

Intraoperative complications include bleeding, arrhythmias, hypotension, hypertension, and air embolism. Bleeding can arise from the adrenal (usually from dorsomedial short perforating arteries), or from retraction injury to the liver and pancreas. Adrenal artery hemostasis is best controlled with vascular clips or electrocautery. Organ parenchymal injuries are prevented by gentle retraction and padded covering with thick laparotomy sponges. Parenchymal bleeding is generally mild and easily stopped with pressure or application of topical hemostatic sponges. Cardiovascular complications mostly arise from catecholamine secretion and are largely preventable (Table 37-1). Use of crystalloid and colloid fluid supplementation will adequately manage most abnormalities; for more severe fluctuations in pressure or rhythm, drug therapy is indicated (Table 37-2). Air embolism occurs if the vascular lumen is not purged before final closure of vessel wall sutures.

Postoperative complications include adrenal insufficiency, pulmonary thromboembolism, infection, and delayed wound healing for adrenal cortical tumors; and arrhythmia, hypotension,

and hypertension for medullary tumors.[7] General complications include persistent organ parenchymal bleeding and pancreatitis from iatrogenic trauma.

Following unilateral adrenalectomy for cortisol producing tumors, glucocorticoid supplementation is required during and for a short period after surgery. Dexamethasone is administered parenterally until the animal is eating, and then oral prednisone is used for ongoing management. Glucocorticoid supplementation can generally be tapered by 6 to 8 weeks. Permanent glucocorticoid and mineralocorticoid replacement therapy is necessary in patients undergoing bilateral adrenalectomy (Table 37-3).[6,8,9] Risk of thromboembolic disease is reduced with heparin and low dose aspirin therapy and treatment is generally tapered as the patient stabilizes over 2 to 5 days. Supplementation with Vitamin A is used to offset cortisol induced delayed wound healing; treatment is generally discontinued at the time of suture removal. Infection is prevented by routine use of perioperative antibiotics; prolonged therapy is avoided except in cases where infection is documented or risk is significant.

Table 37-3. Postoperative management of cortisol producing tumors.

Vitamin A	800-1500 U/kg SID.
Heparin	250 U/kg initial dose and 100 U/kg TID. Dose is adjusted according to daily evaluation.
Dexamethasone	0.1 mg/kg SC daily for 24-72 hours after surgery THEN
Prednisone	0.2-0.4 mg/kg PO daily; gradually tapered over 6-8 weeks.
Following bilateral adrenalectomy	
Fludrocortisone acetate	0.02 mg/kg PO daily maintenance.
OR	
DOCP (desocycorticosterone pivalate)	2.2 mg/kg every 25 days AND
Prednisone	0.2-0.4 mg/kg PO daily.

Paradoxically, following adrenalectomy for catecholamine producing tumors, persistent or episodic hypertension or hypotension can occur. The cause remains unknown, but in people the fluctuations can be severe. Though arrhythmias can occur, incidence generally decreases after tumor removal since peptide hormones have a short half life. Adjustments to crystalloid and colloid fluid supplementation are adequate for management of most abnormalities; for more severe fluctuations drug therapy is indicated (Table 37-2).

Management of persistent parenchymal bleeding is by transfusion and conservative treatment such as abdominal pressure wrap. In severe cases reexploration may have to be considered. Pancreatitis is managed by traditional supportive therapy.

Prognostic factors remain incompletely defined for adrenal tumors, and even histologic grading and determination of malignancy can be difficult. In one study neurologic signs, abdominal distension, and weight loss were more frequently associated with advanced disease and a poorer prognosis.[10] Prognostic factors in humans with pheochromocytomas that indicate malignancy are large tumor size, local tumor extension at surgery and DNA ploidy.[11] In dogs as in humans, clinical evidence of metastasis defines malignancy and the sites reported in the dog are lung, liver, spleen, kidney, bone, heart, pancreas and lymph nodes. About 50% of reported pheochromocytomas are considered malignant and long-term prognosis is undoubtedly poorer with metastatic or invasive disease. However reported survival times following successful resection, even with the presence of metastasis, range from 18 months to 2 years.[5,10,12] The frequency of caval invasion with pheochromocytomas in one report was 54%, and 11% with adrenocortical tumors. The right side was affected in 35% of cases and the left side in 20%. This study also determined that adrenalectomy with thrombusectomy did not significantly increase morbidity and mortality, provided appropriate surgical technique was used.[13] The long term prognosis is generally favorable for cure of adrenal adenoma, and for adrenal carcinoma reported median survival time in one study was 778 days.[14]

Thyroidectomy in the Dog and Cat

Stephen J. Birchard and Joao F. de Brito Galvao

Introduction

Thyroid neoplasia is the primary indication for thyroidectomy in dogs and cats. Thyroid tumors in dogs are usually malignant and non-functional, whereas in cats they are usually benign and functional. Thyroidectomy can range from a straightforward to complex surgical procedure, depending on the invasiveness and size of the tumor. A working knowledge of the regional anatomy, pathophysiology of thyroid and parathyroidectomy disorders, and the principles of pre and postoperative care is necessary for successful patient management. Animals with thyroid tumors tend to be geriatric and frequently have disorders of other organ systems that should be recognized and treated appropriately. This is particularly true for cats with hyperthyroidism, a potentially severe multi-system disorder that can increase the risks associated with anesthesia and surgery.

The purpose of this chapter is to provide an overview of the pathophysiology of thyroid neoplasia, to review the anatomy of the thyroid and parathyroid glands, and to describe the surgical technique for thyroidectomy. Postoperative care and complications are also covered.

Surgical Anatomy

The thyroid gland in the dog and cat is divided into two lobes which are located adjacent to the trachea and just caudal to the larynx. The left lobe is slightly caudal to the right.[1] The normal gland is pale tan. The principle blood supply to each lobe is the cranial thyroid artery, a branch of the common carotid artery[1] (Figure 37-5). The caudal thyroid artery in the dog arises from the brachiocephalic trunk or common carotid artery. The caudal thyroid artery is absent in the cat.[2] Venous drainage of the thyroid is through the cranial and caudal thyroid veins.[1] The thyroid has a distinct capsule that can be bluntly separated from glandular tissue. Small blood vessels may be located on the capsule surface and between the capsule and the parenchyma of the gland. Two parathyroid glands are usually associated with each thyroid lobe. The external parathryoid gland usually lies in the loose fascia at the cranial pole of the thryoid lobe.[2] The internal parathyroid gland is usually embedded in the thyroid parenchyma and is variable in location. The external parathyroid glands are much smaller than the thyroid lobe and can be distinguished from the thyroid tissue by their lighter color and spherical shape. The blood supply to the parathyroid glands also arises from the cranial thyroid artery.[1]

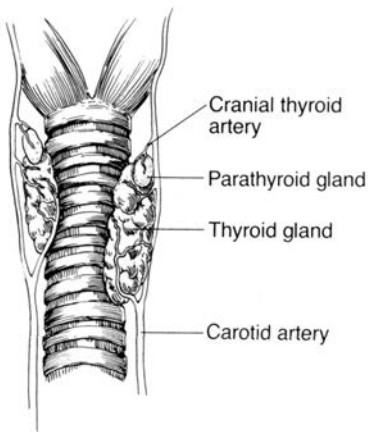

Figure 37-5. Gross appearance of bilateral thyroid tumors in a cat. (From Panciera DL, Peterson ME, Birchard SJ. Diseases of the thyroid gland. In Saunders Manual of Small Animal Practice, 3rd ed., Birchard SJ, Sherding RG, eds. Elsevier, St. Louis, 2006, pgs. 325-340.)

Thyroid Tumors in Dogs

Pathophysiology

Thyroid tumors in dogs account for 1.2% of all canine tumors.[3] The majority of the tumors are malignant, and adenocarcinoma is the most common tissue type reported.[4] Less than 20% of dogs with thyroid tumors have hyperthyroidism.[5] Boxers, beagles, and golden retrievers appear to have a greater risk of developing thyroid carcinoma.[3]

The most common presenting signs in dogs with thyroid tumors are the presence of a palpable neck mass and coughing or respiratory distress.[4] Other reported clinical signs are vomiting, dysphagia, anorexia, and weight loss.[5] Signs of hyperthyroidism are usually not present because elevation of thyroid hormone level is infrequent in dogs with thyroid neoplasia. However, the author has seen 2 dogs with functional thyroid adenocarcinomas that had elevated triiodothyronine (T_3) and thyroxine (T_4) levels but did not have signs of hyperthyroidism. Most thyroid tumors in dogs are malignant and are carcinomas. Thyroid carcinomas in dogs most frequently metastasize to the lungs.[4] Studies have indicated that over 50% of all thyroid carcinomas produce lung metastases.[3,6] The larger the primary tumor, the greater the chance for lung metastasis.[6] The second most common site of metastasis is the cervical lymph nodes.

A key factor in the preoperative evaluation of a dog with suspected thyroid neoplasia is determining whether or not the affected gland or mass is movable. Thyroid masses that are freely movable on palpation tend to be less invasive into surrounding tissues, are surgically resectable, and have a better long-term prognosis than those masses that are invasive and non-movable. One study found that, of 82 dogs with thyroid carcinoma, 20 had movable tumors.[7] These tumors were resected and median survival of the group was 20.5 months. A more recent study evaluated dogs with bilateral thyroid tumors that underwent thyroidectomy. As with unilateral tumors, long-term postoperative survival was good but many dogs required treatment for hypoparathyroidism.[8]

Diagnosis

Diagnosis of thyroid neoplasia in dogs is by physical examination (palpation of a neck mass), and biopsy of the tumor. Fine needle aspiration of the mass should yield cells characteristic of a carcinoma but may be inconclusive due to hemorrhage. A Tru-cut needle biopsy of the tumor may be considered if

cytology is inconclusive but may cause hemorrhage due to the extensive neovascularization of the tumor and therefore is not recommended. Thoracic radiographs are mandatory to rule out pulmonary metastases. Thyroid function should be evaluated with a thyroid- stimulating-hormone stimulation test or free T_4 assay if the dog is showing signs of hyperthyroidism or hypothyroidism. Routine preoperative tests, such as complete blood count, serum chemistry profile, and urinalysis are also recommended.

Preoperative Considerations

Surgical thyroidectomy is indicated for those dogs with small, movable thyroid masses that are not invasive. Treatment options other than surgery should be considered for dogs with large, fixed neoplasms. Radiation therapy has recently been shown to be effective in several dogs with infiltrative thyroid carcinoma.[9] Chemotherapy can also be used and may benefit dogs with nonresectable tumors, or with tumors that have been incompletely excised. Consultation with an oncologist is recommended in such cases.

Surgical Technique

The dog is placed in dorsal recumbency with the front legs tied caudally and the neck slightly hyper extended over a rolled towel or other cushion. The ventral cervical region from the caudal mandible to the manubrium is prepared for aseptic surgery. A ventral midline cervical skin incision is made from the caudal aspect of the larynx to 2 to 3 cm cranial to the manubrium. The paired sternohyoideus and sternothyroideus muscles are separated on the midline and retracted with self-retaining retractors. The trachea is gently retracted and both thyroid lobes are carefully examined.

An attempt should be made to identify the parathyroid glands, although visualization of the glands may be impaired by larger neoplasms (Figure 37-6). The tumor is carefully dissected from surrounding tissues (Figure 37-7). The author usually starts at the caudal aspect of the lobe and works cranially. Care is taken to avoid injury to the esophagus, carotid artery, jugular vein, vagosympathetic trunk, and recurrent laryngeal nerves.

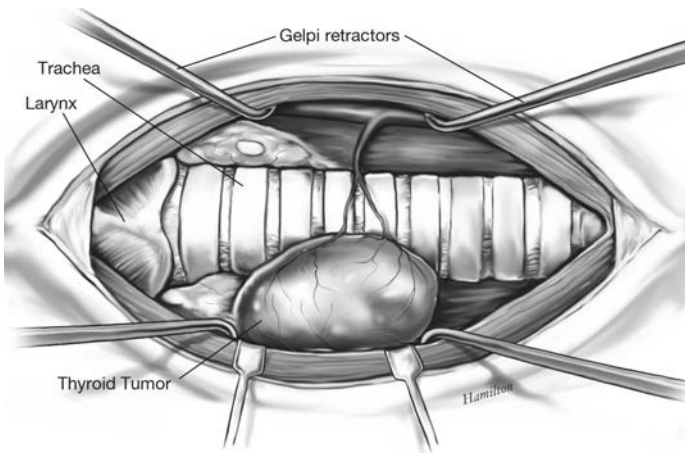

Figure 37-6. Gross appearance of a thyroid carcinoma in a dog. (From Panciera DL, Peterson ME, Birchard SJ. Diseases of the thyroid gland. In Saunders Manual of Small Animal Practice, 3rd ed., Birchard SJ, Sherding RG, eds. Elsevier, St. Louis, 2006, pgs. 325-340.)

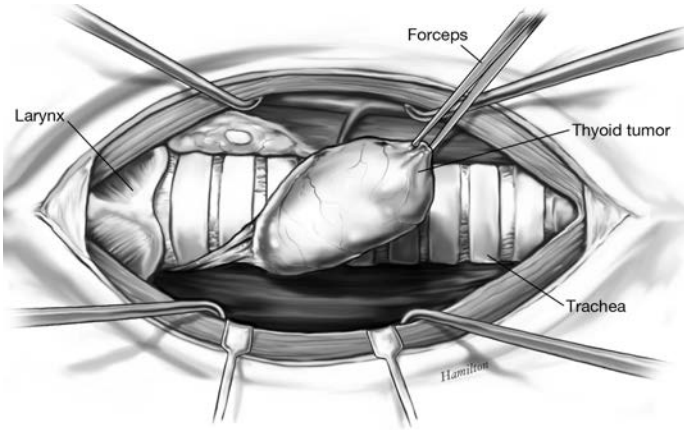

Figure 37-7. Removal of a canine thyroid tumor with a combination of blunt and sharp dissection. The surgeon must identify and preserve the recurrent laryngeal nerve. (From Panciera DL, Peterson ME, Birchard SJ. Diseases of the thyroid gland. In Saunders Manual of Small Animal Practice, 3rd ed., Birchard SJ, Sherding RG, eds. Elsevier, St. Louis, 2006, pgs. 325-340.)

If involved with the mass, the carotid artery, jugular vein, vagosympathetic trunk, and recurrent laryngeal nerve may be removed unilaterally. These tumors are extremely vascular and strict hemostasis is important to prevent serious blood loss. The Ligasure® vessel sealing device is a very useful tool for hemostasis of the highly vascular thryroid tumors in dogs. Even small vessels should be ligated or cauterized since surgery is hampered by a bloody field. Removal of large tumors results in dead space in the tissues; a closed suction drain (e.g. Jackson-Pratt) should be placed in the area of resected tumor to prevent hematoma or seroma formation. The sternohyoideus and sternothyroideus muscles are closed with absorbable suture, such as, (3-0 poliglecaprone 25 (Monocryl) or polydioxanone (PDS)) in a simple continuous pattern. The subcutaneous tissues are closed in the same fashion. Skin is closed with non-absorbable suture (4-0 nylon) in a simple interrupted pattern or with 4-0 absorbable intradermal suture in a simple continuous pattern.

The thyroid tissue should always be submitted for histologic examination. Results of histologic examination help to determine the need for adjunctive therapy, such as chemotherapy, and to evaluate the patient's long-term prognosis. One study found that surgery and chemotherapy did not improve survival in dogs compared to surgery alone.[10]

Postoperative Care

Post-operatively, the animal should be closely observed during recovery for bleeding at the surgical site. Serum calcium levels should be monitored daily for 2 to 4 days post-operatively if a bilateral tumor is resected. Hypocalcemia due to hypoparathyroidism is treated according to the protocol in Table 37-4.[11]

The animal should be reevaluated at 2 weeks, 3 months, 6 months, and 1 year and radiographs of the thorax should be obtained at these rechecks to monitor for metastasis. Prognosis for the individual patient depends upon tumor type and completeness

Table 37-4. Treatment of Hypocalcemia

	N	Content		
Parenteral Calcium*				
Calcium Gluconate	10% solution	9.3 mg of Ca/mL	a. acute crisis: 50-150 mg/kg over 20-30 min	Stop if bradycardia or shortened QT interval occurs
			b. following acute crisis: 1000-1500 mg/kg/day or 42-63 mg/kg/hr	Infusion to maintain normal Ca
				SQ calcium salts–Not Recommended. Can Cause Severe Skin Necrosis/Mineralization
Calcium chloride	10% solution	27.2 mg of Ca/mL	5–15 mg/kg/h IV	Only given IV as extremely caustic perivascularly
Oral Calcium†				
Calcium carbonate	Many sizes	40% tablet	25–50 mg/kg/day	Most common calcium supplement
Calcium lactate	325, 650 mg tabs	13% tablet	25–50 mg/kg/day	
Calcium chloride	Powder	27.2%	25–50 mg/kg/day	May cause gastric irritation
Calcium gluconate	Many sizes	10%	25–50 mg/kg/day	

Vitamin D		**Time for Maximal Effect to occur:**	*Time for Toxicity Effect to Resolve:*
Vitamin D_2 (ergocalciferol)	Initial: 4000–6000 U/kg/day; Maintenance:1000–2000 U/kg once daily to once weekly	5-21 days	1-18 weeks
Dihydrotachysterol	Initial: 0.02-0.03 mg/kg/day Maintenance: 0.01-0.02 mg/kg q 24-48 hrs	1-7 days	1-3 weeks
1,25-$(OH)_2$ D_3 (calcitriol)‡	Initial: 20-30 ng/day Maintenance: 5-15 ng/kg/day	1-4 days	2-14 days

*** Do not mix calcium solution with bicarbonate-containing fluids as precipitation may occur.**

† Calculate dose on elemental calcium content.

‡ Calcitrol is the perferred form of vitamin D for treatment of hypocalcemia.

Table reprinted from: Schenck PA, Chew DJ. Diseases of the Parathyroid Gland and Calcium Metabolism, in: *Saunders Manual of Small Animal Practice, 3rd edition,* eds. Birchard SJ, Sherding RG. Elsevier, St. Louis, 2005, pg. 353

of surgical excision. As previously mentioned, even thyroid carcinoma can be associated with a good prognosis if the tumor is mobile and is completely excised.

Thyroid Tumors in Cats

Pathophysiology

Thyroid masses in the cat are usually benign and functional. The disease can be unilateral or bilateral and histologically the tumors are usually adenomatous hyperplasia. Rarely, (in 1 to 2% of cases), the tumors are carcinomas.[6] Thyroid tumors in cats produce excessive amounts of thyroxine and cats develop the clinical syndrome of hyperthyroidism. Classic clinical signs of hyperthyroidism include tachycardia, hyperactivity, weight loss, polyphagia, and polyuria/polydipsia.[5] In addition to tachycardia a gallop rhythm, systolic murmurs, and arrhythmias can occur due to the catecholamine like effects of the excessive thyroxine on the myocardium. Some cats have apathetic hyperthyroidism, a syndrome characterized by signs opposite to the classic presentation for hyperthyroidism, such as depression, lethargy, and anorexia.[5]

Diagnosis

Diagnosis of feline hyperthyroidism is based on the history and clinical signs, palpation of a neck mass, and elevated serum triiodothyronine and thyroxine concentrations.[5] One or more thyroid nodules are palpable in approximately 85 to 90% of affected cats. The cats may also have leukocytosis, higher than normal packed cell volume, and high alkaline phosphatase.[5] Hyperthyroid cats may also have hypertrophic cardiomyopathy with hypertrophy of the left ventricular free wall and ventricular septum.[5] Renal function should be carefully evaluated prior to treatment of hyperthyroidism in cats. Hyperthyroidism may mask chronic renal failure by increasing renal blood flow.[12] Treatment

of the hyperthyroidism can result in exacerbation of the renal dysfunction when renal blood flow returns to normal. Some clinicians recommend a thirty-day therapeutic trial course of methimazole to assess the effect of decreased renal blood flow on kidney function.

Radionuclide scan of the thyroid gland in cats with hyperthyroidism reveals increased uptake and size of the affected lobes. Nuclear scan can be a useful diagnostic tool in cats that do not have a palpable thyroid nodule or that have had relapse of hyperthyroidism after thyroidectomy.[5] However, nuclear scans have limited practicality because of the specialized equipment and expertise needed to perform the studies.

Treatment options for hyperthyroidism in cats include use of methimazole, which lowers thyroxine by blocking uptake of iodine by the thyroid, radioactive iodine treatment, or surgical removal of the gland (s).[5] Reported success rates are high with all of these treatment methods. Medical treatment with methimazole is the least invasive and least expensive method and may be a reasonable option in high-risk anesthetic patients or where radioactive iodine is not available. However, side effects to methimazole have been reported and problems with owner adminstration may complicate long-term use of the drug.[13] Radioactive iodine therapy has been repeatedly shown to be safe and effective. Anesthetic and surgical complications (e.g. hypoparathyroidism) are avoided with this therapy, however, specialized facilities and expertise limit this to a referral procedure. Thus, availability may be a limiting factor. When this treatment option is not possible, and assuming the cat is a good anesthetic and surgical candidate, surgical thyroidectomy may be an option for long-term resolution of the condition.

Perioperative Considerations

There are several aspects of feline thyroidectomy that should be considered prior to performing surgery. Preoperatively, affected cats are treated with methimazole to establish euthyroidism which makes the animal a better candidate for anesthesia and surgery. Methimazole (Tapazole®, 5 mg orally twice a day) is administered for 7 to 10 days before surgery. The patients thyroxine levels are rechecked and, if normal or significantly reduced, surgery is scheduled. Cats that are only mildly affected by hyperthyroidism (i.e., only mildly elevated thyroxine, normal weight, not severely tachycardic) are operated without pretreatment with methimazole.

In an attempt to prevent postoperative hypocalcemia in dogs or cats undergoing bilateral thyroidectomy, some clinicians administer oral calcitriol (20ng/kg q12h) for 3 to 4 days preoperatively. Calcitriol administration is continued at 5-10ng/kg q12h for 1 week or more postoperatively depending on results of repeated serum ionized calcium assays.

Anesthesia in hyperthyroid cats can be challenging. Anesthetic facilities should allow for adequate monitoring of the cat, particularly since intraoperative electrocardiographic abnormalities are common. If premature ventricular contractions occur during anesthesia and do not resolve by increasing oxygenation, propanolol (0.1 mg IV) can be given to control the arrhythmia.

The surgeon should be comfortable with the regional anatomy, and with performing fine dissection of very small anatomic structures. Surgical instruments that are helpful include tenotomy scissors, DeBakey or Simkin thumb forceps, sterile cotton tipped applicators, and bipolar electrocautery.

Adequate postoperative monitoring is mandatory for recognizing and managing potential complications, such as hypocalcemia.[11] It is recommended that facilities and personnel be suitable for providing intensive postoperative care that is occasionally required.

Surgical Techniques

Thyroidectomy in the cat is performed by a ventral midline cervical approach.[14] Even if only one thyroid lobe appears grossly abnormal bilateral thyroidectomy is recommended since most cats have or will develop disease in both glands. Several techniques for thyroidectomy in cats have been described, some allowing for resection of the capsule (extracapsular dissection) and others preserving the capsule (intracapsular dissection).[14,15] The author typically performs the extracapsular technique because of the reduced incidence of recurrence of hyperthyroidism due to remnants of thyroid tissue left behind that can occur with the intracapsular technique. However, in cats where the parathyroid glands are not visible, the modified intracapsular technique is performed in order to be sure of preserving at least one of the parathyroid glands. Both techniques are described here.

An alternative surgical approach is staged bilateral thyroidectomy.[16] In order to reduce the incidence of postoperative hypocalcemia, one affected thyroid lobe is removed, then the remaining affected lobe removed several weeks later. This technique has been shown to be associated with a reduced incidence of postoperative hypoparathyroidism. However, considering the low risk of this complication in the hands of an experienced surgeon, and the increased cost and morbidity of a second operation, the author prefers to perform bilateral thyroidectomy in one procedure.

Extracapsular Technique

The thyroid lobes are exposed through a ventral midline cervical approach as described in the dog. The affected thyroid lobe is dissected free from surrounding fascia, working from caudally to cranially. The external parathyroid gland is identified at the cranial aspect of the thyroid gland. The thyroid gland capsule is incised adjacent to the parathyroid gland (Figure 37-8). Pinpoint electrocautery is used on any vessels encountered during this dissection with care taken to avoid damage to the parathyroid gland or its blood supply. The parathyroid gland is then carefully separated from the thyroid using sterile cotton-tipped applicators. Once the parathyroid gland is completely separated from the thyroid, the thyroid gland is completely removed using blunt and sharp dissection and pinpoint electrocautery on all vessels. Minor hemorrhage adjacent to the parathyroid glands can be controlled using small amounts of hemostatic gelatin sponge. Closure of the incision is by simple continuous suture pattern

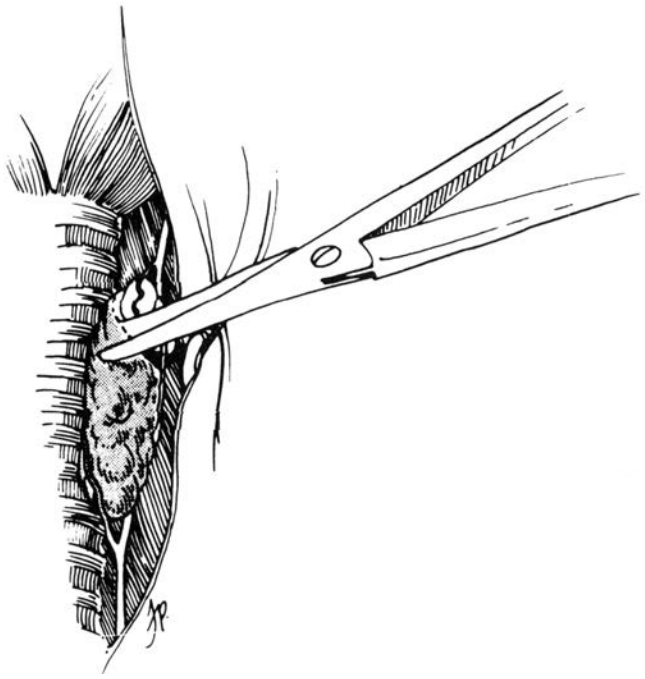

Figure 37-8. Extracapsular dissection for removal of a thyroid lobe in a cat. (From Graves TK, Peterson ME, Birchard SJ. Thyroid gland. In: Birchard SJ, Sherding, eds. Saunders manual of small animal practice. Philadelphia: WB Saunders, 1994:218-228.)

in the sternohyoideus muscle using absorbable suture, simple continuous pattern in the subcutaneous tissues with absorbable suture, and interrupted sutures in the skin with non-absorbable sutures. As an alternative to skin sutures, a continuous absorbable intradermal suture layer may be placed.

Modified Intracapsular Technique

A small nick incision is made in an avascular area of the thyroid capsule (Figure 37-9). This incision is extended with small scissors. The thyroid tissue is then gently separated from the capsule with sterile cotton tipped applicators. Meticulous hemostasis is critical to maintain good visualization of the surgical field. Hemorrhage from small capsular vessels is controlled using pinpoint electrocautery. Extreme care is required during manipulation of the cranial pole of the thyroid to avoid injury to the blood supply of the extracapsular parathyroid gland. If the thyroid gland becomes fragmented during dissection, the surgical field is carefully examined for remnants of thyroid tissue that were not removed. These remnants and associated capsule are removed. Remaining remnants of capsule are also removed since microscopic thyroid tissue may be attached to them. The incision is closed as described under the extracapsular technique. All resected tissue is submitted for histologic evaluation.

Postoperative Care

Postoperatively, the cat is closely monitored for evidence of hemorrhage from the surgical site. Serum calcium levels are monitored for at least 2 days postoperatively. If hypocalcemia develops due to removal or damage to the parathyroid glands, the cat is treated with calcium (parenteral and/or oral administration) and vitamin D as described in Table 37-4. Calcium supplementation potentiates the effect of calcitriol, but calcium supplements alone are not effective for control of hypocalcemia. Early signs of hypocalcemia are muscle soreness or spasm, anorexia, and depression. Later signs are collapse and tetany. Thyroid replacement therapy (L-thyroxine, 0.1 mg orally once daily) is not given routinely but it may be indicated for cats that have had bilateral thyroidectomy and show clinical signs of hypothyroidism (e.g. lethargy, weight gain, skin problems).

Renal function should be monitored closely in cats after thyroidectomy, especially if they have evidence of chronic renal failure preoperatively. As previously described, renal function in some cats worsens after thyroidectomy, presumably due to a decrease in renal blood flow after lowering the thyroxine levels.[12]

The prognosis for hyperthyroid cats after thyroidectomy is good. Treated cats show improved behavior and significant weight gain. Histologic examination of the thyroid tissue usually reveals adenomatous hyperplasia. Rarely, histologic exam of the excised mass reveals thyroid carcinoma.[17] These tumors are much larger and more vascular than the more common benign adenomatous hyperplasia.

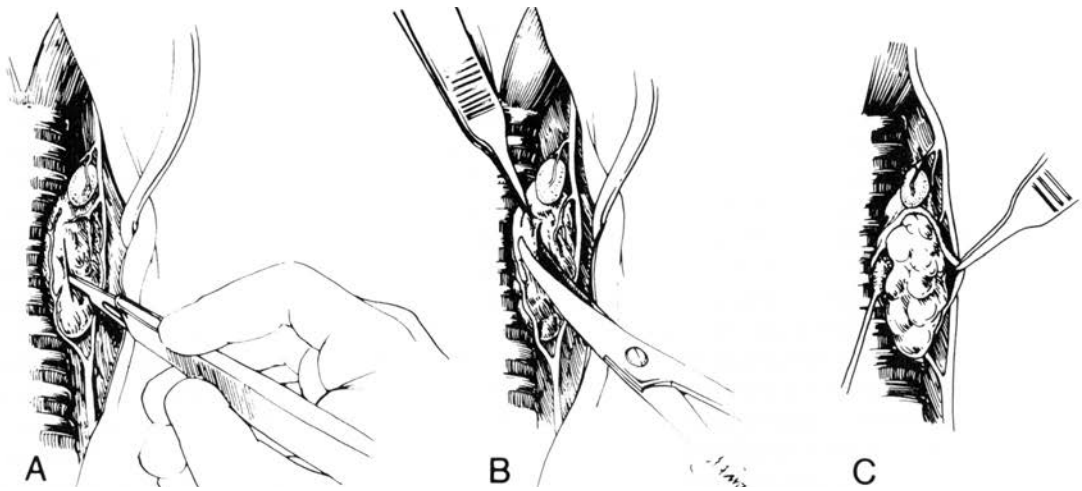

Figure 37-9. A.-C. Intracapsular dissection for removal of a thyroid tumor in a cat. (From Graves TK, Peterson ME, Birchard SJ. Thyroid gland. In: Birchard SJ, Sherding, eds. Saunders manual of small animal practice. Philadelphia, WB Saunders, 1994:218-228.)

Rarely, relapse of hyperthyroidism can occur 1 to 2 years postoperatively due to regrowth of the adenoma.[18] This may be due to incomplete removal of the adenomatous tissue during the first surgery. Postoperative hypocalcemia is more common after reoperation for thyroidectomy.

Hernias

Chapter 38

Hernias

Incisional Hernias

Daniel D. Smeak

Definition and Etiology

An incisional hernia results from disruption of an abdominal wall closure. Acute incisional hernias generally develop within the first 5-7 days after surgery, whereas chronic hernias are seen weeks to years postoperatively.[1] Incisional hernia incidence is reported to be between 0.2 and 5% in humans and up to 16% in large animals depending on the surgical approach to the abdomen, certain predisposing factors, and overall patient status.[2,3,4] Incisional herniation in small animals is uncommon averaging less than 1% of abdominal closures in two large retrospective studies.[5,6]

Predisposing causes for acute and chronic incisional hernia vary and are interrelated. Reported risk factors for acute incisional hernia include increased intra-abdominal pressure from pain, entrapped fat between hernia edges, inappropriate suture material use, infection, long-term steroid treatment, and poor postoperative care.[7] Technical error in surgery, however, is felt to be the most common cause of acute wound disruption.[8,9] Factors associated with chronic incisional hernia in humans include: obesity, hypoproteinemia, cardiopulmonary complications, abdominal distention, skin wound dehiscence, and deep fascial infection. Local wound complications, especially deep infection, appear to be the most important predisposing cause of chronic incisional hernias.[10,11]

Incisional hernias result from either excessive forces acting on the abdominal incision or poor holding strength of the sutured wound. Forces acting to disrupt the abdominal incision are mainly derived from excessive intraabdominal pressure or muscle tension. Increased intra-abdominal pressure is observed in such conditions as obesity, abdominal effusions, pregnancy, or organ distension from ileus or obstruction; all these problems dramatically increase incisional hernia risk.[10,11] Poor control of postoperative pain, or uncontrolled exercise early in the postoperative period, increases the risk of wound breakdown due to excess force on abdominal wound edges.

The choice of suture material used for abdominal closure is rarely the sole cause of incisional hernia, provided the appropriate size is used.[8,12] However, choice of suture type may be critical in patients that have prolonged wound healing or are severely catabolic and when wound infection is present, particularly when an unpredictable, rapidly absorbable suture such as chromic gut is used.[8] Inappropriate knot tying technique or inadequate number of throws for suture knots in an abdominal wall closure increases the risk of herniation.[13] If a continuous pattern is selected for closure it is critical that the suture strand not be kinked, clamped, or knotted, all of which drastically reduce suture strength.[5] The only hernia found in one retrospective study of incisional hernias was due to a broken suture strand in a continuous abdominal wall closure.[5] Consequently, many surgeons choose one size larger suture when closing the abdominal wall with continuous patterns since the entire wall closure could disrupt from breakage of the single suture line.[6]

Whether suture is placed in an interrupted or continuous pattern, or the abdomen is closed in a single or double layer has little significance in incisional hernia formation provided the strength holding layer is incorporated.[5,6,12,13] Knotted interrupted sutures have a lower breaking strength than when unknotted. More shear forces are activated in the simple interrupted pattern than in the continuous pattern when tension is applied to the wound. Tension along the entire suture line becomes equally distributed when using a continuous pattern particularly when appropriate suture spacing is utilized.[5] A suture length to wound length ratio of 4:1 for laparotomy closure has proven in human clinical studies to reduce hernia incidence.[14] However, interrupted suture patterns in abdominal wall closure may be safer to use if wound edges have questionable viability or strength.[1] Excess intrinsic or extrinsic suture tension leads to significantly weaker abdominal closures, so sutures should be placed to appose, not crush, fascia.[14]

The most common cause of incisional hernia in small animals is failure to place sutures in the strength holding layer of the abdomen, with appropriately sized tissue bites.[1,6,8] Successful lasting abdominal wall closures must include the external rectus fascia (the main strength holding layer of the abdominal wall).[5] Sometimes the subcutaneous tissue or suspensory fascia of the prepuce overlying the external rectus fascia is mistakenly incorporated in the abdominal closure, causing incisional hernia. In other instances, sutures do not include at least 0.5 cm of fascia rendering the wound susceptible to breakdown with even minor wound tension.[1] Closure of the internal rectus fascia (including peritoneum) with the external fascia not only prolongs the procedure time and increases trauma from tissue manipulation, but may also increase postoperative pain.[5,15,16] In addition, suture material penetrating the peritoneum is a known potent stimulus for adhesion formation.[5,16] Even without suturing, the peritoneum rapidly covers and seals exposed muscle within several days. Furthermore, the peritoneum is a rather delicate membrane, so it does not offer appreciable strength when included in the abdominal closure. Thus, inclusion of internal rectus fascia or peritoneum in abdominal closure is not required or recommended to ensure successful abdominal repair.[5,15]

Clinical Signs and Diagnosis

Signs of acute incisional herniation usually develop within the first three to five days after surgery.[8] Wound edema and inflammation are signals of altered wound healing from any cause, and these signs may be seen early in the sequence of events leading to herniation. Serosanguineous drainage from the incision and swelling are important and consistent signs of impending acute abdominal wound dehiscence across animal species.[4,17] Swelling is usually soft and painless unless infection or organ compromise is present. Incisional drainage often occurs from a benign problem after surgery such as a seroma, however, this condition must be differentiated from those patients with acute incisional hernia. Early diagnosis and treatment of incisional hernias are vital to reduce the possibility of complete wound dehiscence and evisceration (organ protrusion).[1]

Any wound exhibiting signs of altered wound healing (edema, swelling, inflammation) should be examined carefully for incisional herniation.[1] Seroma, hematoma, cellulitis, or excessive foreign body response to buried suture material are differential diagnoses for acute incisional hernias. The skin incision line should be manipulated laterally during deep palpation over the muscle wall closure to aid in definition of the abdominal suture line. Further diagnostic testing (radiography, ultrasound, and fine needle aspiration) may be required for definitive diagnosis if displaced viscera or a hernial ring cannot be identified. Small amounts of omentum herniated through a small defect cause persistent wound swelling and is rarely diagnosed without wound exploration.

Treatment

Acute Incisional Hernias

Most incisional hernias should be repaired without delay unless they are chronic and freely reducible. Prognosis dramatically worsens if evisceration occurs. Immediate hospitalization and support of the hernia with bandages should be performed as the patient is prepared for surgery. Early surgical intervention is recommended for those patients with eviscerated hernias, or those with overlying skin incision breakdown or devitalization because exogenous contamination could result in fatal septic peritonitis.[1]

The approach is made over the original incision unless organ damage is present; otherwise, a ventral midline approach may be used. When technical failure is suspected (knot, suture, or tissue failure) the entire wound is reopened and repaired. If one significant technical error is present in the hernial ring area, other adjacent areas are also at risk of impending breakdown. The surgeon should pay particular attention to identification of the strength-holding layer and include appropriately sized tissue bites (at least 5 mm) during suturing of this layer. Acute incisional hernias are repaired with primary musculofascial reconstruction if adequate tissue is present to close the hernia without undue tension. The surgeon should remove fat completely between edges to be approximated. Knots are carefully tied with the appropriate number of snug square throws and attention is paid to intrinsic suture tension to avoid crushing tissue. Debridement is contraindicated during repair of acute incisional hernias unless wound edges are nonviable or necrotizing fascial tissue is present. Removing healthy wound edges creates excessive and unnecessary tissue trauma and spreads contamination into sterile areas. Debridement of this actively healing tissue sets the wound back to the substrate phase and delays the onset of rapid wound strength gain.

Chronic Incisional Hernias

Chronic incisional hernias that are not incarcerated have enough strength in the overlying hernia sac and skin to prevent evisceration, so these hernias may be repaired on an elective basis or conservatively managed.[1] Palpable adhesions to protruding organs are, however, indications for early surgical intervention because adhesions may cause obstruction, torsion and vascular compromise of entrapped tissue.

Conservative management of asymptomatic patients with small hernias should be considered only if the patient's owners can be trusted with wound monitoring. Affected patients require daily hernia palpation. Pain, discoloration, incarceration, and rapid increase in hernia size are indications for immediate examination of the animal by the veterinarian. Chronic hernias usually do not cause significant patient discomfort, however, they may be of concern when the animal is used for breeding.[4] Large hernias may prevent delivery (causing dystocia) because of uterine incarceration or lack of adequate abdominal contraction during labor.

Chronic incisional hernias are usually approached surgically over the original incision area. Muscle edges may retract some distance away from the defect, producing a functional loss of abdominal wall. This results in excessive tension during primary hernia repair and thus increases recurrence risk.[7,18]

A major technical difficulty in repair of chronic incisional hernias is accurate identification of normal tissue layers. Surgical dissection and accurate identification of primary strength-holding tissue at hernia margins are critical for lasting repair. Simple imbrication of the hernial sac without extensive scar excision from the hernial ring usually results in recurrence of the hernia because of attenuation of the relatively weak scar tissue. In chronic hernias, muscle and subcutaneous tissues are usually scarred together in one layer. Conservative excision of surrounding scar tissue is recommended until identification of the strength-holding layer is possible.

A condition termed "loss of domain" occurs when the abdominal cavity has become accustomed to a smaller intra-abdominal volume than normal. A functional loss of abdominal wall occurs in this instance. As a result, reduction of the hernial contents and primary closure of the (usually large) defect may be impossible. Closure of the abdominal wall by forcing herniated contents back into the abdomen results not only in excessive tension on the repair, but also in acute pulmonary compromise from restriction of diaphragm function.[7] In most veterinary patients with large chronic defects or areas of abdominal tissue loss, surgical repair is performed with prosthetic materials such as polypropylene mesh.[7,19]

Evisceration

Patients presenting with evisceration require early aggressive supportive therapy. Control hemorrhage and cover exposed organs with sterile bandages to reduce further contamination and tissue damage until vital diagnostic tests are performed and stabilization is attempted. In addition, an Elizabethan collar is placed on the patient if constant monitoring is not possible. Exposed organs are quickly mutilated by animals, and the result is shock from fluid and blood loss. Sepsis may occur from severe wound contamination, particularly when intestines have been violated. Therefore, appropriate crystalloid and colloidal fluid and antibiotic therapy are critical for patient stabilization.

Wound preparation is performed in a clean area after anesthetic induction. The surgeon should avoid contact between potentially irritating and toxic antiseptics and cleansing agents, and the patient's exposed organs during skin preparation. Exposed tissue is covered with saline soaked laparotomy sponges and a larger area of the abdomen is clipped, if necessary. The skin surrounding the wound is prepared routinely. In an aseptic area, the original abdominal wound is extended, if necessary, to explore abdominal viscera completely. The surgeon copiously lavages exposed but viable organs outside the abdominal cavity before further exploration. After isolating damaged areas from the rest of the viscera with laparotomy sponges, the surgeon resects nonviable and irreversibly damaged areas, and repairs organs when necessary. Appropriate specimens are submitted for culture and susceptibility testing. The abdomen is copiously lavaged to help remove particulate foreign material and gross contamination. The decision whether to close the abdominal wall and superficial tissues depends on the amount and location of tissue damage and wound contamination observed at surgery. Primary repair is appropriate for acute herniation with little tissue damage or contamination. Patients with minimal intraperitoneal but significant superficial tissue damage or contamination should have routine abdominal wall closure with closed suction drainage.[20] Superficial tissue layers are best left open for necessary drainage and tangential debridement. Deep, severely contaminated wounds may be managed by an open peritoneal drainage technique.[21]

Aftercare and Prognosis

Postoperative management of patients after repair of acute, closed, incisional hernias is similar to postoperative care of patients that have undergone elective abdominal surgery. Exercise is strictly limited for at least 2 weeks. Extended exercise restriction should be considered if the wound developed complications such as seroma or infection, or if synthetic mesh was used in the repair. Careful observation of the wound is critical for detection of early signs of infection. If infection occurs, the skin and subcutaneous tissue sutures are removed and the wound is left open for second intention healing. A superficial infection is not necessarily fatal to the success of the repair but the longer the infection is present before treatment the more likely the wound will disrupt.[19]

When evisceration has occurred, the nature of the organ damage and repair, and patient status dictate postoperative treatment and monitoring. Intense monitoring and treatment are needed if shock and septic peritonitis are present. Fluid deficits are replenished and infection is treated with antibiotics and appropriate wound drainage. Nutritional management in these critical patients often is the major factor influencing prognosis.

Most patients with incisional hernias have a good prognosis after repair provided initiating causal factors were eliminated and minimal damage occurred to deep structures. Consequently, since most incisional hernias are usually closed and a result of technical failure, most patients have an excellent prognosis as long as appropriate repair was performed. Septic patients with severe peritoneal contamination and organ damage warrant a poor prognosis.[21]

Inguinal Hernia Repair in the Dog

Paul W. Dean, M. Joseph Bojrab and Gheorghe M. Constantinescu

A hernia is an abnormal protrusion of an organ or tissue through a normal body opening. True hernias have a hernial ring and a sac formed of peritoneum surrounding the hernia contents; false hernias lack the peritoneal sac. Hernias are either reducible or irreducible. Irreducible hernias can become strangulated if the circulation to the contents becomes interrupted.

Inguinal hernias are formed when an organ or tissue protrudes through the inguinal canal. Indirect inguinal hernias, the most common type, occur when tissue protrudes through the normal evagination of the vaginal process in females or the vaginal tunica in males. A direct inguinal hernia occurs when the peritoneal evagination occurs separate from, and lies alongside the vaginal process or vaginal tunica as a separate outpouching of tissue.

Surgical Anatomy

The inguinal canal is a passage through the abdominal wall. During development, it is occupied by the gubernaculum of the testis, the vaginal tunic that will ensheathe the descended testis, the descending testis, and the spermatic cord, which consists of the vessels, nerves, and ductus deferens. In the bitch, the gubernaculum persists within the broad ligament of the uterus as the round ligament that traverses the inguinal canal.[1] In the female cat the vaginal process is absent.[2] In veterinary anatomy, it is customary to consider the inguinal canal as the passage between the internal inguinal ring and the external inguinal ring.[1] The cranial boundary of the internal inguinal ring is formed by the caudal edge of the insertion of the internal abdominal oblique muscle. It is bordered ventromedially by the rectus abdominis muscle and the prepubic tendon and caudally and laterally by the edge of the pelvis and the arcus inguinalis.[3] The external inguinal ring is formed as a slitlike orifice in the insertion of the external abdominal oblique muscle and overlies the internal inguinal ring. The anatomy of the inguinal canal varies among species, depending on the caudal extent of the internal abdominal oblique muscle.[1]

Etiopathogenesis

The exact etiopathogenesis of inguinal hernias is unknown. Congenital inguinal hernias have been noted in certain breeds. Inguinal hernias have been shown to be hereditary in the basenji, regressing spontaneously by 12 weeks of age.[2] Other breeds exhibiting a greater risk of inguinal hernias include the basset hound, cairn terrier, Pekingese, and West Highland white terrier. The Pekingese also exhibits a greater incidence of concurrent umbilical hernia.[3] The cause of congenital inguinal hernias is unknown, but the disorder has been attributed to normal anatomic variations, polygenic inheritance, and infectious diseases.[3]

Acquired inguinal hernias are noted most often in the middle-aged intact bitch.[4-6] Most cases of herniation occur in the estral or pregnant bitch, suggesting hormonal involvement. Inguinal hernia has not been reported in the neutered bitch.[6] Other factors that may be involved include weakening of the abdominal wall, trauma, obesity, and the accumulation of fat in the vaginal process.[1,5]

Clinical Signs and Diagnosis

Most dogs with inguinal hernias have a soft, doughy mass in the inguinal region that is usually not painful on palpation. The mass can have been present for up to a year and may or may not be reducible on palpation. Elevation of the patient's hindquarters may aid the examiner in reducing the hernia and allows palpation of the defect in the abdominal wall. The hernia can contain a gravid or infected uterus that is unable to be reduced. Other tissues and organs that can be contained within the hernia include omentum, intestine, bladder, prostatic fat, and spleen. Diagnosis of inguinal herniation is aided by radiography demonstrating gas-filled loops of intestine or the appearance of the ossifying fetal skeleton after 43 to 45 days of gestation. The bladder can be identified by contrast radiography after catheterization and aspiration of bladder contents. Inguinal hernia must be differentiated from subcutaneous fatty tissue accumulation, abscess, hematoma formation, and mammary gland neoplasia. The hernia can appear as a swelling lateral to the vulva and must be differentiated from a perineal hernia.[7]

Surgical Techniques

A ventral midline incision can be used for all inguinal hernias. This approach allows visualization of both inguinal rings and repair of bilateral herniation through a single incision. It also permits extension of the incision cranially, when necessary, without invasion of mammary tissue or its blood supply.[5,8]

The surgical incision extends from the cranial brim of the pelvis as far cranially as necessary to allow exposure of the hernial sac. This incision is continued through the subcutaneous tissue down to the ventral rectus sheath. Dissection proceeds bluntly under the mammary tissue, and the mammary tissue is undermined and retracted laterally to expose the superficial inguinal ring and hernial sac (Figure 38-1). After the hernial sac is dissected from the subcutaneous tissue, the hernial sac is opened, and the contents are inspected (Figure 38-2). Any adhesions between the sac and the viscera are broken down, and the contents are returned to the abdominal cavity.

In some cases, it may be necessary to enlarge the hernial ring cranially to facilitate reduction of the hernia. If the urinary bladder is included in the hernia, aspiration of urine facilitates reduction. When one or both horns of the uterus are included and ovariohysterectomy is performed, extending the incision in a cranial and medial direction may be necessary to complete the procedure.[4,5]

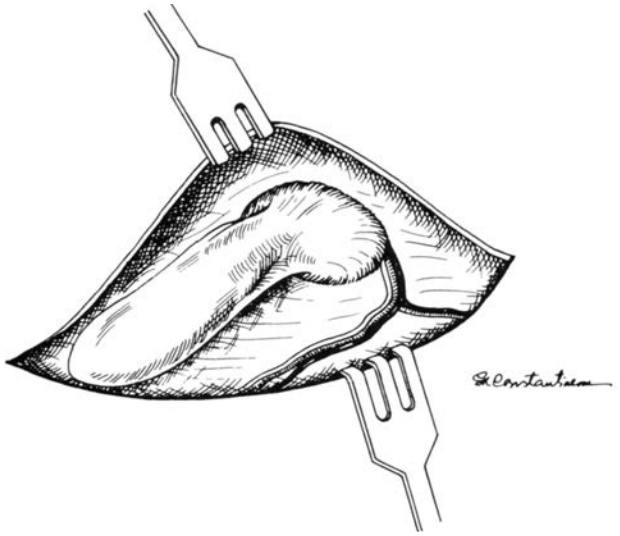

Figure 38-1. Lateral retraction of the midline incision exposes the hernial sac and its contents.

Should the hernia contain a gravid uterus, up to the seventh week of pregnancy the hernia can be replaced into the abdomen and the pregnancy can be allowed to continue to completion. After the seventh week of pregnancy, ovariohysterectomy is recommended, depending on the age and value of the bitch as a breeding animal.[5]

After replacement of viscera into the abdomen, the redundant sac is trimmed at the margins of the superficial inguinal ring. Twisting the redundant sac may help to maintain reduction of the contents within the abdomen (Figure 38-3). The hernial ring is sutured with simple interrupted sutures of 2-0 nonabsorbable suture material (Figure 38-4).[9] Care must be taken during closure to avoid the external pudendal vessels and genitofemoral nerve, which exit from the caudomedial aspect of the ring. In males, the inguinal ring must be closed without compromising the spermatic cord as it traverses the inguinal canal.

The inguinal ring on the other side is inspected, the vaginal process in female dogs or the vaginal tunic in males is removed, and the ring is sutured closed. The mammary tissue is then drawn back to the midline, and the subcutaneous tissues are closed using absorbable sutures, with care taken to eliminate potential dead space. If necessary, a Penrose drain can be placed before closure and made to exit from a separate stab incision ventrally if a large amount of dead space in which fluid could accumulate is present. The skin is closed routinely.

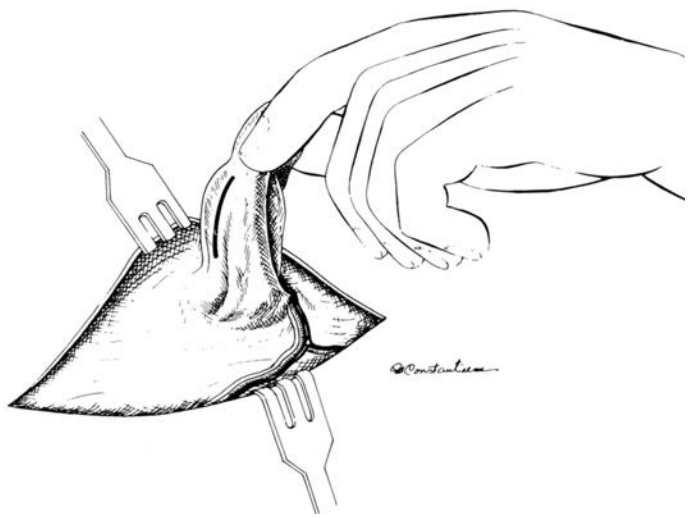

Figure 38-2. The hernia sac is incised, and its contents are inspected and returned to the abdomen. (The line indicates the incision in the sac.)

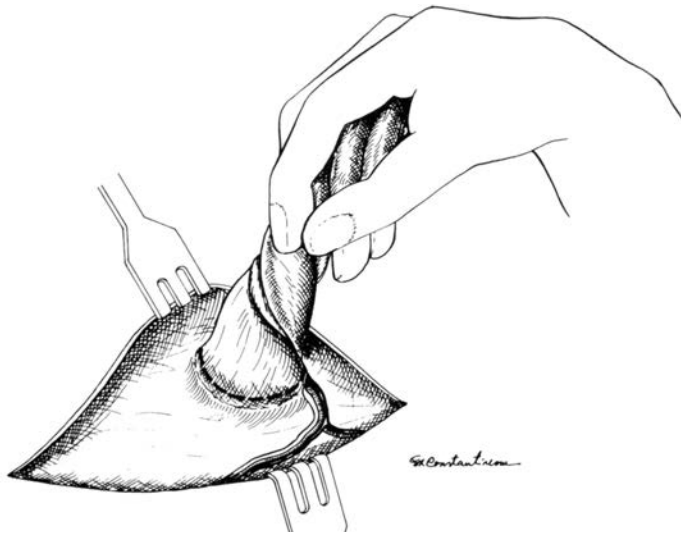

Figure 38-3. The edges of redundant sac are excised. Twisting of the sac facilitates maintenance of the reduced contents within the abdomen.

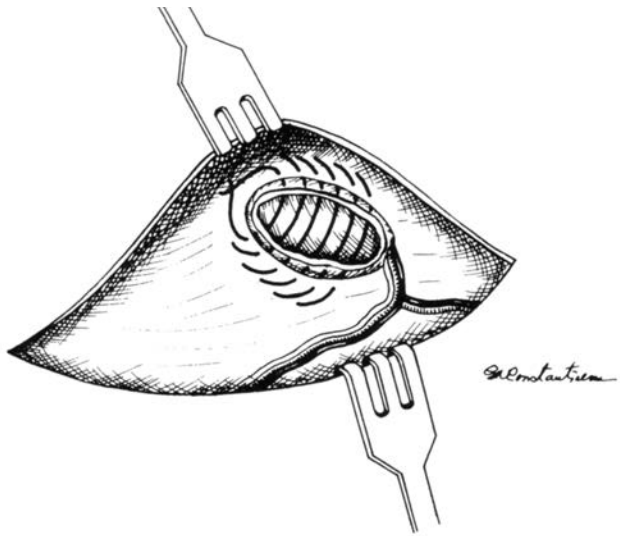

Figure 38-4. The edges of the inguinal ring are apposed using nonabsorbable suture material in a simple interrupted pattern. Care must be taken not to compromise the external pudendal vessels and genitofemoral nerve as they exit the caudomedial border of the ring.

Postoperative Care

The caudal abdomen is bandaged immediately after the procedure. Bandaging helps to eliminate dead space and increases the comfort of the patient. If used, drains should be covered with an absorbent dressing and bandage and can be removed 3 to 5 days postsurgicaly, before the patient's discharge from the hospital. Broad-spectrum antibiotic treatment is used if a drain is in place and for 3 days after drain removal.

Surgical Techniques for Treatment of Perineal Hernia

F. A. Mann, G. M. Constantinescu and Mark A. Anderson

Introduction

The perineum is the region that closes the pelvic outlet, surrounding the anal and urogenital canals.[1] On the surface of the dog, the perineum is limited by the tail dorsally, the scrotum or beginning of the vulva ventrally, and the ischiatic tuberosity on both sides. Deeply, the perineum is bounded by the third caudal vertebra dorsally, the sacrotuberous ligaments on both sides (absent in cats), and the arch of the ischium ventrally. The pelvic diaphragm is the vertical closure of the pelvic canal through which the last segments of the digestive and urogenital viscera pass.[2]

Perineal hernia is the result of weakness and separation of the muscles and fascia that make up the pelvic diaphragm. The pelvic diaphragm is composed of levator ani and coccygeus muscles, and the internal and external perineal fascia.[1] The exact cause of the muscular weakness is unknown but several factors have been proposed.[3-14] As a result of the muscular weakness, caudal displacement of intra-abdominal organs or deviation or dilation of the rectum into the perineum can occur.[3,4] Retroflexion of the urinary bladder occurs in approximately 20% of the cases.[15,16] Other intra-abdominal contents found within the hernial sac include jejunum, colon, and prostate.[16] The hernial space often contains retroperitoneal fat and fluid with or without abdominal and/or pelvic organs.[17]

Perineal hernia has been reported in multiple species, but is most problematic in dogs. Some breeds of dogs are over-represented in the occurrence of perineal herniation. Boston terriers, Pekingese, collies, boxers, Welsh corgis, kelpies, miniature poodles, German shepherd dogs, Bouviers de Flandres, old English sheepdogs, dachshunds, and mongrels have all been shown to have an increased incidence.[9,15,17] Perineal hernia occurs commonly in the male dog, particularly in sexually intact males, and rarely in females. Most dogs with perineal hernia are between 7 and 9 years of age.[9,18]

Perineal herniation may be unilateral or bilateral. Some investigators have reported an increased incidence of perineal herniation on the right side, but the criteria used to determine unilateral versus bilateral and left versus right are subjective. In fact, the occurrence of the hernia on one side versus the other may be related to the rate and extent of tissue deterioration rather than one side being affected preferentially.[17]

Clinical Signs

Tenesmus, constipation and perineal swelling are the three most consistent clinical features of dogs presented with perineal hernia.[3,17] In as high as 80% of dogs presented for perineal hernia, straining to defecate was the primary complaint. Tenesmus is the result of excessive feces that collect in a rectal dilatation or sacculation in the perineal hernia.[4] Furthermore, the perineal swelling may be the combination of abdominal contents and/or a feces-filled rectum.

Retroflexion of the urinary bladder into the perineal hernia may result in urinary obstruction. The obstruction results from an abrupt change in direction of the urethra.[16] Clinical signs associated with bladder retroflexion include stranguria, dysuria, and anuria.[16] Although perineal hernia is not considered a surgical emergency, immediate repositioning of the bladder or urine evacuation is required. If the bladder cannot be reduced and urine evacuation cannot be achieved, surgical intervention on an emergency basis may be required.

Other less commonly reported clinical signs have been depression/lethargy, vomiting, anorexia, perineal pain, stringy stool, weight loss, and fecal incontinence.[15]

Diagnosis

The diagnosis of a perineal hernia is based on the history, clinical signs, physical examination, and radiography. The diagnosis may be difficult during the early stages when the hernia is forming.[3] However, with progression of the clinical signs, the diagnosis usually becomes more obvious. Rectal palpation is the most important part of the physical examination when diagnosing perineal hernia. When performing a rectal examination, the index finger is directed cranially into the middle of the herniated rectum which lies lateral to the anus and medial to the wall of the pelvic canal.[19] Generally, the rectum is filled with feces making identification of the extent (unilateral versus bilateral) of the hernia difficult. Manual removal of the fecoliths from the rectum allows better assessment of the pelvic diaphragm muscles. When evaluating the rectum for abnormalities such as a deviation, sacculation, or diverticulum, a rectal barium enema[4] may be helpful, but is usually not necessary. Differentiation

between rectal sacculation (full-thickness outpouching of the rectal wall) and diverticulum (protrusion of mucosa/submucosa through a muscular defect) requires inspection of the muscular coat of the rectum at surgery.

When there are clinical signs of urinary tract involvement with a perineal hernia, caudal abdominal radiography including the perineum are performed. The contents of the perineal hernia and the location of the urinary bladder is identified. If the urinary bladder cannot be visualized on routine radiography, retrograde urethrography and/or cystography can be done.[3,16] Alternately, ultrasonography can be used to identify the location of the urinary bladder (either within the hernia or abdomen) and can be used to assist decompression via syringe and needle.

Conservative Therapy

Conservative management of perineal hernia includes the use of stool softeners, periodic enemas, and digital evacuation of the feces from the rectum as needed.[3,17] Dogs considered for conservative medical and dietary management include dogs that are poor anesthetic/surgical candidates because of known organ disease and dogs with owners who refuse to have surgery performed.[3,20] Dogs with straining as the primary clinical complaint during the initial presentation are reported to have a poor response to medical management over an extended period of time.[20]

Hormonal therapy either by castration, low-dose estrogen therapy, or progestins can decrease the size of the prostate and alleviate clinical signs associated with prostatic hyperplasia. However, there are no reported studies that have evaluated the efficacy of hormonal therapy on controlling the long-term clinical signs associated with prostatomegaly and a concomitant perineal hernia.[17] Castration is recommended by the authors because of its beneficial effects regarding prostatic disease prophylaxis despite its questionable role in perineal hernia recurrence prevention. The authors caution against other forms of hormonal therapy for prostatic disease since severe and fatal complications such as bone marrow aplasia may result.

Surgical Anatomy

The structures involved in surgical repair of perineal hernia include the pelvic diaphragm, the perineal fasciae, and the nerves and vessels in the proximity of these structures (Figures 38-5 and 38-6). Additionally, extraperineal muscle flaps can be transposed for perineal herniorrhaphy (i.e., the semitendinosus muscle flap).[21]

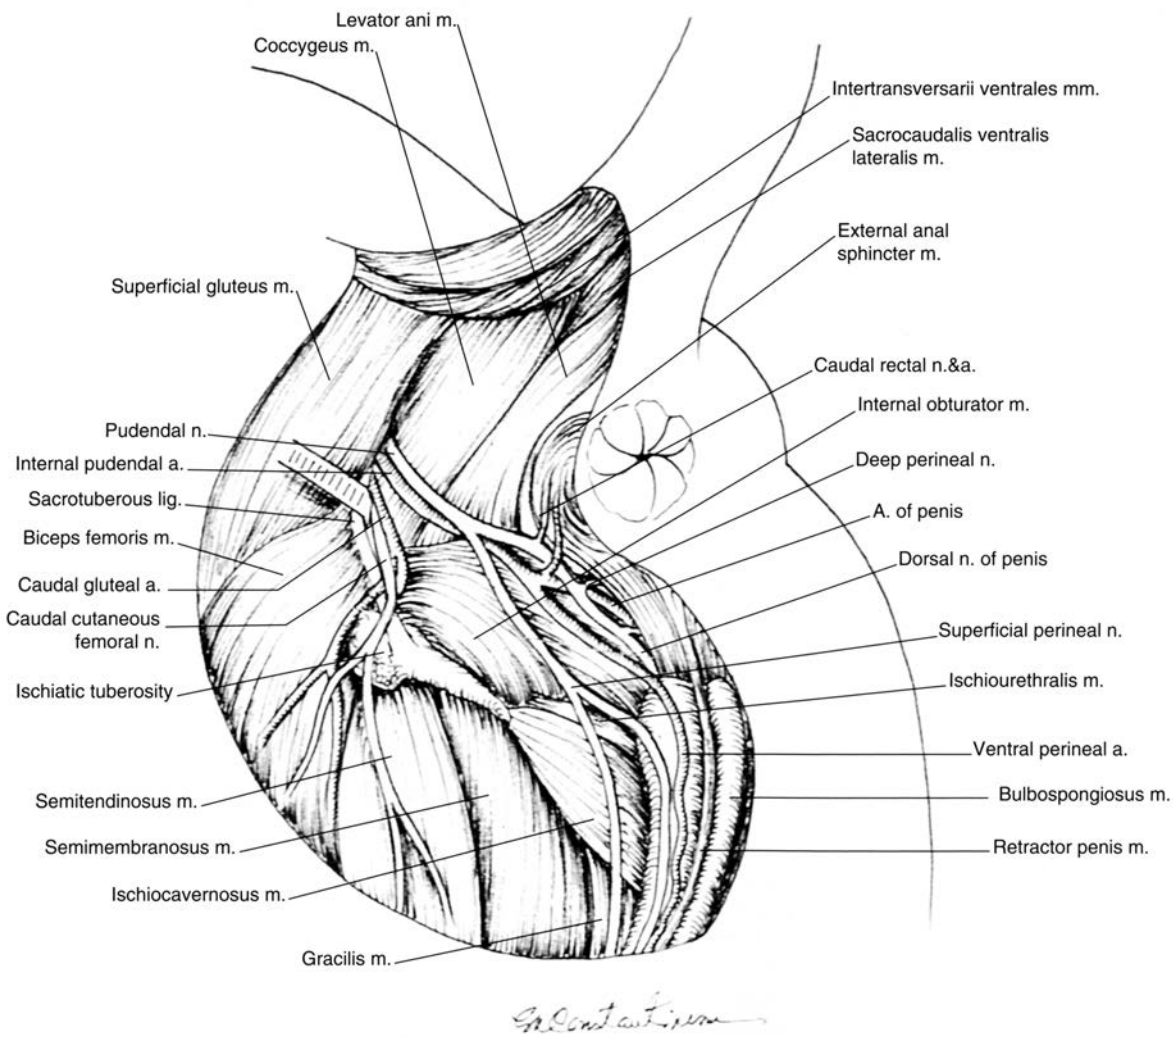

Figure 38-5. Surgical anatomy of the canine left perineum, caudal aspect.

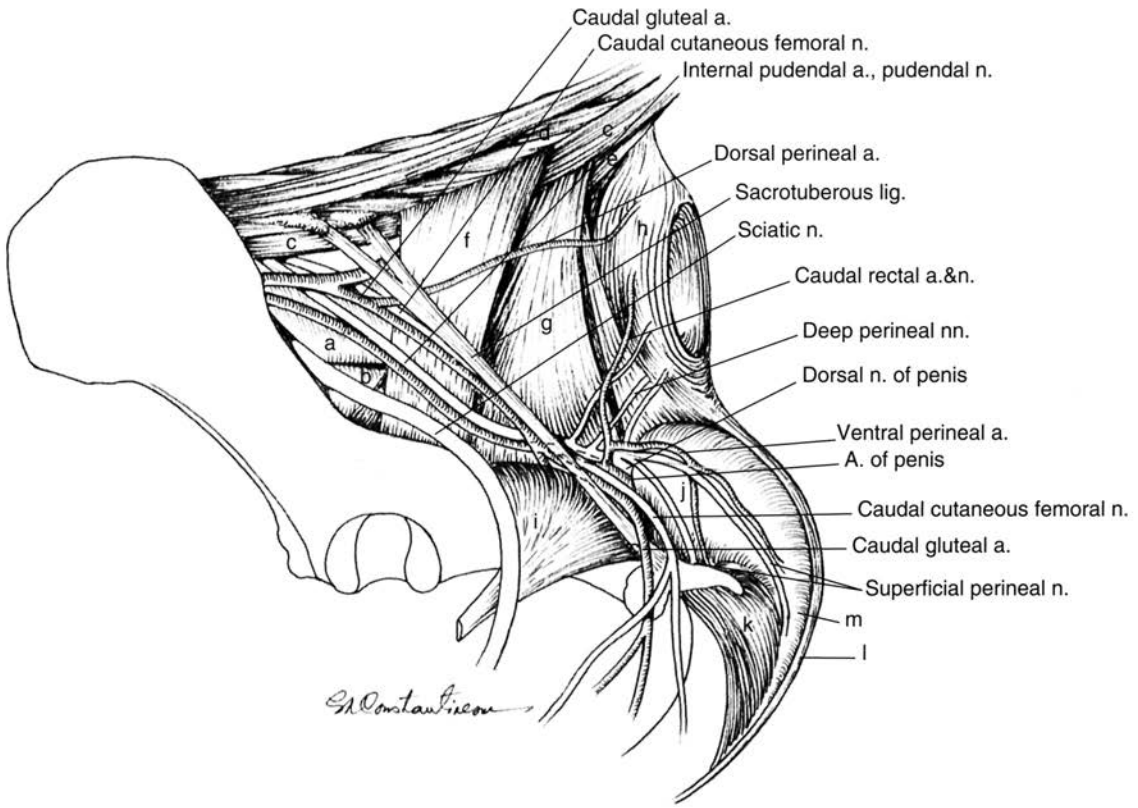

Figure 38-6. Surgical anatomy of the canine left perineum, lateral aspect. *a*- Rectum, *b*- Pelvic urethra, *c*- Sacrocaudalis lateralis ventralis m. (labeled twice), *d*- Intertransversarii dorsales caudae mm., *e*- Rectococcygeus m., *f*- Coccygeus m., *g*- Levator ani m., *h*- External anal sphincter m.–superficial part, *i*- Internal obturator m., *j*- Root of the penis, *k*- Ischiocavernosus m., *l*- Retractor penis m., *m*- Bulbospongiosus m.

The levator ani and coccygeus muscles originate from the medial side of the ischial spine and medial side of the body of the ilium/dorsal surface of the pubis cranial to the obturator foramen, respectively. The levator ani and coccygeus muscles insert on the third through seventh caudal vertebrae, and the first through the fourth caudal vertebrae, respectively. These two muscles form the lateral boundary for the rectum or the medial boundary of the pelvic diaphragm.[2,20]

The sacrotuberous ligament and the superficial gluteal muscle form the lateral aspect of the pelvic diaphragm. The sacrotuberous ligament originates from the ischiatic tuberosity and inserts on the sacrum and first caudal vertebra. The superficial gluteal muscle originates on the lateral aspect of the sacrum, first caudal vertebra, and the cranial half of the sacrotuberous ligament. The superficial gluteal muscle forms a tendon lateral to the perineal region and runs over the dorsal aspect of the greater trochanter to insert on the third trochanter.[2,20]

The ventral aspect of the perineal region is bounded by the internal obturator muscle, which can be transposed for perineal herniorrhaphy. The internal obturator muscle originates on the cranial and medial border of the obturator foramen and the internal surface of the ischium (ischiatic table), and inserts as a flat tendon embedded in the bellies of the gemelli muscles in the trochanteric fossa of the femur.[2,20]

The external anal sphincter muscle is a striated muscle that surrounds the anal canal. This muscle is divided into three parts: the cutaneous part, the superficial part, and the deep part. The cutaneous part lies directly under the skin in the subcutaneous fascia. The superficial part attaches to the third and fourth caudal vertebrae and passes around the lateral aspect of the anus and anal sacs to insert on the bulbocavernosus muscle (male) or the constrictor muscle of the vulva (female). The deep part surrounds the anal canal, passing medial to the anal sacs. The superficial and deep parts can interchange with each other.[2,17]

The semitendinosus muscle is a striated muscle that originates from the ischiatic tuberosity and inserts on the tibia and on the tuber calcanei.[1] Although it does not directly bound the perineal region, the semitendinosus muscle has been used to reconstruct perineal hernia defects.[21]

The internal pudendal artery and vein, and the pudendal nerve are bound together by loose connective tissue, and this neurovascular bundle passes ventrolaterally to the coccygeus muscle and continues caudomedially across the dorsal surface of the internal obturator muscle. At the caudal border of the ventral aspect of the external anal sphincter muscle, the pudendal nerve gives off the caudal rectal nerve. This branch of the pudendal nerve provides motor innervation to the external anal sphincter muscle.[2]

The perineal fascia is the connective tissue covering of the perineal musculature and is divided into deep and superficial layers. The deep perineal fascia is the fascia that tightly covers the musculature. The superficial perineal fascia is the loose connective tissue that makes a thin hernial sac. The superficial

perineal fascia is not considered to be of adequate strength to suture as the primary layer for hernia repair.

Patient Preparation

A perineal hernia is not usually considered a surgical emergency unless the urinary bladder is retroflexed.[16] If the urinary bladder is retroflexed into the perineal hernia, the urinary bladder should be manually reduced. If the urinary bladder cannot be reduced, a urinary catheter should be placed or paracentesis must be performed. Removal of urine from the urinary bladder should assist in reduction. Serum biochemistries (serum urea nitrogen and creatinine) should be evaluated. Dogs with azotemia should be treated appropriately and surgery postponed until the patient is stable.[16]

If the perineal hernia does not contain the urinary bladder, the surgical repair is a nonmergent procedure. Since the majority of dogs with perineal hernias are geriatric, a minimum data base including a complete blood count, serum biochemistries, thoracic radiographs and a complete urinalysis should be performed.[3]

Some surgeons prepare the dog for surgery by having the rectum cleaned of all feces with several enemas the day before surgery, and by fasting the dog for 24 hours prior to surgery. Enemas run the risk of rectal trauma and make for fluid fecal material which is difficult to contain during surgery; therefore, the authors prefer to avoid enemas. Instead, gentle digital extraction of feces is performed after the dog is anesthetized immediately prior to surgery.

After the dog is anesthetized, the perineal region is liberally clipped. The anal sacs are evacuated, a lubricated gauze tampon is inserted into the rectum, and a purse-string suture is placed in the anus. A preliminary scrub is performed to remove gross contamination from the perineum. The dog is positioned in sternal recumbence at the end of the surgical table (Figure 38-7A and B). The pelvic limbs are placed off the end of the table and are gently pulled forward. The table can either be tilted forward, or the dog can be placed in a perineal stand. If a perineal stand or tilt table are not available, sand bags or other padding can be used to elevate the dog's perineum. When pulling the pelvic limbs over the end of the table, the front of the limb should be protected by padding to prevent femoral and fibular (peroneal) nerve injury. If a tilt table is used to help position the dog, excessive tilting of the table should be prevented because of the concern for respiratory compromise. Since the perineal position causes the dog's head to be placed downward, the abdominal contents encroach on the diaphragm and intermittent positive pressure ventilation is required.

After the patient is positioned, the tail can be wrapped and adhesive tape placed above the base of the tail and then directed towards the dog's head. This pulls the tail over the dog's back. After the tail has been positioned, a final scrub can be performed.

Perioperative antibiotics are used by some surgeons; however, the use of antibiotics should not preclude good aseptic surgical technique. If antibiotics are chosen, a broad spectrum antibiotic with activity against gram-negative enteric organisms should be used.

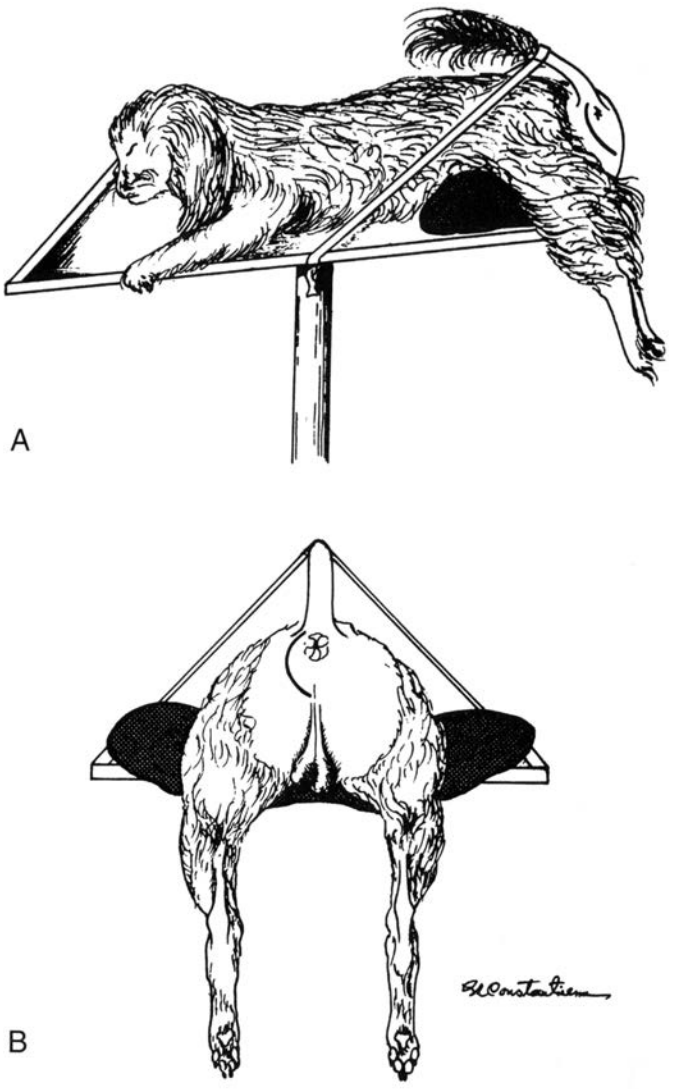

Figure 38-7A and **B.** Positioning for perineal herniorrhaphy. The sand bags provide padding. Tape secures the tail in a midline position over the back. Tape may also be used to secure the pelvic limbs in position, but care must be exercised to avoid excessive tension. The semicircular line to the left of the anus indicates the proposed incision. Surgical drapes are not pictured in order to allow anatomical reference.

Surgical Technique

Draping of the perineal region should be performed so that none of the anus is exposed after the skin incision is made, but accessible to visualization if necessary. Castration is performed on sexually intact male dogs prior to herniorrhaphy. Caudal castration[22] may be performed with the dog in the perineal position to decrease the overall length of the surgical procedure by avoiding the repositioning associated with standard prescrotal castration.

We prefer the internal obturator muscle transposition technique for perineal herniorrhapy. If there is questionable integrity of the internal obturator muscle, porcine small intestinal submuscosa (SIS) may be used in place of the obturator muscle.[23,24] Understanding the surgical anatomy and manipulations for the internal

obturator and SIS techniques is facilitated by an understanding of the traditional perineal herniorrhaphy procedure. Therefore, the traditional technique is discussed first below.

Traditional Perineal Herniorrhaphy

The incision is made over the hernia from just lateral of the tail base to just below the hernial mass (See Figure 38-7A and B). The incision is curved slightly laterally in a dorsoventral direction. Care must be taken to not incise too deeply and injure the hernial contents.

Blunt dissection is used to enter the hernial sac (superficial perineal fascia) and expose the hernial contents. Once the contents of the hernia are exposed, redundant fat can be excised and hernial fluid removed. If jejunum, prostate, colon, or urinary bladder are encountered, these structures can be reduced by digital manipulation in a cranial direction back to their pelvic or abdominal location and maintained with a gauze sponge. A suture can be tied to the gauze sponge to facilitate its removal prior to tying the herniorrhaphy sutures.

Following reduction of the hernia, the muscular defect and landmarks for surgical closure are identified (Figure 38-8). The medial side of the defect is bounded by the rectum, ending with the anal sphincter muscle caudally. The coccygeus muscle and, if present, the levator ani muscle are dorsolateral to the defect. The sacrotuberous ligament can be palpated as the lateral landmark of the repair. This ligament is a broad fibrous cord that extends from the sacrum and first caudal vertebra to the ischiatic tuberosity. The ventral boundary of the hernia is formed by the internal obturator muscle on the floor of the pelvis. Ventrolateral to the coccygeus and levator ani muscles and dorsal to the internal obturator muscle is the neurovascular bundle (internal pudendal artery and vein, and pudendal nerve) of this region. Identification of the neurovascular bundle is important because the pudendal nerve supplies motor function to the external anal sphincter muscle. Bilateral pudendal nerve injury may result in permanent fecal incontinence.[3] Unilateral pudendal nerve injury may lead to temporary incontinence until reinnervation or compensation from the opposite side occurs.

Before pelvic diaphragm repair the presence or absence of rectal disease must be ascertained.[4,8] Rectal deviation occurs as a result of a potential space created by the hernia. Perineal herniorrhaphy should alleviate rectal deviation and small sacculation. Large rectal sacculation and rectal diverticulum may cause straining to expel feces. Therefore, surgical excision of rectal diverticulum or large sacculation, followed by an inverting suture pattern, should be performed to prevent perineal hernia

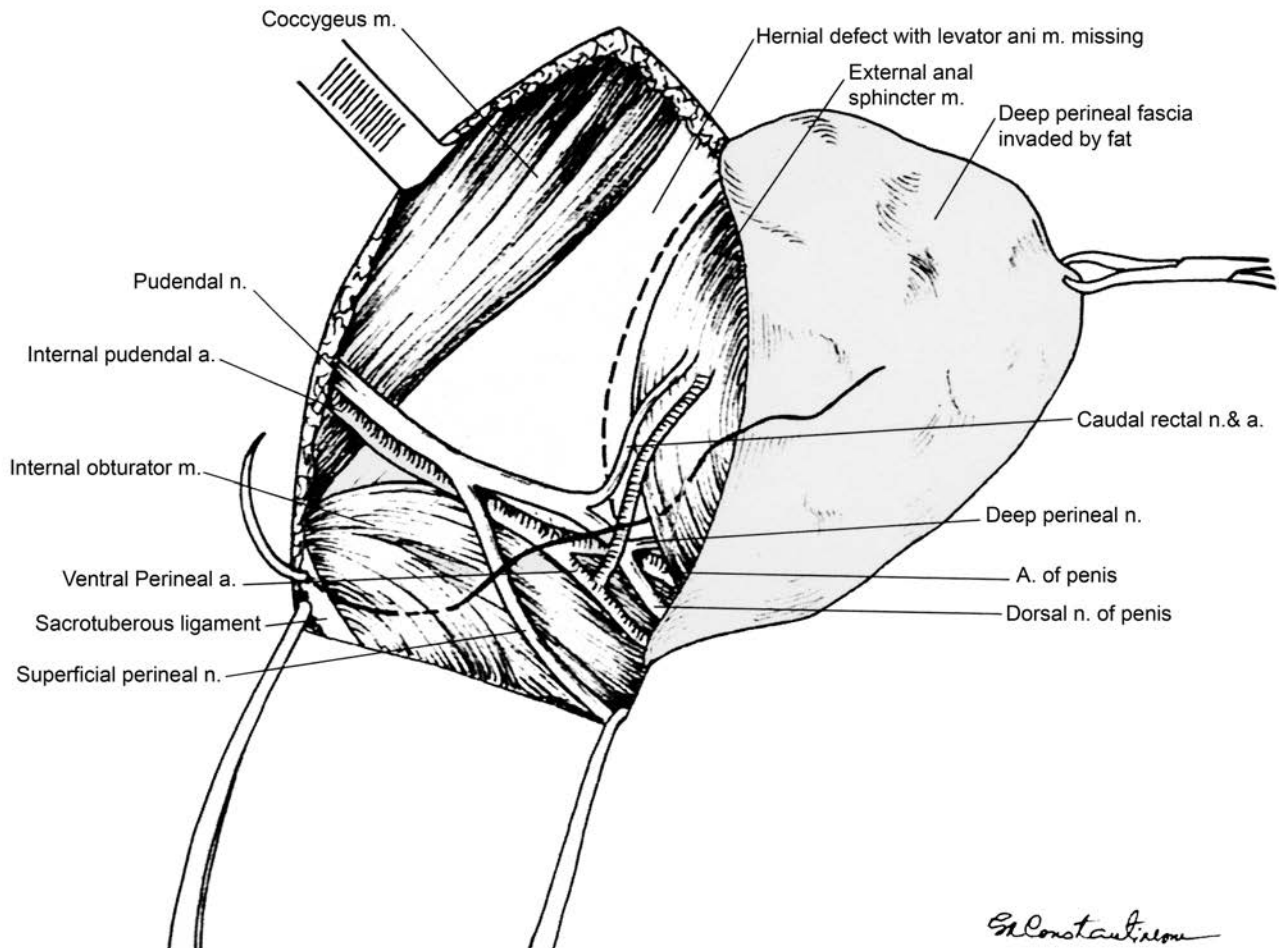

Figure 38-8. Operative view of left perineal hernia with placement of the first suture using the standard herniorrhaphy technique. The first suture is placed in the most ventral position, from the internal obturator muscle to the external anal sphincter. [Note: The levator ani muscle may be atrophied such that it is not recognizable.]

recurrence due to straining caused by impacted feces.[4]

All herniorrhaphy sutures should be preplaced before they are tied (Figure 38-9). The authors recommend synthetic nonabsorbable monofilament suture such as polypropylene for the primary closure of the hernial defect. Suture placement is begun from the most ventral aspect of the defect. The first suture is placed from the internal obturator muscle laterally to the external anal sphincter muscle medially, or vice versa, depending on the side of the hernia and the surgeon (right- versus left-handed). Care should be taken when passing sutures through the internal obturator muscle to not incorporate sutures into the neurovascular bundle in this region. Since the recurrence rate is high with the traditional suture technique, placement of an adequate number of sutures ventrally is important to success.[3] Additional sutures are placed dorsally to the internal obturator suture(s) incorporating bites from the external anal sphincter into the sacrotuberous ligament, the coccygeus muscle, and, when present, the levator ani muscle.[3] When placing sutures through the sacrotuberous ligament, care must be taken to not include the caudal gluteal artery/vein or the sciatic nerve which lie cranial to the ligament. Placing a finger medial and cranial to the sacrotuberous ligament may assist in determining the depth of suture placement by palpation of the caudal gluteal artery's pulse.[3] Furthermore, the suture should be placed through the fibers of the sacrotuberous ligament instead of encircling the entire structure. When placing sutures through the external anal sphincter muscle multiple fibers are gathered onto the needle. Care should be taken to avoid penetration of the rectum or anal sac(s). Once all sutures are preplaced they are tied from dorsal to ventral. As sutures are tied the anus may be visualized to ensure that it has not been grossly distorted.

Following closure of the hernial defect, the superficial perineal fascia is mobilized laterally from the skin. After mobilization, the perineal fascia can be used to reinforce the closure by suturing the fascia caudally to the external anal sphincter muscle using synthetic absorbable suture material. The subcutaneous tissue and skin are closed routinely. Strategic subcutaneous suture placement to minimize dead space eliminates the need for placement of drains. Drains are to be avoided in the perineal region because of postoperative contamination risks.

If bilateral hernia repair is considered, the hernias can be repaired at the same surgery; however, some surgeons will wait 4 to 6 weeks between repairs to decrease the stress and distortion of the external anal sphincter muscle associated with the traditional herniorrhaphy technique.[3]

We believe that castration should be performed for its benefits relative to treating prostatic disease. It is unlikely that castration prevents pelvic diaphragm muscle weakness.[12,13,25]

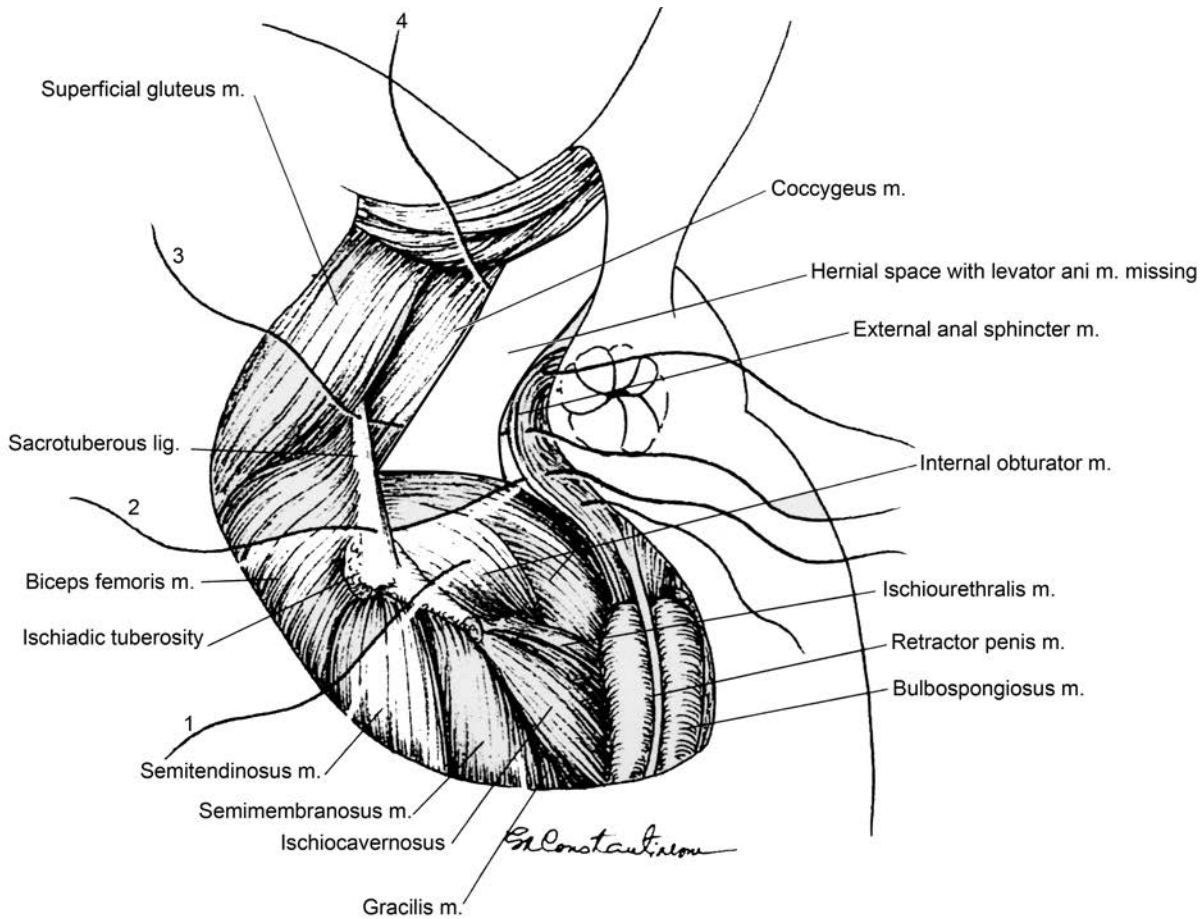

Figure 38-9. Placement of sutures in the standard perineal herniorrhaphy technique. Suture placement is from ventral to dorsal: *(1), (2), (3),* and *(4).* All sutures are preplaced and then tied. More than one suture may be placed in any of the four basic positions depending on the size of the dog. If the levator ani muscle is recognizable, it is engaged with suture along with the coccygeus muscle in positions *(3)* and *(4).*

After all procedures have been completed, the anal purse-string suture and rectal gauze tampon are removed. A thorough rectal examination should be performed to evaluate the integrity of the repair.

Internal Obturator Muscle Transposition

With the dog ventrally recumbent in the perineal position a semicircular skin incision similar to the one used for the traditional herniorrhaphy technique is made in the perineal skin from the tail base to the median raphe ventrally. The subcutaneous tissue is carefully incised and the skin edges are retracted to expose the perineal structures (Figure 38-10). After the hernial contents are isolated and reduced, the internal obturator muscle is subperiosteally elevated from the ischiatic table starting caudomedially and proceeding laterally and cranially. The internal obturator tendon is cut just before it disappears beneath the sacrotuberous ligament, and the muscle is lifted dorsally (Figure 38-11). Failure to completely incise the internal obturator tendon may result in inadequate coverage of the hernia by the muscle. The transposed internal obturator muscle is sutured medially to the external anal sphincter and laterally to the sacrotuberous ligament, the coccygeus muscle, and, if present, the levator ani muscle using polypropylene sutures (Figure 38-12). Any residual defect in the dorsal aspect of the repair is closed

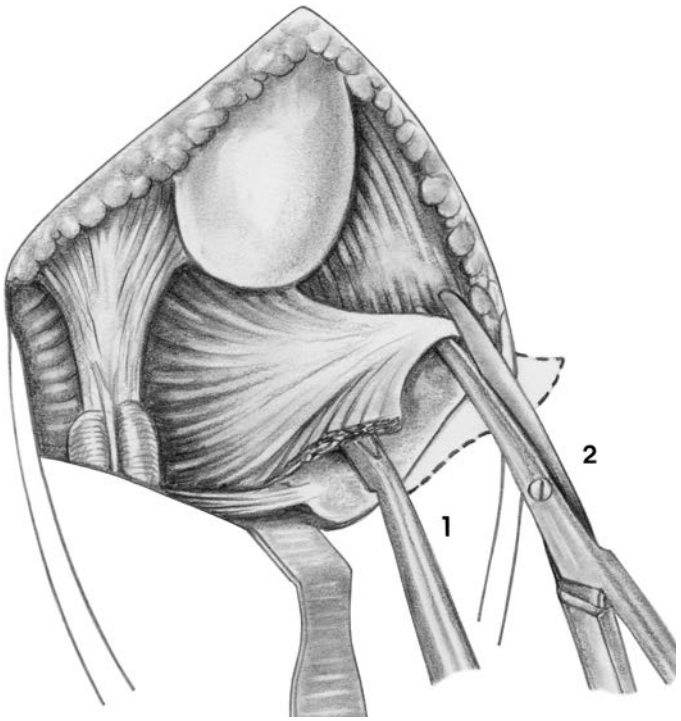

Figure 38-11. Elevation of the internal obturator muscle from the ischiatic table *(1)* and cutting of the internal obturator tendon *(2)*.

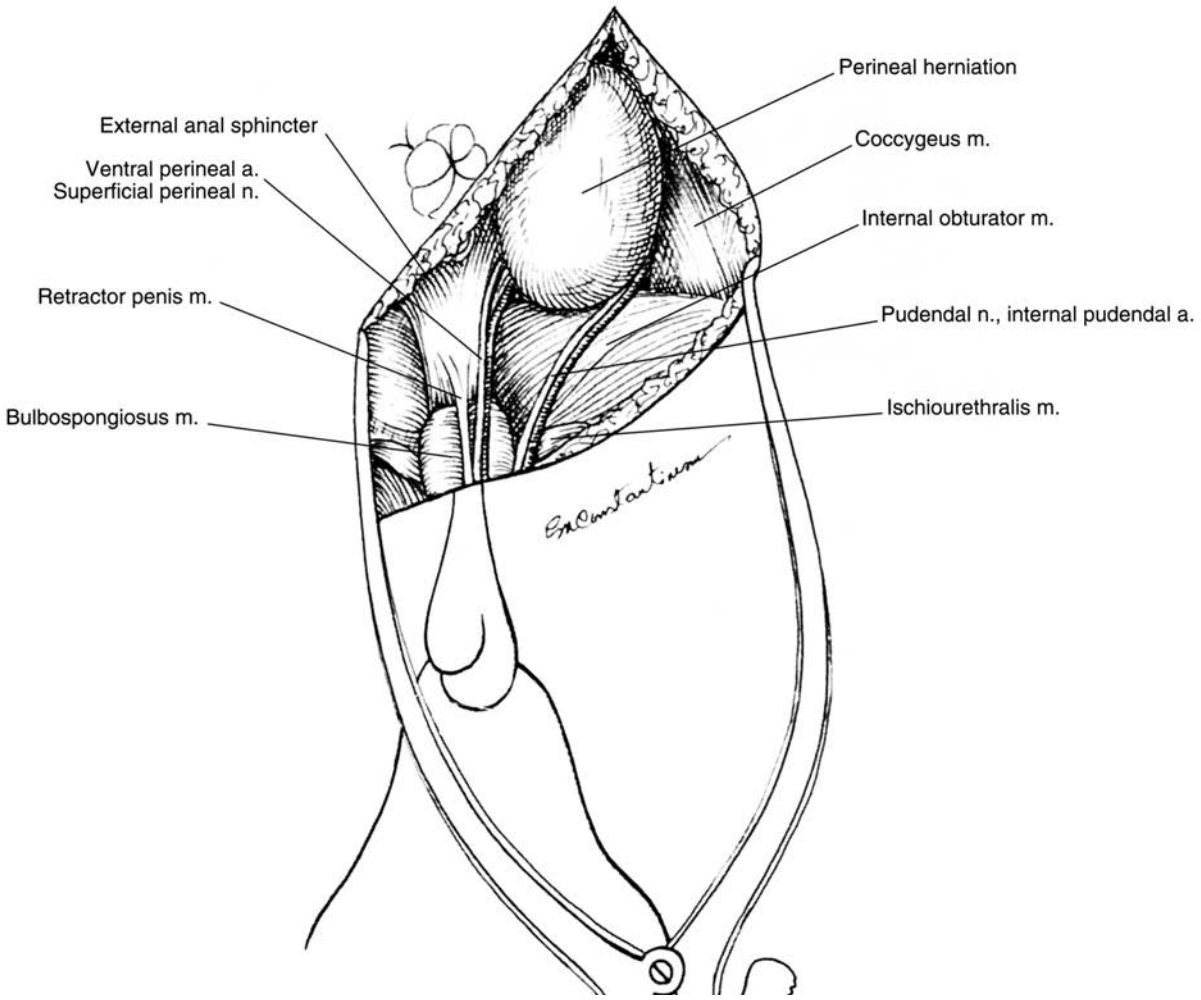

Figure 38-10. Exposure of the right perineum for perineal herniorrhaphy using the internal obturator muscle transposition technique.

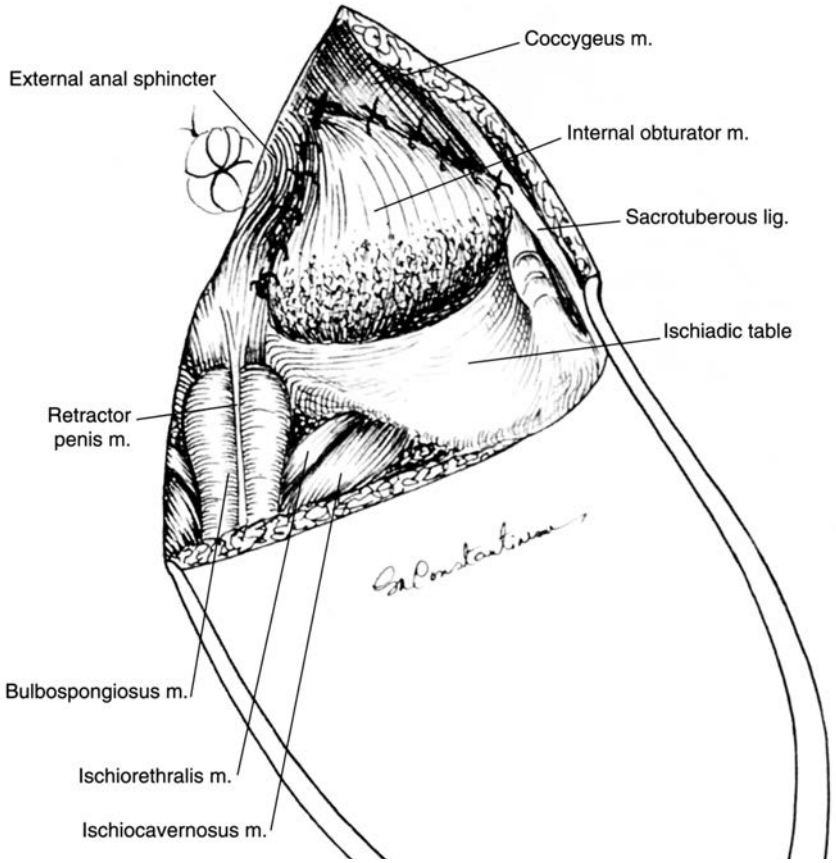

Figure 38-12. Right internal obturator muscle transposition. The transposed internal obturator muscle has been sutured to the external anal sphincter medially, and to the sacrotuberous ligament and coccygeus muscle laterally.

with additional interrupted sutures from the coccygeus muscle to the external anal sphincter. The perineal fascia, subcutaneous tissue, and skin are closed in similar fashion to the traditional perineal herniorrhaphy technique.

Failure of internal obturator muscle transposition most commonly occurs in the ventromedial aspect of the transposed muscle. To prevent failure care should be exercised during subperiosteal elevation to prevent excessive trauma to the muscle, and the ventromedial sutures from the internal obturator muscle to the external anal sphincter should be secure.

Perineal Herniorrhaphy using Porcine Small Intestinal Submucosa (SIS)

The skin incision and surgical approach are similar to the traditional and obturator muscle transposition techniques. Once the hernia is reduced, a 4-ply sheet of SIS is trimmed to dimensions slightly larger than the defect in the pelvic diaphragm. Horizontal mattress sutures (synthetic, absorbable or nonabsorbable, monofilament) are pre-placed from the external anal sphincter, coccygeus muscle, sacrotuberous ligament, and internal obturator muscle to the SIS, leaving a 5 to 10-mm edge on the SIS. After all mattress sutures are placed, they are tied, resulting in closure of the pelvic diaphragm defect (Figure 38-13). Any residual defect in the dorsal aspect of the repair is closed with additional interrupted sutures from the coccygeus muscle to the external anal sphincter. The perineal fascia, subcutaneous tissue, and skin are closed in similar fashion to the traditional perineal herniorrhaphy technique.

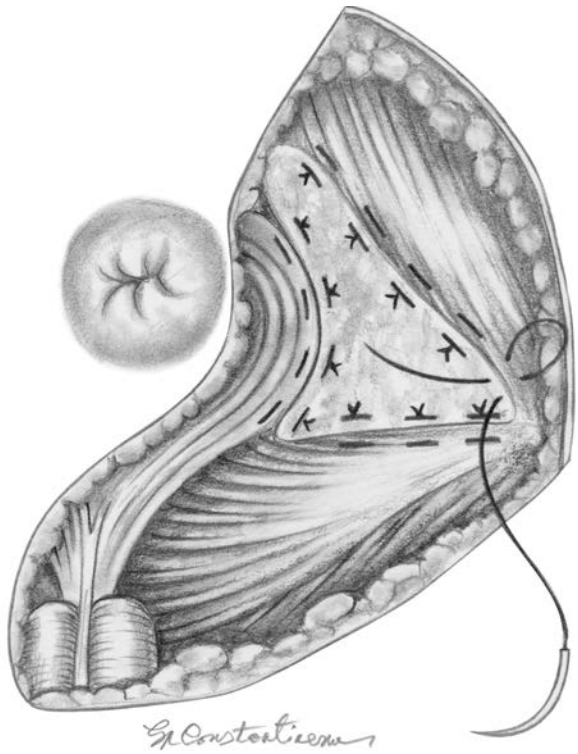

Figure 38-13. Porcine small intestinal submucosa sutured in place with horizontal mattress sutures to close the pelvic diaphragm defect. Medially, the mattress sutures engage the external anal sphincter muscle; laterally, the sutures engage the coccygeus muscle (dorsally) and the sacrotuberous ligament (not shown); and ventrally, the sutures engage the internal obturator muscle.

Postoperative Management

Efforts should be made to ensure a smooth recovery from anesthesia to prevent undo stress on the repaired perineum. To this end, light sedation is occasionally necessary in conjunction with routine analgesics in the early postoperative period.

Prophylactic use of antibiotics to lower the incidence of infection with perineal hernia repair is not straightforward. In a retrospective evaluation of 100 dogs, the authors recommended the use of perioperative antibiotics rather than administering antibiotics after surgery unless an infection has been documented.[15] Good aseptic surgical technique is more important than antibiotics to prevent infection. We select prophylactic antibiotics on an individual case basis.

A low-residue diet can be fed the first few days to help prevent straining during defecation which may lead to disruption of the perineal hernia repair. If straining to defecate does not resolve, digital palpation should be performed to rule out a suture placed in the rectal mucosa. If a suture is not the cause for straining, the pain usually resolves, but analgesics may be necessary in the interim.

If the dog chews or licks excessively at the incision, an Elizabethan collar or similar restraint device should be used to prevent the dog from chewing or licking the incision. Dogs should be returned in 10 to 14 days for skin suture removal.

Complications

Several potential postoperative complications can be associated with repair of perineal hernia. These complications include sciatic nerve injury; fecal incontinence; infection around the incision site; rectal prolapse associated with excessive straining; misplacement of sutures into the anal sac(s) or rectal lumen; urinary bladder necrosis; urinary incontinence; and recurrence of the perineal hernia.[25] Recognition, prevention and appropriate management of these postoperative complications are essential to a successful surgical outcome.

Sciatic nerve injury or entrapment can occur if the nerve becomes encircled or is penetrated by a suture passed around the sacrotuberous ligament. Entrapment of the sciatic nerve is identified immediately after recovering from surgery. The dog will show signs of extreme pain over the hip and perineal region. Furthermore, a sciatic nerve palsy may be detected on a neurologic examination. The treatment of sciatic nerve entrapment is removal of the suture through a caudolateral approach to the hip.[26] This surgical approach allows good visualization of the sciatic nerve and does not require disruption of the perineal hernia repair. Occasionally, epidural medicant administration is used for postoperative analgesia in patients having pelvic or perianal surgery. Because this analgesic technique can cause transient sciatic palsy, the authors recommend alternate means of controlling postoperative pain after perineal herniorrhaphy to avoid confusion with iatrogenic surgical injury to the sciatic nerve. Potentially, observation of sciatic palsy would subject the dog to unnecessary sciatic nerve exploration if the neurologic deficit was due to the epidural analgesic technique.

Fecal incontinence may be only temporary due to postoperative pain and inflammation associated with the surgery. Unilateral damage to either the pudendal nerve or the caudal rectal nerve may be associated with temporary incontinence that resolves after the contralateral caudal rectal nerve reinnervates the damaged nerve's side.[17,25] Return of full fecal continence may take several weeks after unilateral caudal rectal nerve damage. Permanent fecal incontinence is likely if bilateral caudal rectal or pudendal nerve damage occurs, or if damage to the external anal sphincter muscle or other pararectal tissue is excessive.[25] Permanent fecal incontinence is best avoided because the reported prosthetic implants and muscle transpositions used for treatment have demonstrated inconsistent success in reestablishing fecal continence.[21,27]

Incisional complications have been reported as a function of the surgical location.[15] Exposure of the incision to feces either during surgery or before a good fibrin seal has occurred can cause a wound infection. If an infection occurs surgical drainage of the site and administration of antibiotics based on culture and susceptibility is ideal. If antibiotics need to be instituted without knowledge of culture and susceptibility, a broad spectrum antibiotic with activity against Escherichia coli should be used.[25]

Rectal prolapse can sometimes occur immediately after surgery. Rectal prolapse can occur as a result of excessive straining postoperatively due to placement of suture(s) in the rectal lumen, or because of pain associated with bilateral hernia repair. Rectal disease and external anal sphincter nerve injury have been two other predisposing factors to rectal prolapse. The rectal prolapse should be reduced and a purse-string suture placed in the anus. If straining is excessive and unresponsive to narcotics, an epidural can be administered. The anal purse-string suture should be maintained until the straining has resolved. Generally, this may take several days. If the rectal prolapse recurs after multiple attempts at reduction, a colopexy should be performed.[25]

Misplaced suture(s) into the rectal mucosa can occur because of difficulty in identifying perineal structures due to excessive tissue inflammation and swelling. Misplaced sutures can lead to excessive straining, or, uncommonly, development of a rectocutaneous fistula. Misplacement of suture(s) into the anal sac can also lead to draining tracts. The treatment of chronic fistulas associated with misplaced sutures is by fistulectomy and anal sacculectomy, depending on the anatomic structure involved.[25]

Complications relative to retroflexion of the urinary bladder into the perineal hernia are seen infrequently. Retroflexion of the urinary bladder can stretch the nerves that supply the urinary bladder and urethral sphincter, stretch the detrusor muscle resulting in bladder atony, or interfere with the blood supply to the urinary bladder. Usually, clinical signs seen with this complication are temporary. Manual decompression of the urinary bladder or catheterization may be necessary to keep the urinary bladder empty until its muscle tone returns. Urinary bladder necrosis has been associated with long-standing cases secondary to urinary bladder obstruction and distention. The clinical signs secondary to urinary bladder necrosis are rupture and uroperitoneum. Exploratory celiotomy and resection of the

necrotic portion of the urinary bladder may be required; however, in some cases, excessive urinary bladder necrosis may prohibit a successful resection.[25]

Recurrence of a perineal hernia after repair has ranged from 5 to 46%.[8-11,28] Although some surgical procedures offer better results and less chance of recurrence, the accurate identification of all anatomic structures is paramount to the success of any procedure. Furthermore, understanding the limitations of each particular technique is important in the surgical decision-making process and may help in reducing the failure of any technique.

The association between castration and the recurrence of a perineal hernia after surgical repair has been reported to be 2.7 times greater in dogs that were not castrated versus those dogs that were castrated.[9] However, in a later study, no correlation was found between castration and perineal hernia recurrence. Failure of perineal hernia repair was thought to be more related to lack of experience with the surgical technique than any effect from castration.[15]

Salvage Techniques for Failed Perineal Herniorrhaphy

Recurrence of canine perineal herniation following traditional herniorrhaphy has been reported to be as high as 46%.[10] Recurrence rates as low as 5% have been reported for the internal obturator muscle transposition herniorrhaphy technique.[11] Nonetheless, until the ultimate cause of canine perineal hernia can be identified and controlled, a certain degree of recurrence can be expected regardless of refinements in surgical technique. When the traditional herniorrhaphy technique fails, the simplest and usually most effective means of salvage is to perform an internal obturator muscle transposition to reconstruct the pelvic diaphragm. Alternately, the SIS technique could be employed. When the internal obturator muscle transposition fails, SIS might be used to close the defect; however, absence of the internal obturator from its normal ischial location may make it difficult or impossible to anchor the SIS ventrally. When the internal obturator muscle transposition and SIS techniques are not options, the authors recommend choosing from one of the following two options: (1) semitendinosus muscle transposition[21,29] for perineal reconstruction or (2) colopexy/cystopexy[30-32] for preventing herniation of important structures.

Semitendinosus Muscle Transposition

The semitendinosus muscle transposition is particularly useful for reconstructions in which the ventral aspect of the perineum is severely affected as is the case with some bilateral perineal hernias. For unilateral perineal herniation the contralateral semitendinosus muscle is recommended for pelvic diaphragm reconstruction.

With the dog in the perineal position a skin incision is made in the perineal skin from the tail base to the median raphe ventrally just as is done for traditional, internal obturator muscle transposition, and SIS repairs, and the incision is continued across midline toward the ischiatic tuberosity where it curves and progresses distally on the caudal aspect of the pelvic limb to end at the caudomedial aspect of the transition between the stifle and the crus (Figure 38-14). The hernial contents are exposed and reduced in similar fashion to other herniorrhaphy techniques prior to isolation of the semitendinosus muscle. The subcutaneous tissues over the semitendinosus muscle are incised to expose the muscle (Figure 38-15). The semitendinosus muscle is bluntly isolated from surrounding structures taking care not to injure the proximal vascular pedicle (the caudal gluteal artery and vein). The semitendinosus muscle is transected as distally as possible near the stifle and is further isolated for mobilization to the perineal region. Incision of the lateral portion of the semitendinosus tendinous attachment to the ischium may be necessary for maximal mobilization, but care must be taken to avoid proximal vascular pedicle trauma or kinking that may occur with excessive mobilization. Using polypropylene or nylon suture, the transected portion of the semitendinosus muscle is sutured to the sacrotuberous ligament and the coccygeus muscle. The medial aspect of the semitendinosus muscle (now adjacent to the external anal sphincter muscle dorsally) is sutured to the external anal sphincter, and the lateral aspect of the semitendinosus muscle (now adjacent to the ventral aspect of the perineum) is sutured to the remnant of the internal obturator muscle, the ischiourethralis muscle, perineal fasciae, and/or the periosteum of the dorsal surface of the ischium (Figure 38-16). Synthetic absorbable sutures are used to obliterate dead space and close the subcutaneous tissues. The skin is closed with the routine closure of the surgeon's choice.

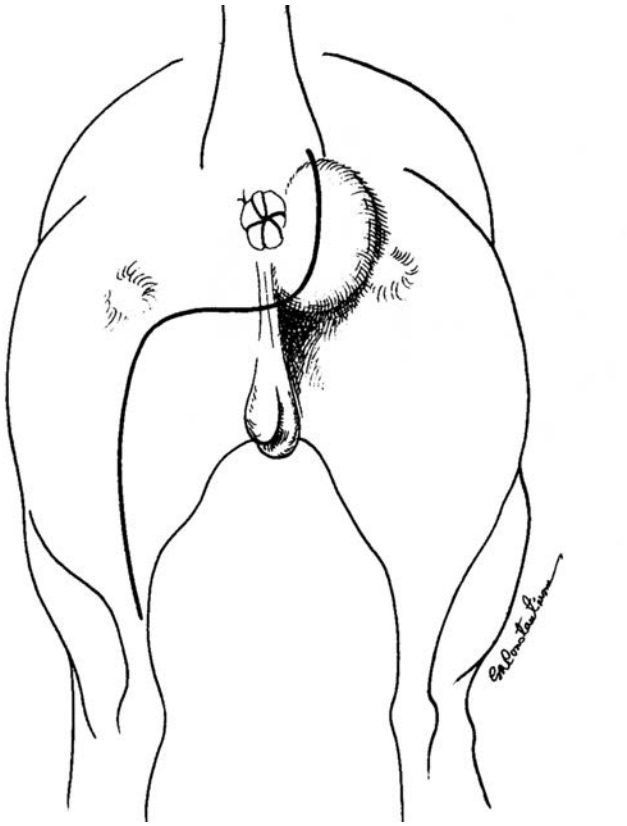

Figure 38-14. Skin incision for left semitendinosus muscle transposition to repair a failed right perineal herniorrhaphy.

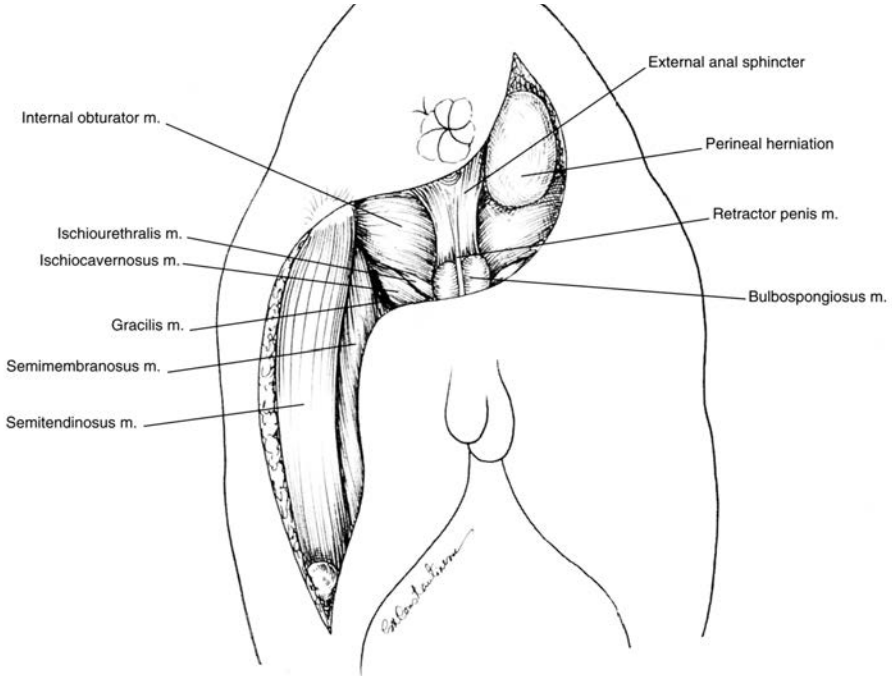

Figure 38-15. Left semitendinosus muscle exposed prior to isolation and mobilization to reconstruct a failed right perineal herniorrhaphy.

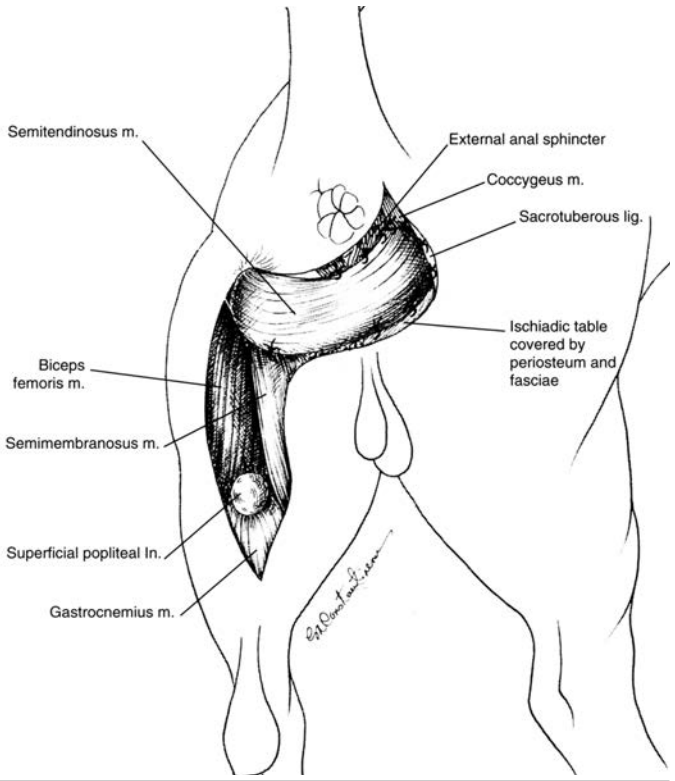

Figure 38-16. Transposed left semitendinosus muscle sutured dorsally to the external anal sphincter muscle, laterally to the right sacrotuberous ligament and coccygeus muscle, and ventrally to the internal obturator muscle fascia, the ischiourethralis muscle fascia, and the ischial periosteum.

Colopexy/Cystopexy for Failed Perineal Herniorrhaphy Salvage

Colopexy with cystopexy via deferent duct fixation is designed to prevent herniation of the most problematic organs (colon, prostate, urinary bladder) that may become entrapped in the perineal hernia space. This technique is typically reserved for cases where perineal reconstruction using muscle transpositions have failed or when the surgeon anticipates failure of muscle transposition.

The dog is positioned in dorsal recumbence for ventral midline celiotomy (Figure 38-17). If the dog is not castrated, standard prescrotal castration is performed prior to celiotomy. Once the abdomen is open, the colon and urinary bladder are exposed by packing the other abdominal organs cranially with moist laparotomy sponges (Figure 38-18). Cranial traction is applied to

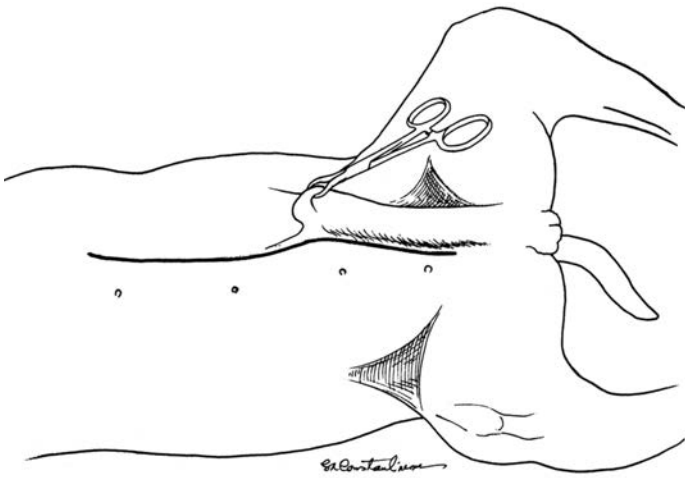

Figure 38-17. Skin incision for colopexy/cystopexy treatment of failed or complicated perineal herniorrhaphy.

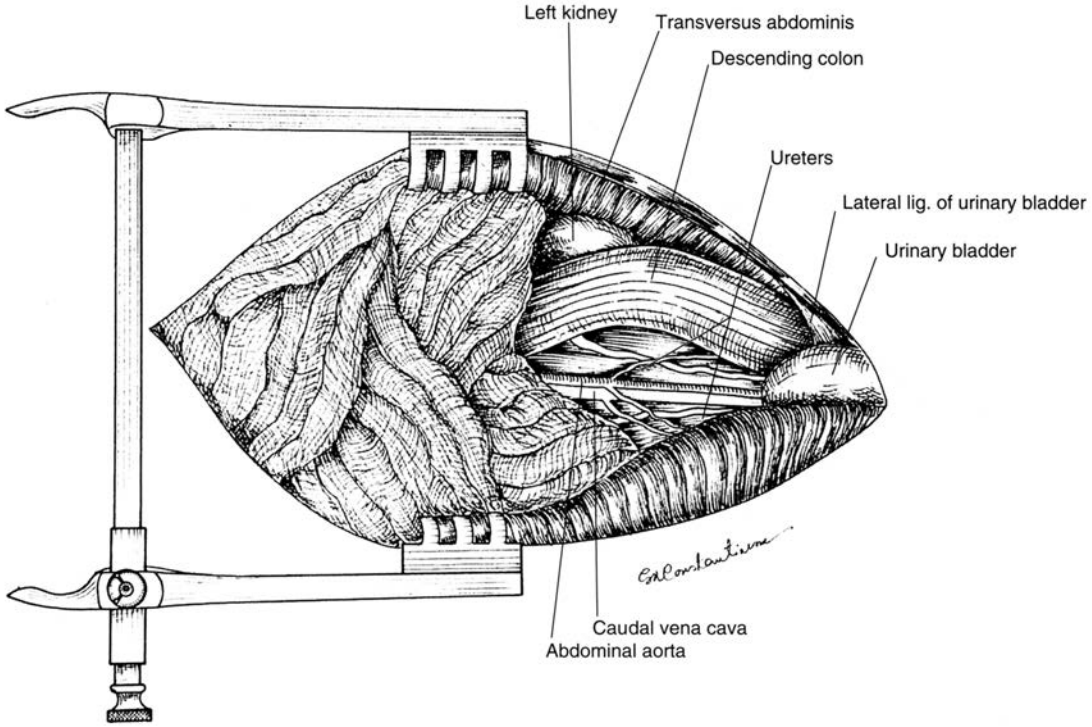

Figure 38-18. Exposure of caudal abdominal organs and positioning of the descending colon adjacent to the left dorsolateral body wall for colopexy. Abdominal organs are packed cranially with moist laparotomy sponges.

the colon to reduce herniated rectum and prevent the rectum from migrating into the perineal space. The colon is secured in this position to the dorsolateral body wall with two staggered rows of mattress sutures (three to four mattress sutures per row) of polypropylene placed in full-thickness fashion through the colon (Figure 38-19).

A stay suture is placed in the apex of the urinary bladder to aid in exteriorization and exposure of the deferent ducts. Both deferent ducts are gently pulled into the abdomen from the vaginal canals. A stay suture is placed at the severed end of the left deferent duct to assist manipulation. A 1 to 2 cm belt loop is created dorsolaterally in the left transversus abdominis muscle midway between the left kidney and urinary bladder. The belt loop is created by making two stab incisions parallel to the transversus abdominis muscle fibers and bluntly dissecting beneath the muscle between the stab incisions with hemostatic forceps. The stay suture in the deferent duct is grasped with hemostatic forceps and pulled from caudal to cranial through the belt loop to pull the deferent duct through the loop until it is taught. The deferent duct is then folded back (caudally) over the belt loop and is sutured to itself and to the belt loop with simple interrupted polypropylene sutures (Figure 38-20). The manipulated end of the deferent duct with the stay suture is excised. The right deferent duct is secured to the right body wall in the same fashion. After removal of the laparotomy sponges and urinary bladder stay suture, the celiotomy is closed routinely.

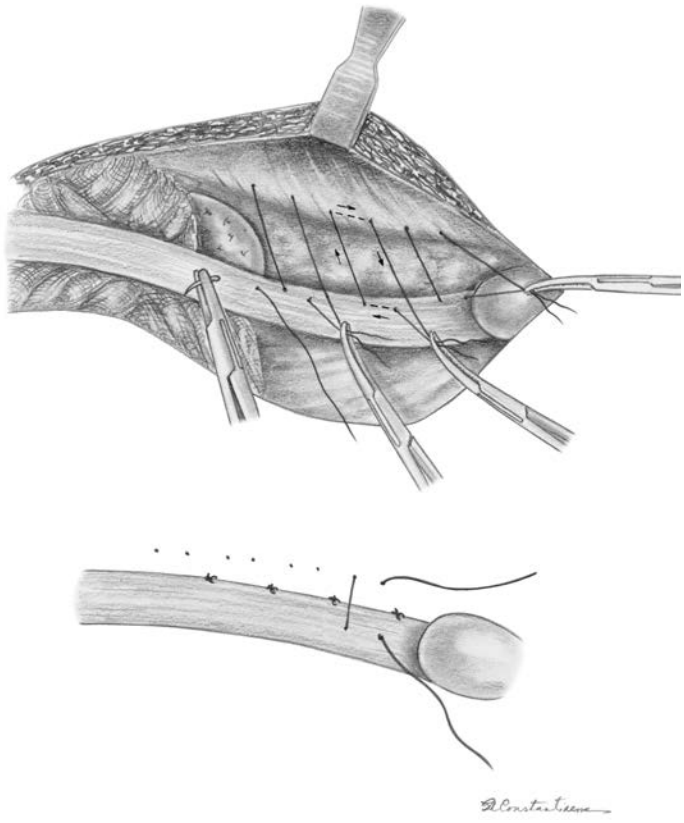

Figure 38-19. Colopexy. The mattress sutures in the first row are preplaced (top drawing) and tied (bottom drawing) before the second (staggered) row of sutures is completed.

Caudal Castration in the Dog

An alternative to standard prescrotal castration is desirable in dogs when castration is indicated in conjunction with perianal

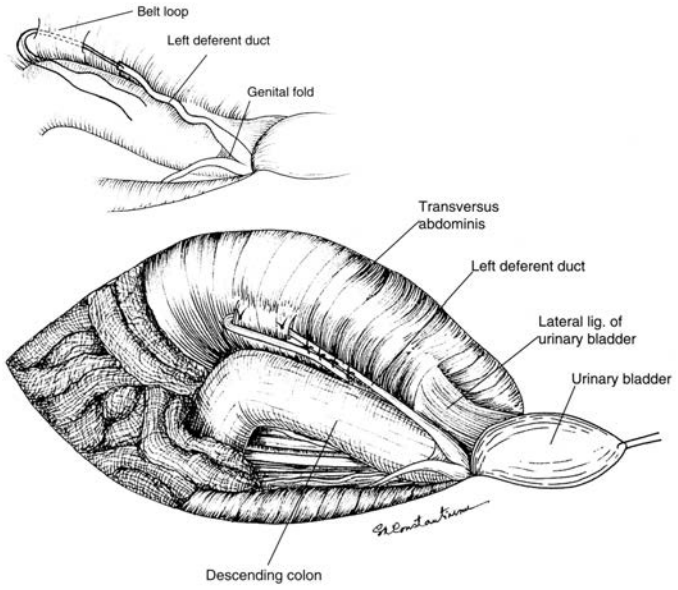

Figure 38-20. Cystopexy via deferent duct fixation. The left deferent duct is passed through a belt loop created in the left transversus abdominis muscle with the aid of a stay suture *(inset)* and is folded onto itself and sutured to itself and to the belt loop.

or perineal surgery. Although the role of castration in canine perineal hernia is debatable,[13] many surgeons continue to perform castration in conjunction with perineal herniorrhaphy. Whenever a dog is undergoing castration at the same time as a procedure that requires perineal positioning, caudal castration can decrease operative time by eliminating the need for intraoperative repositioning.[22]

Patient preparation: For caudal castration, the dog must be surgically prepared such that the scrotum is in the aseptic surgical field once the surgical drapes are in place. Therefore, gentle clipping of scrotal hair with a cool clipper blade is performed before clipping of the remainder of the surgical field. After clipping and hair removal are complete, the dog is placed in the perineal position (See Figure 38-7) for aseptic surgical preparation. We prefer to use chlorhexidine instead povidone iodine for scrotal disinfection, to minimize the chance of scrotal dermatitis. On completion of skin disinfection, surgical drapes are placed such that the scrotum is within the surgical field (Figure 38-21), and caudal castration is performed before the other scheduled surgical procedure (perineal herniorrhaphy, perianal adenoma excision). The anus and perianal region may be temporarily covered with drapes to minimize contamination of the castration procedure.

Surgical technique: The skin incision begins on the median raphe and extends ventrally onto the scrotum over the left testicle (Figure 38-22). Open castration is then performed. The left testicle is pushed toward the skin incision to allow incision of the internal spermatic fascia and parietal lamina of the vaginal tunic exposing the testicle. The excess internal spermatic fascia and parietal lamina of the vaginal tunic is excised, and the testicle is removed using a three clamp technique (Figure 38-23). The right testicle is approached through the same skin incision through the interdartoic septum and is removed in a fashion similar to that of the left testicle. A few subcutaneous subcuticular sutures of synthetic absorbable suture are used for closure. The perineal position is maintained for the subsequent surgical procedure, and the scrotum may be draped out of the surgical field to minimize contamination of the castration incision.

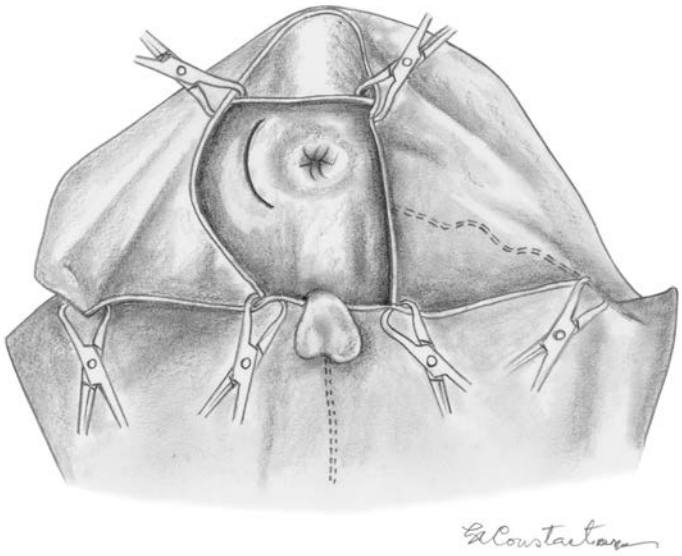

Figure 38-21. Aseptic draping for caudal castration and perineal herniorrhaphy. Castration is performed first, but the proposed herniorrhaphy incision is outlined to demonstrate draping of both sites in the surgical field. A rectal gauze tampon and anal purse-string suture (not shown) placed prior to the final skin preparation will prevent gross fecal contamination, but a temporary drape may be placed over the anus during the castration to further minimize contamination.

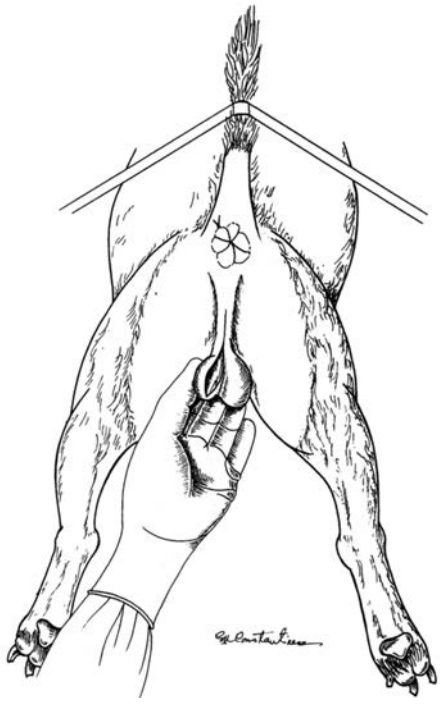

Figure 38-22. Caudal castration skin incision. Surgical drapes are not shown to allow anatomic reference. Both testicles are removed through the same skin incision.

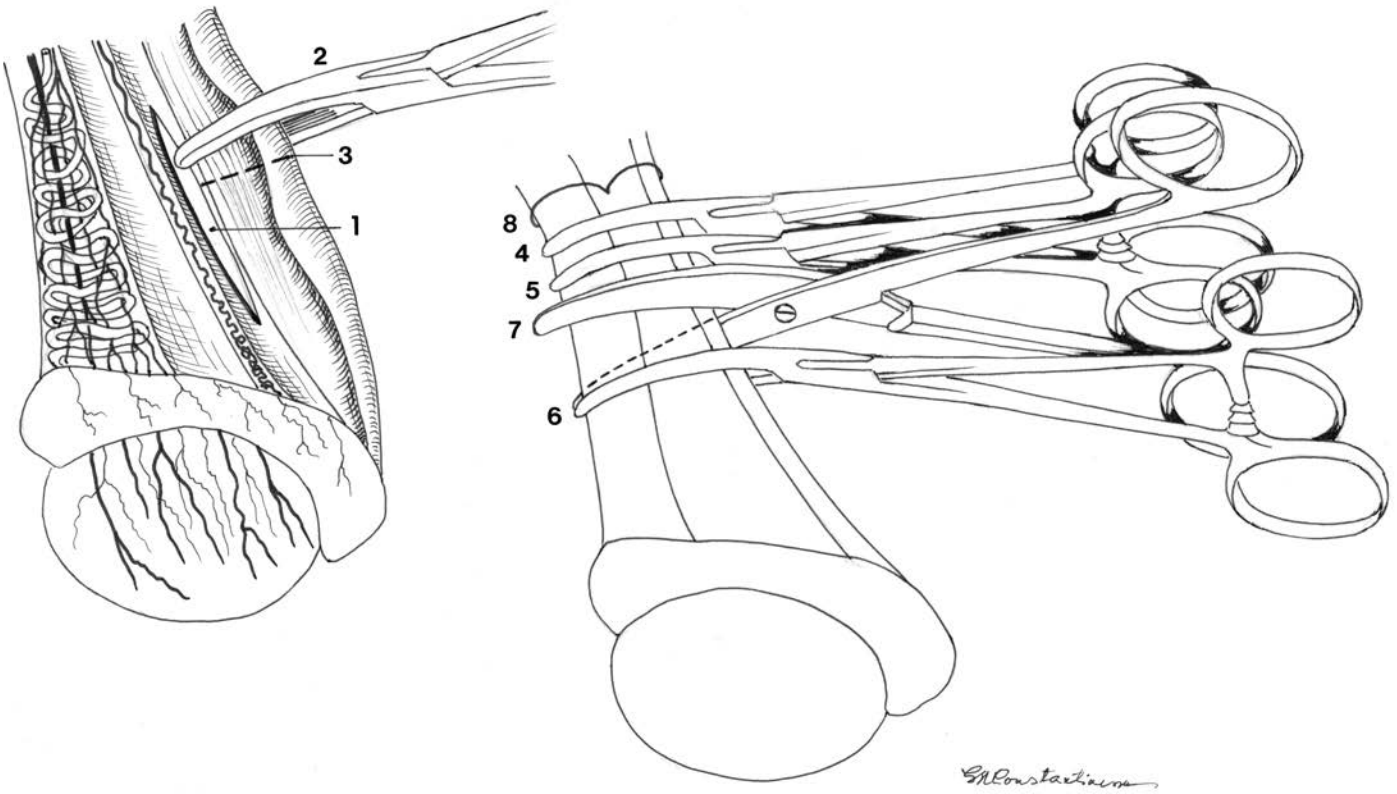

Figure 38-23. Three clamp technique for caudal castration (open technique) of the left testicle. A fenestration *(1)* is made in the mesofuniculus to allow a Carmalt forceps *(2)* to be placed across the tunic containing the cremaster muscle. An incision *(3)* is made distal to the Carmalt forceps. A transfixation ligature (not shown) is placed proximal to the Carmalt forceps and tied as the forceps is removed to control hemorrhage from the cremaster muscle. Three Carmalt forceps *(4, 5, and 6)* are placed across the spermatic cord, the proximal forceps applied first and the distal forceps applied last. The testicle is excised by cutting *(7)* between the two most distal forceps, and a ligature *(8)* is placed proximal to the most proximal Carmalt forceps and tightened as the most proximal forceps is removed. After the ligature is tied, the remaining forceps is removed. The numbers represent the steps of the procedure. (Alternately, the pampiniform plexus testicular artery complex and the deferent artery and ductus deferens may be excised and ligated using two separate three-clamp procedures.)

Perineal Herniorrhaphy in the Cat

The etiopathogenesis of perineal hernia in cats differs from that of dogs. In cats, perineal hernia may occur as a long-term complication of perineal urethrostomy or may be associated with megacolon. Feline perineal hernias that are not associated with either of these two situations are considered idiopathic; a hormonal influence has not been seriously considered because both genders are typically represented, most affected cats being spayed or castrated.[33-36] A left-sided perineal hernia in an 8-week-old cougar was thought to be congenital.[37] Most perineal hernias in cats are bilateral.[33]

The perineal herniorrhapy techniques used in dogs may be applied to cats, but attention should be paid to anatomical differences. Feline perineal muscles are smaller than like muscles in the dog, and the cat does not possess a sacrotuberous ligament (Figure 38-24).[38,39] Because feline perineal hernia is often bilateral, the internal obturator muscle transposition is preferred to the traditional technique to avoid excessive tension on the external anal sphincter. Although not yet reported in cats at the time of this writing, SIS repair could also be performed. The semintendiosus muscle transposition repair has been reported in a cat.[40]

Complications after perineal herniorrhaphy in cats seem to be less common than in dogs, but one should be vigilant for the same possible complications as described for dogs. Additionally, concurrent disease that might contribute to straining, such as megacolon, must be addressed for optimal success.

Prepubic Hernia Repair

Daniel D. Smeak

Introduction

Prepubic hernia or cranial pubic ligament (CPL) rupture is the most common abdominal hernia caused by blunt trauma (particularly vehicular trauma) in small animals.[1,2] The lateral paralumbar (flank) region hernia is also seen with some frequency after blunt trauma presumably because it is another area that lacks elasticity, and it is not supported by the rectus abdominis muscle.[3] Because of their close anatomic relationship, many patients with prepubic hernias have coexisting inguinal ligament rupture and organs such as the bladder and/or intestines may be found within the hernia. These organs may extend into the inguinal canal or femoral vascular lacunae area causing swelling reaching from the caudal-ventral abdominal wall into the medial thigh and flank (Figure 38-25). One case report described a rare bladder incarceration within a chronic prepubic hernia in a dog with a vesicular-cutaneous fistula.[4]

The CPL attaches to the cranial aspect of the pubis and extends from one iliopectineal eminence and pectineus muscle to the other (See Figure 38-25). It serves as the principal attachment of the rectus abdominis muscle to the pelvis and is under constant tension. Blunt trauma causes avulsion of the cranial pubic ligament from its boney attachment or, less commonly, a tear occurs at the musculotendinous junction. In contrast, CPL rupture is spontaneous in large animals, and most often occurs during the last two months of gestation apparently due to increasing uterine weight.[5]

Blunt trauma severe enough to cause rupture of the abdominal wall may also cause widespread crush, rupture, or avulsion damage to surrounding structures and intra-abdominal organs. As many as 75% of small animals with traumatic abdominal hernias have other serious injuries, most are orthopedic in nature usually involving the pelvis. Other important common injuries are to soft tissues, including respiratory, gastrointestinal, and genitourinary systems.[2,3] Following patient stabilization, a thorough physical examination and diagnostic workup are indicated to evaluate for more insidious, often life-threatening, injuries.

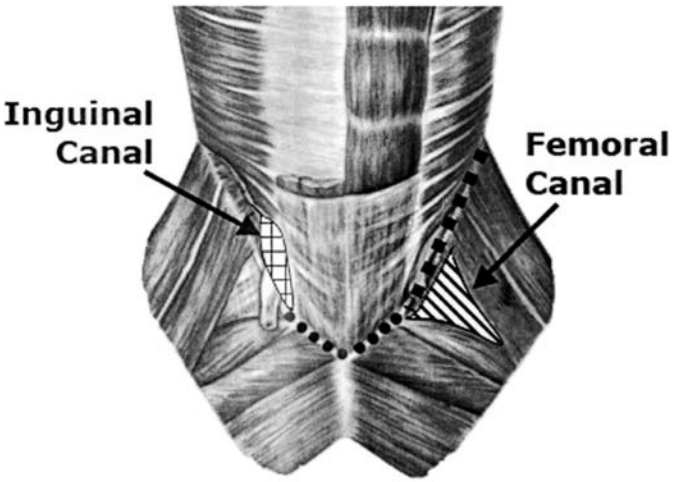

Figure 38-25. Caudoventral abdominal wall and inguinal anatomy. Dotted line indicates the rectus abdominis muscle attachment to the pelvis (the cranial pubic ligament). The dashed line marks the inguinal ligament separating the inguinal and femoral canals. (Modified from Robinette JD, Hernias. In Gourley IM, Vasseur PB eds. General Small Animal Surgery. Philadelphia, JB Lippincott, pp759, 1985.)

The diagnosis of prepubic hernia is often confirmed by palpating a defect in the caudal abdominal wall, by reduction of tissue back into the caudal abdomen, or by palpation of organs in the subcutaneous space near the pubic or thigh areas. Organs such as the intestine may not be confined to the local area and may migrate a considerable distance from the hernia, such as down the medial thigh or along the abdominal wall and thorax. Pain and swelling from trauma or hemorrhage may not allow detection of a hernial ring or herniated tissue during physical examination. In these instances, abdominal radiographs or ultrasound of the local area are indicated. Routine ventral-dorsal and lateral radiographs aid in identifying the abdominal stripe, or lack thereof, any malposition of the abdominal contents, and the presence of fluid in the abdomen. When radiographs or ultrasound are not conclusive, a positive contrast peritoneogram may help to delineate the abdominal wall defect. Patients should be thoroughly evaluated for concurrent injuries such as urinary tract rupture, abdominal hemorrhage, fractures, and thoracic trauma. Survey thoracic and abdominal films (including the pelvic area), and blood workup are usually indicated for all severely traumatized patients. If electrocardiography is available, a rhythm strip should be evaluated, otherwise, detection of an irregular rhythm or dropped beats while examining the pulse may indicate traumatic myocarditis. A complete blood count and serum chemistries should be evaluated to determine if significant blood loss or organ compromise has occurred.

Stabilization of the patient's condition takes precedence over hernia repair. Because these hernias are usually large, the risk of incarceration or strangulation of viscera is low. Therefore, if the patient is stable and serious intra-abdominal trauma has been ruled out, the hernia can be repaired several days later, after swelling and hemorrhage begins to subside and tissues reestablish their blood supply. If the patient does not stabilize with resuscitative measures, serious intra-abdominal injury or contamination should be suspected and further diagnostic tests and/or emergency exploratory laparotomy may be indicated.

Surgical Technique

Surgical correction is usually performed through a ventral midline approach. When an exploratory laparotomy is indicated, the entire abdomen should be prepared aseptically, and if the hernial sac extends to adjacent areas, these areas should be liberally prepared also. The way in which the patient is positioned on the operating table may be critical for successful closure of a prepubic hernia. Closure may be virtually impossible if the patient is placed in a routine dorsal recumbent position (limbs pulled caudally and abducted and trunk in slight dorsal flexion (Figure 38-26A). The rear limbs should be pulled cranially and the body ventroflexed to relieve tension during hernia repair (Figure 38-26B). If transposition of the cranial sartorius muscle is planned to augment the primary hernia repair, the adjacent hind limb is also prepared for aseptic surgery (Figure 38-27). Prophylactic antibiotics are administered during preparation of the surgical site.

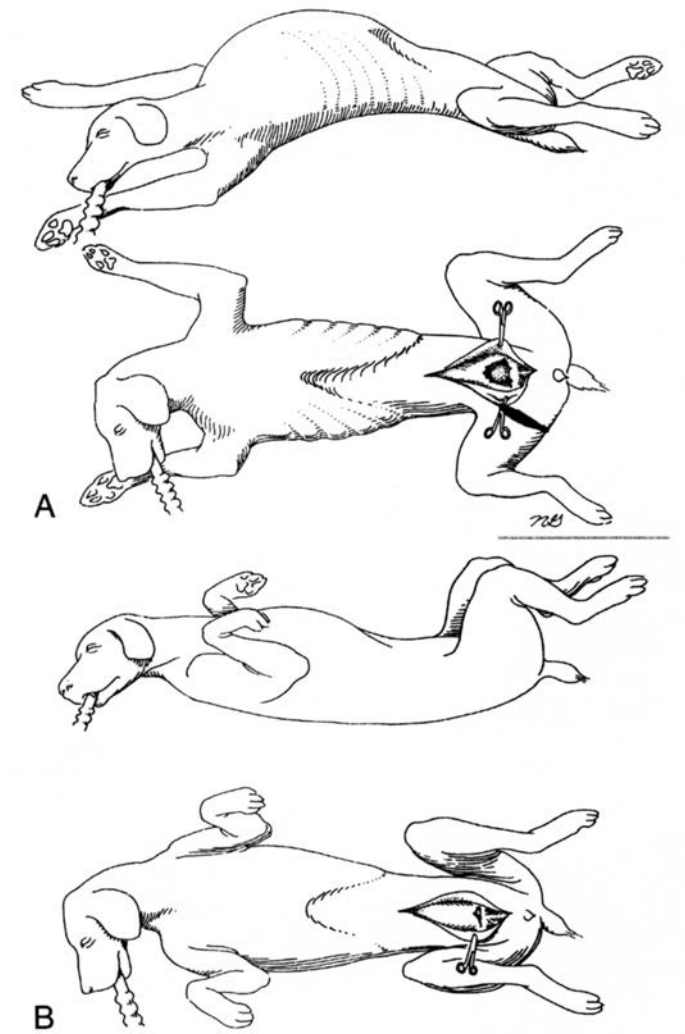

Figure 38-26A and **B.** Example after altering position to relieve tension on a prepubic hernia repair. **A.** Dorsal recumbency position for prepubic hernia repair; rear limbs are pulled caudally and are extended, causing undue tension. **B.** Modified dorsal recumbency position; rear limbs are flexed slightly and are pulled cranially. This creates truncal ventroflexion, reduces the size of the defect, and decreases tension during hernia repair. (Reprinted with permission from Smeak DD: Management and prevention of surgical complications associated with small animal abdominal herniorrhaphy. Prob Vet Med 1:259, 1989.)

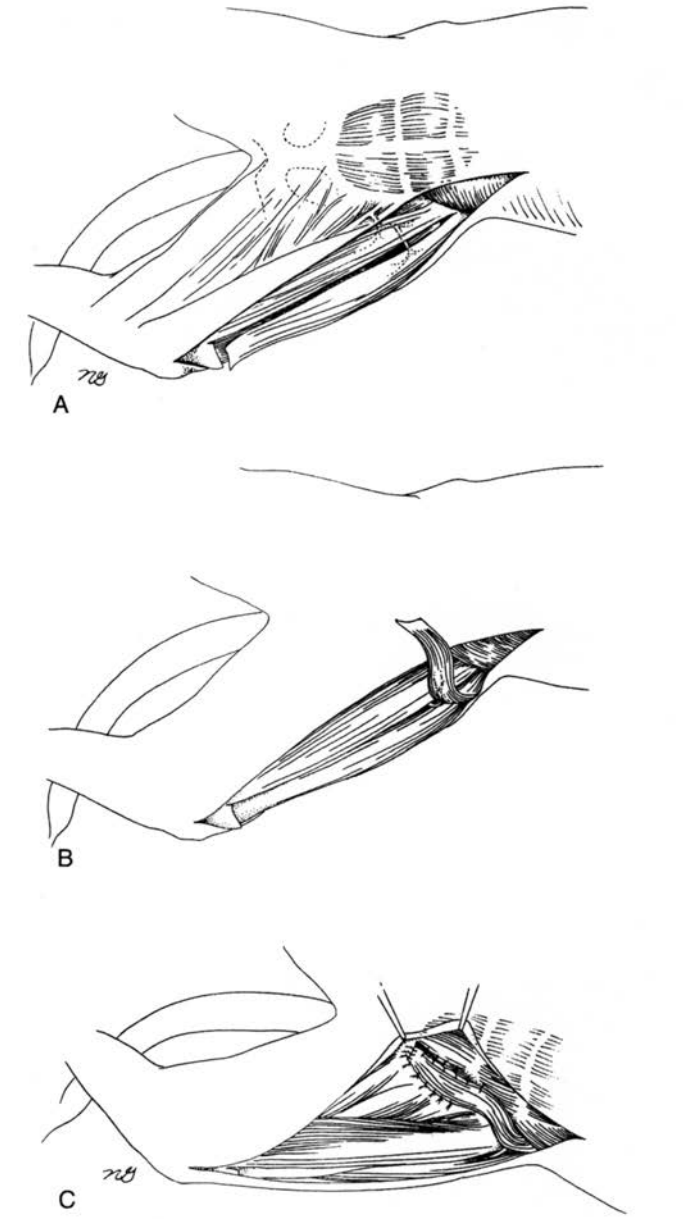

Figure 38-27. Illustration of a cranial sartorius muscle flap used to repair an inguinal hernia. **A.** The cranial sartorius muscle is elevated from its distal insertion. **B.** Mobilization of the muscle to the level of the vascular pedicle. **C.** Transposition of the cranial sartorius muscle to the caudal abdominal wall region so that its external surface is in contact with the external abdominal oblique muscle. (Reprinted with permission from Smeak DD. Abdominal Hernias. In Slatter D ed. Textbook of Small Animal Surgery. Philadelphia, Saunders, 463, 2003.)

Due to serious concurrent soft tissue injuries related to acute traumatic abdominal hernias, the abdomen should be aseptically prepared for thorough exploration before efforts are made at hernia repair.[3] In dogs surviving the acute insult that develop a chronic prepubic hernia, the defect can be safely approached locally without abdominal exploration. When prepubic hernias become chronic, significant muscle contraction and loss of tissue elasticity occurs, exerting excessive tension on the repair. In some cases, it is impossible to appose tissues. If tension is difficult to overcome, muscle or tendon has been lost, or the defect is very large, the use of a mesh prosthesis is recommended.[6] Besides

hernia recurrence, wound infection, seroma, and skin slough are the most common complications after repair.[6] Traumatized skin and soft tissues are handled with utmost care, and excessive blunt dissection is avoided because the vascular supply may be tenuous and further insult could result in tissue loss or an increased risk of infection.[6] After abdominal exploration, and necessary organ repair is completed, the abdominal cavity is lavaged, and the linea alba is closed routinely.

The prepubic hernia is exposed by careful dissection and debridement of devitalized tissue (Figure 38-28). Excision of connective tissue surrounding the hernia is avoided unless it is devitalized or infected, and will not support sutures. The surgeon carefully inspects the lateral margins to determine whether the hernia extends into the inguinal and femoral areas. Important vascular and neural structures are isolated and protected, particularly if the femoral region requires reconstruction. If femoral or inguinal areas are involved, the regional anatomy is studied carefully before undertaking herniorrhapy. The prepubic hernia component is repaired first, to help align tissues correctly for anatomic reconstruction of the inguinal and femoral hernias, if present. The cranial public ligament is reattached with large 2-0 to 0 size monofilament (prolonged absorbable) suture or nonabsorbable suture. If enough healthy tendon is present, the surgeon anatomically repairs the hernia with preplaced interrupted sutures incorporating large bites of tissue. As adjacent preplaced sutures are pulled firmly, knot the individual sutures. This maneuver helps reduce the risk of suture cutout during repair. In most prepubic hernias, the ligament is avulsed from the pubic bone leaving scant soft tissue attached. In this case, holes are drilled in the cranial brim of the pubis to anchor sutures. When the hernia cannot be repaired without excess tension, a cuff mesh reinforcement of the prepubic tendon can be performed using polypropylene mesh (Figure 38-29). Concurrent femoral or inguinal hernias are repaired by carefully isolating the hernia edges and anatomic reconstruction. Often, the inguinal ligament is ruptured, and sutures are preplaced between the abdominal oblique fascia and the musculature of the proximal medial thigh. Extreme care is required to avoid damaging, incorporating or obstructing important vascular and neural structures of the inguinal or femoral canal. If mesh is used for reconstruction, I prefer to transpose the cranial sartorius muscle to provide a seal and bring additional blood supply over the repair to support rapid healing and incorporation of the mesh (See Figure 38-27).[7,8] I also consider using this muscle to augment inguinal or femoral defects when tissue edges are tenuous or when the wound will not support synthetic mesh (heavily contaminated wounds). The surgeon should recognize that this muscle is not covered by heavy fascia so the muscle alone should not be expected to maintain abdominal wall continuity under excessive tension.

Usually a large amount of dead space is present in the subcutaneous tissues after herniorrhaphy. Gravity dependent drains such as Penrose drains or, preferably, closed suction drain systems (Jackson-Pratt) should be used in most cases. Avoid placing open-drain systems directly against buried mesh to reduce the risk of ascending infection.

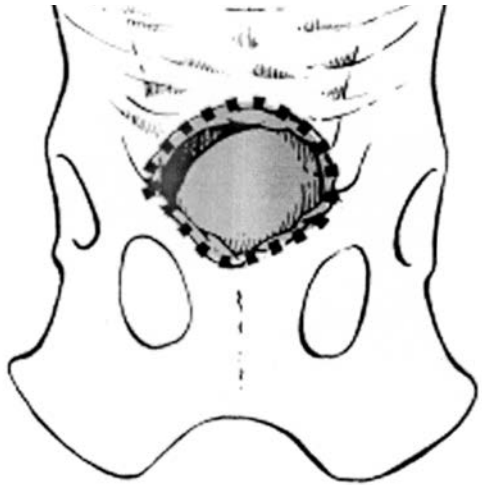

Figure 38-28. Ventral view of pelvis showing prepubic defect. Dashed line indicates hernia ring. (Modified from Robinette JD, Hernias. In Gourley IM, Vasseur PB eds. General Small Animal Surgery. Philadelphia, JB Lippincott, pp759, 1985.)

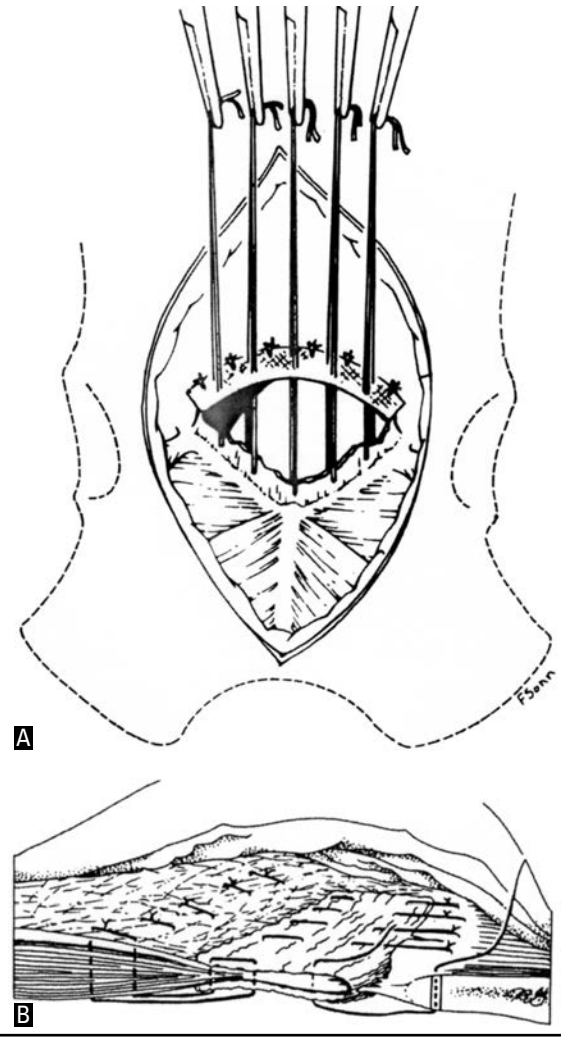

Figure 38-29. Cuff mesh reinforcement of a prepubic hernia. **A.** The prepubic defect is closed with preplaced sutures between holes drilled in the pubic bone, and a mesh reinforced edge of torn rectus abdominis muscle and prepubic tendon. **B.** Section through caudal abdominal wall showing cuffed mesh reinforcement of the rectus abdominis tendon, and fixation of the mesh to the pubis. (A, modified from Robinette JD, Hernias. In Gourley IM, Vasseur PB eds. General Small Animal Surgery. Philadelphia, JB Lippincott, pp755-776, 1985.)

Postoperative Care

Monitoring and postoperative care instructions are dictated by the nature and severity of the injury. The surgeon should continue to monitor the patient's vital signs and remains aware of possible problems related to occult visceral damage. Patients should be given analgesic agents for at least 24 hours after the surgical procedure. An epidural using narcotic analgesics is very effective to prevent postoperative pain. Unless contraindicated, nonsteroidal anti-inflammatory drugs are also administered to reduce postoperative wound edema and pain. Wounds and drains should be monitored for signs of infection or hernia recurrence. Drains should be bandaged, if possible, and removed when discharge has diminished. This is usually possible within 3 days. If infection occurs, wounds are opened, cultured, debrided, and secondarily closed. Strict exercise limitation is recommended for at least four to six weeks particularly if a prosthetic mesh was implanted. If the inguinal or femoral areas have been reconstructed along with the prepubic hernia, the surgeon should consider placing the patient's hind limbs in hobbles to prevent tension from excess limb abduction. An Elizabethan collar is used to guard against premature drain removal or wound mutilation.

Prognosis

Based on a report of a series of patients undergoing prepubic herniorrhaphy, approximately 80% will survive and have successful hernia repair. If a hernia recurs (about 15% do) the defect is usually evident by one month after surgery. Repair of these recurrent hernias is usually successful provided the repair is anatomic, is free of tension, and incorporates strong tissue. The remaining 20% have poor results because of the severity of accompanying injuries.[1,3]

Chapter 39

Feline Onychectomy

Jonathan M. Miller and Don R. Waldron

Introduction

Onychectomy is the surgical removal of the distal (third) digital phalanx (P3). This procedure is performed frequently in young cats as a primary surgery or at the time of gonadectomy. The forelimbs only (routinely) or all four paws (rarely) may be declawed however the latter requires the cat to be a totally indoors pet. Indications for onychectomy include destructive indoor scratching behavior, trauma, neoplasia, or infection. Onychectomy is estimated to be performed on at least 24% of all domestic cats in this country. The procedure has become controversial due to owner perceived postoperative pain, a relatively high rate of postoperative complications and anecdotal descriptions of negative behavioral side effects. Contrary to this belief, the scientific literature suggests that onychectomized cats ambulated normally by 9 days to 6 months postoperatively and declawing provided a protective effect against relinquishment to animal shelters which may result in euthanasia. Advances in perioperative analgesic protocols and refinement of surgical technique have improved the postoperative management of this procedure. Alternatives to declawing a cat with destructive scratching behaviors include repeated nail trimming, periodic application of plastic nail caps, behavioral training, or deep digital flexor tendonectomy.

Surgical Anatomy

The feline digit is composed of three phalanges. The third phalanx is comprised of an ungual crest which articulates with the second phalanx, and an ungual process which protrudes into the continually growing nail, also called the unguis. During onychectomy, the third phalanx is entirely or mostly removed. Paired dorsal elastic ligaments and axial and abaxial collateral ligaments span the joint space. Tendons of the common and lateral digital extensor muscles cross the dorsal surface of the 3rd to 5th digits. The deep digital flexor tendon attaches to the palmar flexor process portion of the ungual crest. Nail growth originates from the germinal epithelial tissue present in the ungual crest. This collection of dividing cells is located in the proximal and dorsal portion of the ungual crest, and if germinal epithelial tissue is incompletely removed claw regrowth can occur.

Anesthesia and Analgesia

Onychectomy requires general anesthesia. Adjunctive preoperative opioids and non-steroidal anti-inflammatory drugs have been shown to greatly improve postoperative comfort in cats. Buprenorphine (0.01 mg/kg intramuscularly) and application of a transdermal fentanyl patch (25 ug/hr) were shown to be the most effective opioids. Meloxicam (0.3 mg/kg subcutaneously) was proven more effective than butorphanol for pain control. Additionally, local anesthesia in the form of a ring block proximal to the paw is routinely performed. Bupivicaine (1 mg/kg) is distributed perineurally through a 25 gauge needle to selectively block nerve impulses in the sensory branches of the radial, median, and ulnar nerves (Figure 39-1). Bupivicaine has a 15 to 20 minute onset of action and lasts 6 to 8 hours.

Surgical Techniques

The most important component of any surgical technique for onychectomy is adequate removal of the third phalanx to avoid nail regrowth. Preparation of the paw aseptically is performed with surgical scrub and alcohol but without a need for clipping the hair. A tourniquet is applied for all but the laser technique to reduce intra-operative hemorrhage. Placement of the tourniquet distal to the elbow (proximal third of the antebrachium) is essential in preventing postoperative radial nerve dysfunction. For laser declaw, alcohol, due to its flammable nature, is avoided during surgical preparation and a tourniquet is not used.

Dissection Technique

With the cat in lateral recumbency, a #11 or 12 surgical blade is used to incise the skin along the distal ungual crest. Hemostatic forceps or Allis tissue forceps can be used to grasp the nail for manipulation. The third phalanx is extended and the skin overlying the P2-P3 articulation sharply incised. The ligamentous and tendonous attachments to the third phalanx are sharply transected using caution to not damage the digital pad (Figure 39-2). With proper technique, the smooth articular surface of the second phalanx should be easily visualized. Closure of the skin wound can be performed with small loosely tied absorbable suture or with tissue adhesive. When applying tissue adhesive (n-butyl cyanoacrylate), dried skin is compressed digitally in a medial to lateral direction and 1 to 3 drops are applied to the skin only. Subcutaneous application of adhesive will induce an inflammatory response that can be associated with postoperative draining tracts or persistent lameness.

Guillotine Technique

After tourniquet application and aseptic preparation, either a sterilized guillotine type (Resco) or scissors type (White) commercially available nail trimmer is used. The nail is grasped with forceps and the proximal cutting blade is placed between the ungual crest and the second phalanx. Care should be taken to avoid damage to the digital pad during cutting. A small portion of the palmar flexor process is often left with this method, but as long as the entire central and dorsal portions of the ungual crest are excised, nail regrowth rarely occurs. Skin closure is similar to the dissection technique.

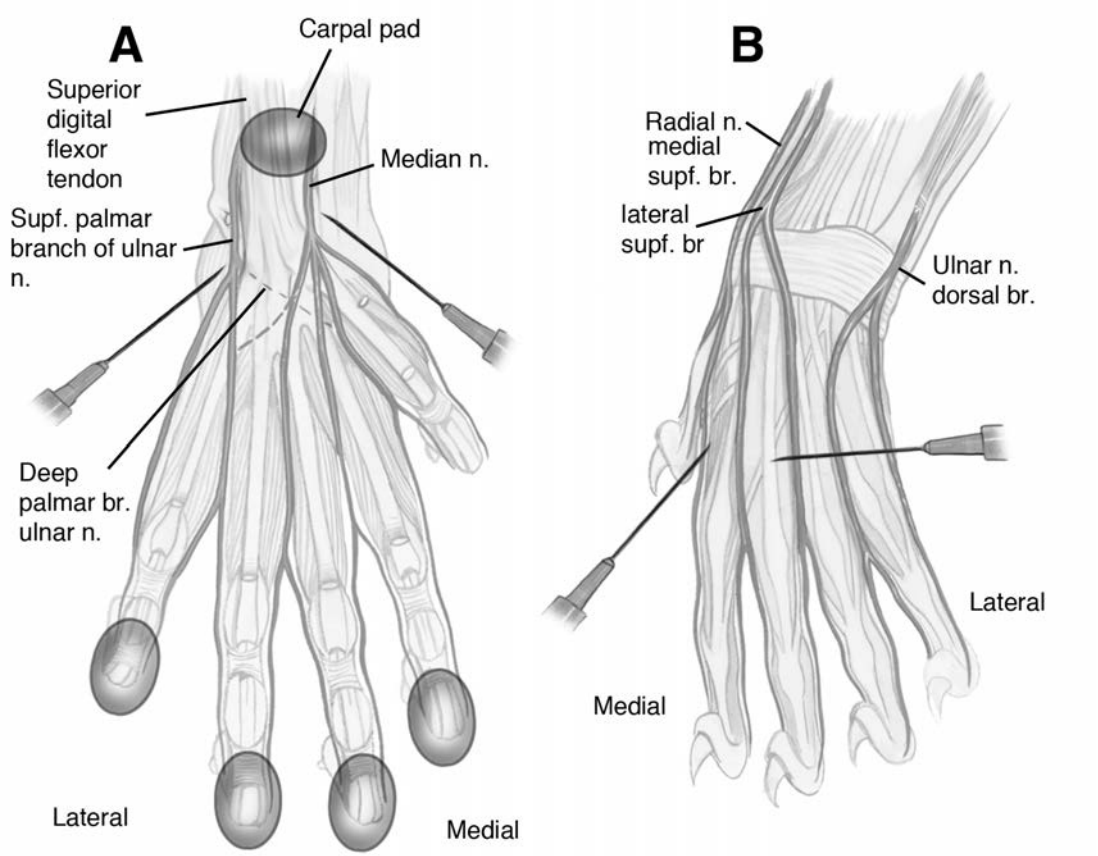

Figure 39-1. Note the anatomic location of needle placement for regional nerve block to the cat paw prior to forelimb declaw.

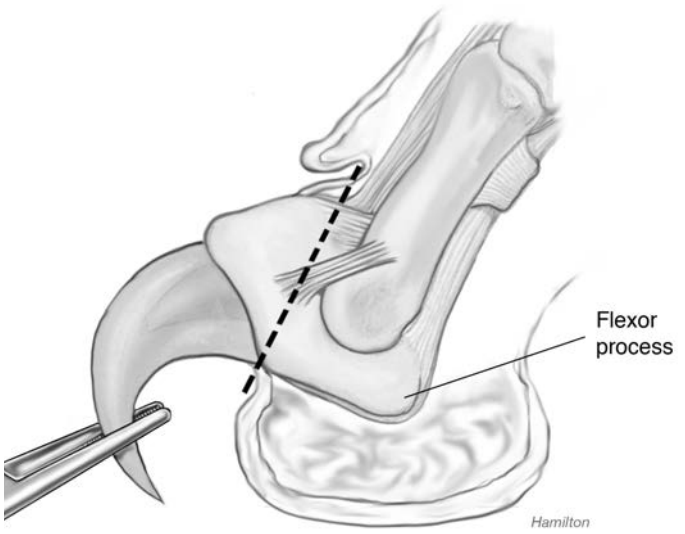

Figure 39-2. The anatomy of the feline digit is illustrated; note the flexor process of the third phalanx on the palmar surface extending proximally.

Laser Technique

Proposed benefits of laser onychectomy include reduced hemorrhage, decreased postoperative pain, and the reduced need for a tourniquet, skin closure, or postoperative bandaging. A CO_2 laser with a 0.4 to 0.8 mm tip set at 4 to 6 watts is used to perform onychectomy similar to the scalpel blade dissection technique. When performing laser surgery, appropriate planning and technique is required to prevent injury to the patient, surgeon, and other personnel. Protection of inspired oxygen in the endotracheal tube from combustion is accomplished by wrapping the tube with saline moistened gauze. Careful technique is required to protect the digital pad and the second phalanx from laser damage. The surgeon and any staff in the room should wear approved laser protective eyewear and facemasks, and a smoke evacuator should be utilized to minimize inhalation exposure of vapor. Any excessive char is wiped away before suture or tissue adhesive skin closure. Skin closure as with all declaw techniques is optional however less hemorrhage is seen postoperatively when closure is performed.

Postoperative Management and Complications

Following onychectomy, a light bandage is often applied for the first 12 to 24 hours during hospitalization. This consists of a dry 4x4 gauze sponge, kling, and self adhesive material placed to the proximal antebrachium. Hemorrhage following bandage removal is usually minimal, but may require longer term bandaging. Care must be taken when applying any bandage postoperatively to prevent ischemic injury to the foot. All bandages are removed prior to patient discharge from the hospital. Shredded paper or commercially available recycled newspaper litter is used for 7 to 10 days in the litter-box at home to minimize possible wound contamination. Pain should be managed by oral opioids (Buprenorphine), a fentanyl patch, and/or oral meloxicam or robenacoxib postoperatively. Lameness occurring postoperatively can be affected by the technique and pain management protocol selected but is usually self limiting and resolves in 1 to 2 weeks. One report of flexor tendon contracture lameness, occurring 6 to 12 weeks postoperatively, required tendon release and was thought to be

associated with excessive tissue trauma. Postoperative infections can be associated with subcutaneous tissue adhesive application and are best treated by opening the wound for drainage and allowing second intention healing with appropriate wound care. Nail regrowth, occurring in up to 10% of nail trimmer onychectomies, is often associated with draining tracts or fistula formation weeks to months after surgery. Radiographs will aid in the diagnosis, and treatment requires reoperation to remove the remaining ungual crest. Proper surgical technique and postoperative management will reduce the reported 24 to 50% complication rate associated with feline onychectomy.

Editor's Note: Management of postoperative pain is recommended for 7-10 days postoperatively. Repeated use of metacam in cats has been associated with acute renal failure and death. Metacam solution for injection is approved for one-time use in cats before surgery to control postoperative pain associated with orthopedic surgery, spays and neuters.

Chapter 40

Mammary Glands

Mastectomy

H. Jay Harvey and Jonathan M. Miller

Introduction

Mastectomy, the removal of varying amounts of mammary tissue, is the primary method for treating tumors of the mammary gland in dogs and cats. However, the amount of tissue to remove is a subject of some controversy. Cure rates for patients with malignant mammary disease are still low even after massive amounts of tissue have been removed. The biologic behavior of the tumor, not the extent of treatment, determines the eventual fate of the patient. Nonetheless, properly performed surgical treatment of mammary tumors can modify disease progression, prolong comfortable survival, and be curative in some instances.

Surgical Anatomy

Mammary glands in the dog and cat are modified sudoriferous skin glands with an apocrine compound lobuloalveolar structure. Mammary glands are arranged in two parallel paramedian rows from the axillary to the inguinal regions. The glands are surrounded by subcutaneous adipose tissue, which is scant in the thoracic region and abundant in the inguinal region.

Individual glands are discerned by the corresponding teat, although mammary tissue can be confluent between adjacent cranial and caudal glands. The midline separation between mammary chains is distinct. Glands are signified by name (cranial and caudal thoracic, cranial and caudal abdominal and inguinal) or by number (1 through 5 cranial to caudal). Dogs usually have five pairs of mammary glands, and cats have four, although the number can range from four to six in either species.

Thoracic glands adhere directly to the underlying pectoral muscles with little intervening fat or areolar connective tissue. Abdominal glands are loosely attached to the external fascia of the rectus abdominus muscle by connective tissue and fat. Inguinal glands are suspended from the body wall by an extension of the cutaneous trunci muscle. Blood is supplied to the thoracic glands by perforating branches of the internal thoracic artery, by cutaneous branches of intercostal arteries, and by the lateral thoracic artery. Cranial abdominal glands receive blood predominately from the cranial superficial epigastric artery. Caudal abdominal and inguinal glands are supplied by the caudal superficial epigastric artery and by perivulvar branches of the external pudendal artery. Veins parallel arteries, except for numerous veins that traverse the midline, which enlarge during lactation.

Lymphatic drainage of the mammary glands is subject to individual variation and also is influenced by the stage of lactation and by the presence of space-occupying masses.

Lymph generally flows from the cranial three pairs of mammary glands toward the axillary lymph nodes and from the caudal two pairs toward the inguinal lymph nodes. A lymphatic connection between the cranial and caudal abdominal glands is present in some bitches.

Mammary Gland Neoplasia: Incidence and Prognosis

Neoplasia is the major indication for mastectomy in dogs and cats. Mammary tumors are the most common type of neoplasia in dogs and the third most common type in cats. Mammary neoplasia affects middle-aged and older animals, with a median age of onset of 10 to 11 years.

Only about half of all canine mammary tumors are malignant, whereas most (86%) feline mammary tumors are malignant. Prognosis for both dogs and cats with malignant tumors is guarded to poor. Although length of survival is inversely correlated with the growth rate of the tumor, the extent of local infiltration, and the status of regional lymph nodes and lungs, the major statistically significant survival factor is tumor volume. Both dogs and cats with large (> 3 cm) malignant mammary tumors have significantly shorter survival times than those with small malignant tumors, emphasizing the importance of early diagnosis and treatment.

Treatment failure is represented by intractable local recurrence or, more commonly, by the development of metastatic disease. Because metastatic mammary cancer is found most frequently in the lungs, thoracic radiography is a common screening test before mastectomy. Dogs with mammary cancer affecting the caudal mammary glands, especially when the inguinal lymph nodes are palpably enlarged, should also be radiographically or ultrasonographically checked for enlarged sublumbar lymph nodes, because metastasis through sublumbar lymphatics is often detectable before the radiographic appearance of lung metastases. Enlarged lymph nodes should be excised at the time of surgery in dogs and the draining lymph nodes routinely removed in cats. Axillary lymph nodes are not routinely removed unless palpably enlarged while the inguinal lymph node is removed when the inguinal mammary gland (#5) is excised. Lymph node removal is regarded as a staging rather than therapeutic procedure in most dogs.

Mammary neoplasia can be prevented by ovariohysterectomy performed when the bitch or queen is young (i.e., before the first estrus). Ovariohysterectomy loses its protective effect after the 4th estrus in the canine. However, although estrogen, progesterone, and other receptors have been found in canine and feline mammary tumors, it is controversial as to whether ovariohysterectomy has any beneficial effect as a treatment for existing mammary neoplasia. The current recommendation is to spay the animal at the time of mammary tumor excision.

Selection of Surgical Procedure

The amount of mammary tissue to remove from a dog or cat with mammary neoplasia is influenced by several factors: the size, consistency, and location of the tumor; the size, age, and physiologic status of the patient; and the beliefs and prejudices of the surgeon. Unfortunately, subjective criteria still play a major role in the selection of a mastectomy procedure because objective data for choice are inconclusive.

The extent of tissue removal with various mastectomy procedures is illustrated in Figure 40-1. For the purposes of this chapter, these procedures are defined as follows:

Lumpectomy (nodulectomy): Removal of the tumor only with 1 to 2 cm of surrounding normal tissue. Generally, lumpectomy is used when a tumor is small, encapsulated, and noninvasive, thus requiring a minimum of surgical dissection for removal.

Partial mammectomy: Removal of the tumor and a surrounding margin of mammary tissue. This procedure usually is indicated for tumors that are small to moderate in size (up to 2 cm in diameter) and occupy only a portion of an individual gland. The tumor may be suspected to be invasive and may or may not have palpable distinct margins.

Simple mastectomy: Removal of the entire mammary gland containing the tumor.

Regional mastectomy (modified radical mastectomy): Removal of groups of mammary glands depending on which glands contain tumor. The rationale for regional mastectomy depends on the presumed anatomy of mammary gland lymphatic drainage and the assumption that mammary cancer spreads from one gland to another along lymphatic pathways, which are not altered by space-occupying masses.

Complete unilateral mastectomy (radical mastectomy): Removal of all ipsilateral mammary glands, intervening tissues, and regional lymphatics.

Complete bilateral mastectomy (bilateral radical mastectomy): Removal of both entire mammary chains, intervening tissues, and regional lymphatics. If performed, a 3 to 4 week interval between sides is recommended to reduce skin tension and postoperative complications.

Available data indicate that the extent of surgery had little influence on either the survival time or the rate of recurrence of mammary cancer in dogs. In other words, no evidence indicates that complete unilateral mastectomy (radical mastectomy) is any more beneficial for treating a 2 cm tumor in the fourth mammary gland of a dog than is a simple mastectomy. Until further data is available, selection of a surgical procedure in dogs is dictated by what is most efficient with the goal of attaining clean surgical margins by complete removal of the tumor. Good oncologic surgical principles still apply, however, regardless of the procedure used, invasive tumor should be widely resected with deep and centrifugal 2 cm en bloc margins of normal tissue with early ligation of blood vessels performed.

In cats, complete unilateral mastectomy is the surgical procedure of choice for all mammary tumors. This approach has been

recommended by veterinary oncologists because most feline mammary tumors are highly malignant. The 10 to 15% of cats with benign mammary nodules are overtreated by this philosophy.

Surgery is contraindicated for inflammatory carcinoma of the mammary gland. Inflammatory carcinoma of the mammary gland is a fulminant and aggressive malignant disease. Affected tissues are diffusely thickened, inflamed, painful, and frequently ulcerated. A space-occupying mammary mass may or may not be obvious. Commonly, the tissues are so diffusely thickened that discrete tumors are not apparent. The condition closely resembles severe mastitis and is frequently misdiagnosed as such. Surgery is unrewarding because it is virtually impossible to remove the affected tissues completely, and, more important, because most affected dogs also suffer from disseminated intravascular coagulation. Attempts at extensive surgical therapy often result in severe, intractable bleeding from the incision, deterioration of the patient over 12 to 24 hours, and death. Inflammatory mammary carcinoma is invariably fatal, usually within a month after clinical signs are obvious. Treatment is strictly palliative and consists of antiinflammatory drugs, analgesics, and antibiotics.

Surgical Techniques

Mastectomy procedures are performed similarly in cats and dogs, although the laxity of feline skin generally makes surgery easier in cats.

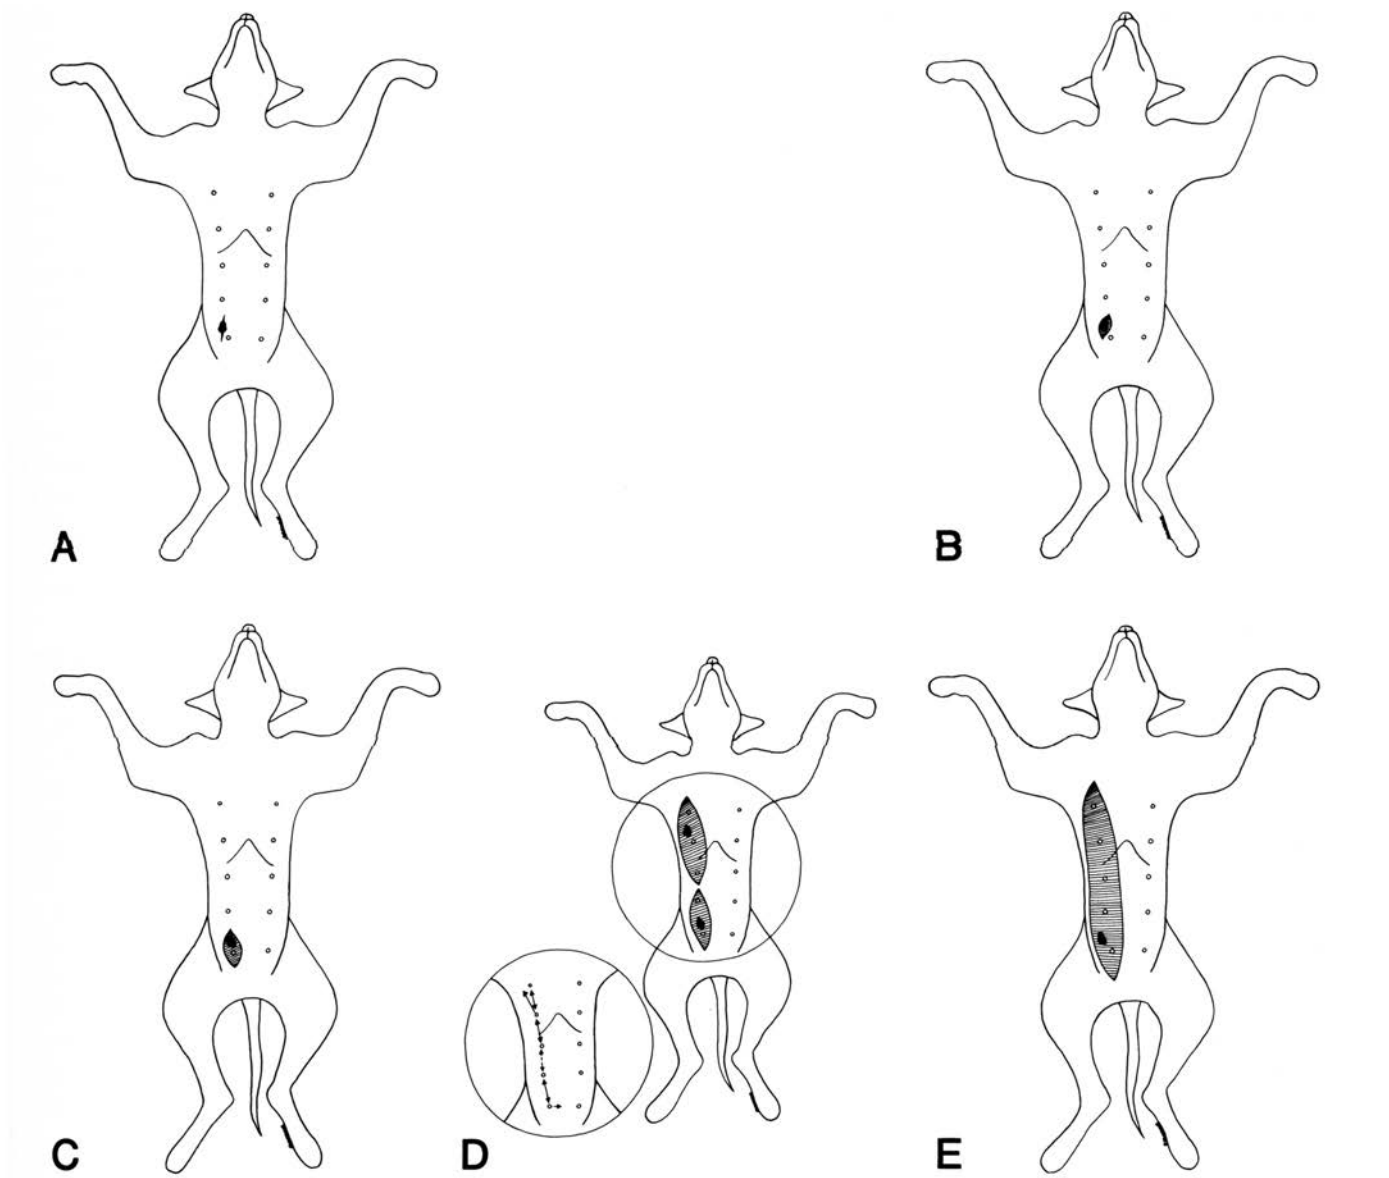

Figure 40-1. Comparison of extent of tissue removal with different mastectomy procedures. **A.** Lumpectomy. Skin incision is made directly over the tumor. **B.** Partial mastectomy. An elliptic skin incision is made, encompassing the tumor and a portion of the surrounding mammary tissue. **C.** An elliptic skin incision is made to encompass the gland that contains the tumor completely. **D.** Regional mastectomy. An elliptic skin incision is made to encompass the glands to be removed, as determined by the location of tumor and the presumed pathways of lymphatic drainage (inset). Generally, the first three glands are removed en bloc when tumor exists in any one of them; likewise, the last two glands are removed en bloc when tumor exists in either of them. Some authors recommend that the third gland be removed whenever the fourth and fifth are excised because of the "inconstant" lymphatic drainage between the third and fourth glands. **E.** Complete unilateral mastectomy. The skin incision encompasses all ipsilateral mammary glands. See the text for details of the dissection.

Lumpectomy

A lumpectomy is initiated by making a skin incision directly over the tumor. The mammary tissue overlying the tumor is bluntly separated. The periphery of the tumor is grasped with forceps, and the natural tissue planes adjacent to the isolated tumor are defined by blunt dissection with mosquito hemostats or by wiping the tissues away from the tumor with a sponge (sponge dissection). The tumor is removed, partially sectioned, and placed in 10% buffered formalin. After hemorrhage is controlled, the wound is closed by approximating mammary tissue with fine (4-0) absorbable suture. Skin is closed with suture of the surgeon's choice.

Partial Mammectomy

A liberal incision is made over the tumor. If the tumor contacts or is adherent to the skin or subcutaneous tissue (i.e., if the tumor is "fixed" to skin), an elliptic incision is made that encompasses both the tumor and the affected skin. An artificial plane of dissection is developed in normal mammary tissue surrounding the tumor. A liberal amount of tissue, often approaching one-third to one-half of the affected gland, is removed. Closure of the defect in the gland is by direct apposition of tissue if possible. Subcutaneous tissue apposition with 4-0 or 3-0 absorbable suture is performed to reduce tension on the skin closure. The skin is closed routinely.

Simple Mastectomy, Regional Mastectomy, and Complete Unilateral Mastectomy

The basic technique for simple mastectomy, regional mastectomy, and complete unilateral mastectomy is the same. All these procedures involve removal of the skin segment that encompasses the affected mammary gland or glands. Surgery is initiated by making an elliptic incision with 2 cm margins around the mammary gland or glands to be removed. The incision is extended sharply through the subcutaneous tissue to the body wall. In the thoracic region, the body wall is represented by the pectoral muscle and in the abdominal region by the external rectus fascia. A plane of dissection that allows the skin segment and associated mammary tissues to be cleanly stripped from the body wall is then established. The proper plane of dissection is deep to the adipose tissue and directly on the muscle fascia.

In the abdominal and inguinal regions, the glands are loosely adherent and can be stripped from the underlying fascia with a sponge (Figure 40-2A). In the thoracic region, the glands adhere to the underlying muscle, and the plane of dissection must be developed by a combination of sharp and blunt dissection with scissors (Figure 40-2B). The proper thoracic plane is represented by lacy but tough strands of fibrous connective tissue. Traction on the rostral portion of the skin segment facilitates dissection. Dissection proceeds from cranial to caudal without, in most cases, the need to damage underlying muscle. When removal of tissues is completed, intact muscle should be clearly visible in the thoracic region and rectus fascia should be seen in the abdominal region.

Invasion of underlying tissue by tumor, whether pectoral muscle in the thoracic region or rectus fascia in the abdominal region, requires en bloc resection of the affected body wall tissue with the tumor. In extreme cases, full-thickness resection of the body wall must be done to remove all visible tumor, even though body wall invasion by tumor is a grave prognostic sign, and even massive surgical resection is seldom curative.

Inguinal gland removal entails en bloc removal of the inguinal fat. Care must be taken to isolate and ligate the caudal superficial epigastric artery and vein, which emerge from the inguinal canal (Figure 40-3). The vaginal process, the finger-shaped protrusion of fat extending through the inguinal canal, along with the artery, vein, and vaginal ligament, may be bluntly separated from the inguinal fat and left behind or ligated and removed. Inguinal lymph nodes are removed along with the skin segment, mammae, and inguinal fat when the dissection is done correctly. Arteries and veins from the pudendal vessels enter the inguinal glands caudally from the tissues around the vulva and may require ligation or cauterization depending on their size.

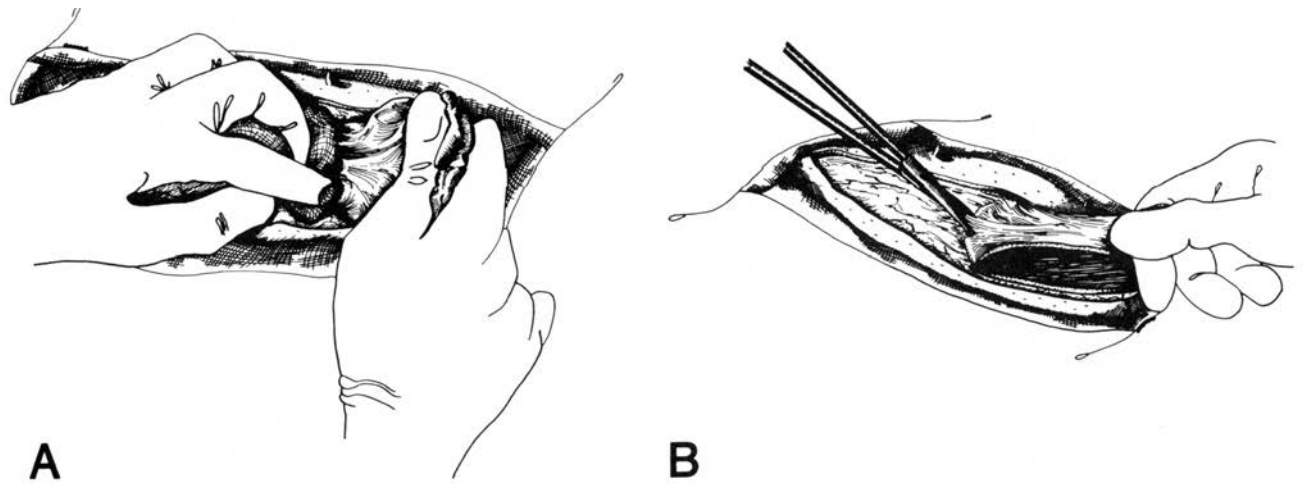

Figure 40-2. Developing a proper plane of dissection greatly facilitates simple, regional, and complete unilateral mastectomy procedures. **A.** In the abdominal and inguinal regions, the loosely adherent mammary glands can be stripped from the underlying fascia with a sponge. **B.** In the thoracic region, the glands adhere to the underlying muscle, so dissection with scissors is required.

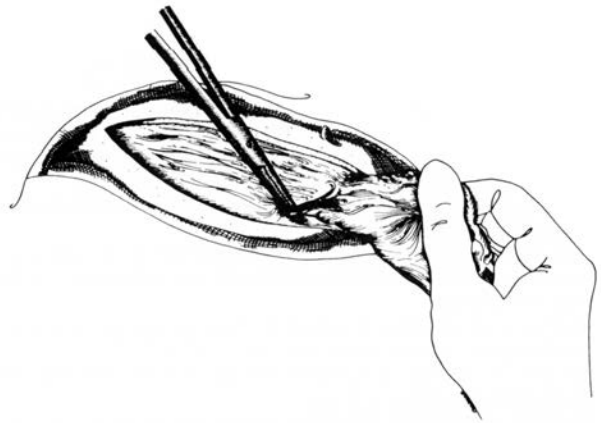

Figure 40-3. The superficial epigastric artery and vein emerge from the inguinal canal deep to the fifth mammary gland in the dog. When this gland is excised, these vessels must be isolated, clamped, divided, and ligated. The inguinal lymph node is contained with in the fat pad that is excised along with the gland.

Closure of the tissue defect left after a simple, regional, or complete unilateral mastectomy must account for the considerable dead space created. In most instances, drains, stents, bandages or reconstructive procedures are not necessary. Even large defects can be closed by initially apposing skin edges with subcutaneous absorbable suture. An interrupted pattern is preferred. The subcutaneous tissue may be tacked to the underlying body wall to reduce dead space. Skin is then closed according to the surgeon's preference. An interrupted cruciate suture pattern of 2-0 or 3-0 monofilament nylon can be placed quickly and distributes tension well (Figure 40-4). This pattern has the advantage of being an interrupted pattern, but one that spans a longer segment of incision per suture than a simple interrupted pattern. Regardless of the suture pattern used for skin closure, the ultimate success of skin apposition depends on placement of a proper subcutaneous suture line.

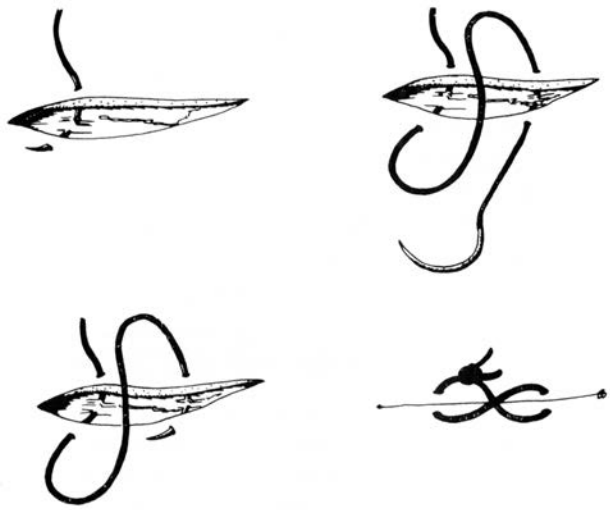

Figure 40-4. An interrupted cruciate suture pattern is recommended for closure of skin incisions with simple, regional, or complete unilateral mastectomies.

Postoperative Care and Complications

Postoperative complications associated with mastectomy include seroma formation, wound dehiscence, and edema of one or both rear limbs. Seroma formation is most common in the inguinal region and may be treated by the use of warm, moist compresses. Drainage by aspiration helps temporarily but increases the risk of infection. Wound dehiscences, if not extensive, are best left to heal by second intention. Extensive dehiscences may require debridement and delayed or secondary closure.

Rear limb edema may occur because of the surgical procedure or because of lymphatic invasion by the tumor. Removal of inguinal mammary tumors temporarily interrupts lymphatic drainage by removing lymphatic vessels and nodes. Moderate exercise, warm compresses, and time usually result in edema resolution. More ominous is the edema that results from tumor emboli in lymphatic vessels between the mammary glands and the sublumbar nodes and from tumor metastasis to sublumbar lymph nodes.

The latter situations are grave prognostic indications, and whereas edema may subside as potential lymphatic pathways become established, the chances for complete return to normal tissue fluid homeostasis are remote. Blockage of lymphatic vessels or nodes by tumor infiltration sometimes results in "retrograde metastasis." For example, inguinal tumor may extend distally in a string of nodules on the medial aspect of the hind leg.

Ovariohysterectomy, may improve survival time and may be desired at the time of mastectomy for other reasons. Spaying should performed before the mastectomy, taking care to not contaminate or introduce tumor cells into the abdomen. After the ovariohysterectomy and closure of the linea alba are completed, the skin incision forms part of the medial border of the mastectomy incision and is extended as needed to encompass the mammary gland or glands to be removed. Mammary tumors that extend across the midline should be removed before the ovariohysterectomy.

Chapter 41

Skin Grafting and Reconstruction Techniques

Skin Grafting Techniques

Michael M. Pavletic

In general, the simplest closure techniques are considered for problematic skin wounds, provided that the closure provides the appropriate durability and restores reasonable function to the area. Primary closure by apposition of skin margins normally is the simplest skin closure technique. Tension relieving techniques can be used to facilitate primary closure. In some cases, healing by contraction and epithelization is a practical option for wound closure, provided that this physiologic process can achieve the desired results in a timely fashion. There are occasions where open wound management can be more expensive than other surgical closure options. Skin stretchers, simple skin flaps, skin grafts, and axial pattern flaps are additional options for closing more challenging skin defects.

Anatomic Considerations

Preserving circulation is key to skin survival in wound management and closure. Direct cutaneous vessels are the primary vascular channels to the interconnecting cutaneous vascular network: the deep or subdermal plexus; middle or cutaneous plexus; and the superficial or subpapillary plexus (Figure 41-1). The elastic direct cutaneous arteries travel parallel to the overlying skin surface: they arborize to supply blood to the major capillary network, the subdermal plexus.[1,2]

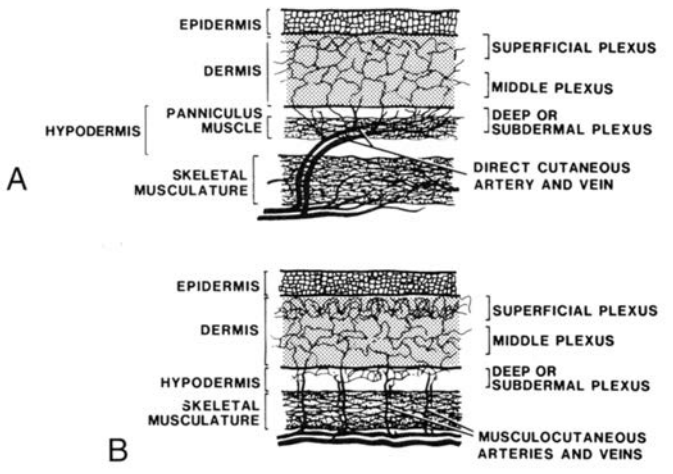

Figure 41-1. A. Cutaneous circulation in the dog and cat. **B.** Human cutaneous circulation. The subdermal plexus is formed and supplied by terminal branches of direct cutaneous vessels at the level of the panniculus muscle in the dog and cat. Note the parallel relationship of the direct cutaneous vessels to the overlying skin in the dog and cat, in contrast to the perpendicular orientation of musculocutaneous vessels in the human. (From Pavletic MM. The integument. In: Slatter DH, ed. Textbook of small animal surgery. Philadelphia: WB Saunders, 1980.)

The direct cutaneous vessels and subdermal plexus reside in the hypodermal tissue layer beneath the dermis. Both are closely associated with the panniculus muscle layer, in areas where this cutaneous muscle layer exists. The major panniculus muscles include the cutaneous trunci, platysma, sphincter coli superficialis, and supramammarius muscles. This close relationship can be exploited to help preserve skin circulation during surgery.[1,2]

Undermining Skin

Undermining skin is normally performed to facilitate the mobilization of the skin for wound closure and skin flap elevation. The following points should be considered to help preserve circulation to the skin:

1. Undermine skin below the panniculus muscle layer when present, to preserve the subdermal plexus and associated direct cutaneous vessels supplying the overlying skin.
2. Undermine skin, lacking a panniculus muscle layer (eg. middle, distal portions of the extremities) in the loose areolar fascial plane below the dermis.
3. Preserve direct cutaneous vessels encountered during undermining of the skin, if possible.
4. Elevate skin closely associated with an underlying muscle by including a portion of the outer muscle fascia with the dermis to preserve the subdermal plexus.
5. If possible, avoid or minimize the surgical manipulation of skin recently traumatized until circulation improves, as noted by the resolution of contusions, edema, and infection.

Avoid direct injury to the subdermal plexus by using atraumatic surgical technique. Sharp scalpel blades should be used to incise skin; avoid cutting skin with scissors. Skin hooks, stay sutures, Brown Adson forceps and DeBakey forceps can be used to manipulate the skin; avoid crushing instruments, including the use of Allis tissue forceps.[2-5]

Technique Selection

Wound size and location usually dictates the technique(s) that should be considered for closure. The local availability of a loose, elastic skin will help determine if simpler closure techniques can be considered in a given case. Other potential sources of donor skin are then assessed. The primary goal is to restore function to the injured area, preferably with reasonable cosmetic results.[5]

Lower extremity wounds are particularly problematic due to the relative lack of circumferential skin. Wounds less than 90° circumference may close by second intention in some cases; the probability of contraction and epithelization decreases as the circumference of the defect increases.[5]

Clearly wounds approaching half or more of the limb's circumference require closure with a skin graft or flap. By contrast, the trunk has variable amounts of loose, elastic skin to facilitate wound closure by second intention, skin advancement, flaps, or simply by applying skin stretchers. In many cases, skin stretchers are simpler and more effective to use for closure of moderate to large skin defects.[5]

Although open wound management may be both practical and economical in managing many wounds, costs can add up especially in those cases where contraction and epithelization is slow. Bandages, dressings, topical agents, and recheck appointments cumulatively can approach or exceed surgical closure. Periodic reassessment of the wound, and clear communication can eliminate misunderstandings that occasionally occur with the pet owner. Flap and/or graft closure may be reserved for those wounds where 2nd intention healing fails to make significant gains in wound closure.[5]

Unlike humans, skin flaps generally are considered a more practical method to close problematic wounds in veterinary medicine; in human reconstructive surgery skin grafts are often preferred. Skin grafts are most useful for the more problematic lower extremity defects, and large surface area wounds where flaps and skin stretchers are not practical options.[5]

Skin Flaps (Pedicle Grafts)

A skin flap is an elevated portion of skin and subcutaneous tissue with a vascular attachment to the body. The base or pedicle of the flap may be a cutaneous attachment (with its intact capillary network), or an "island" segment of skin tethered by a single direct cutaneous artery or vein. Flaps also may be elevated with an underlying muscle which provides a source of circulation though interconnecting vascular channels: they are termed myocutaneous or musculocutaneous flaps.[3,5]

Skin flaps are particularly useful in small animals, allowing the veterinarian to utilize local or regional loose skin for closure of problematic wounds. They can be transplanted into areas devoid of circulation, unlike skin grafts which rely on revascularization from underlying healthy vascularized tissues for survival. Because the complete dermis and hypodermis are present, skin flaps have excellent durability and hair growth. Properly developed and transferred, skin flaps do not require the more elaborate bandage protection and immobilization needed for skin graft survival.[3,5]

Pedicle grafts can be classified according to their (1) type of circulation; (2) location in relation to the recipient (wound) bed; and (3) tissue composition (eg., myocutaneous flaps, compound/composite flaps). Most skin flaps are based on the subdermal plexus circulation *(subdermal plexus flap)* (Figure 41-2) incorporation of a direct cutaneous artery and vein results in the formation of an axial pattern flap (Figure 41-3). A variation of the axial pattern flap is the *island arterial flap*, in which the entire skin flap is detached from the body, but tethered by a paired direct cutaneous artery and vein (Figure 41-4). Because of their excellent blood supply, axial pattern flaps can be developed of greater dimensions for closing sizeable skin wounds.[3,5-7]

Flaps elevated immediately adjacent to the recipient bed are termed *local flaps*, whereas flaps elevated from a more remote location are termed *distant flaps*. Flaps made adjacent to a wound are technically easier to perform, provided that sufficient skin is available for their development. Distant flaps normally are more difficult to elevate and transfer. Historically distant flaps have been classified according to the method of transferring the skin to a given wound, including: delayed tube flap (indirect

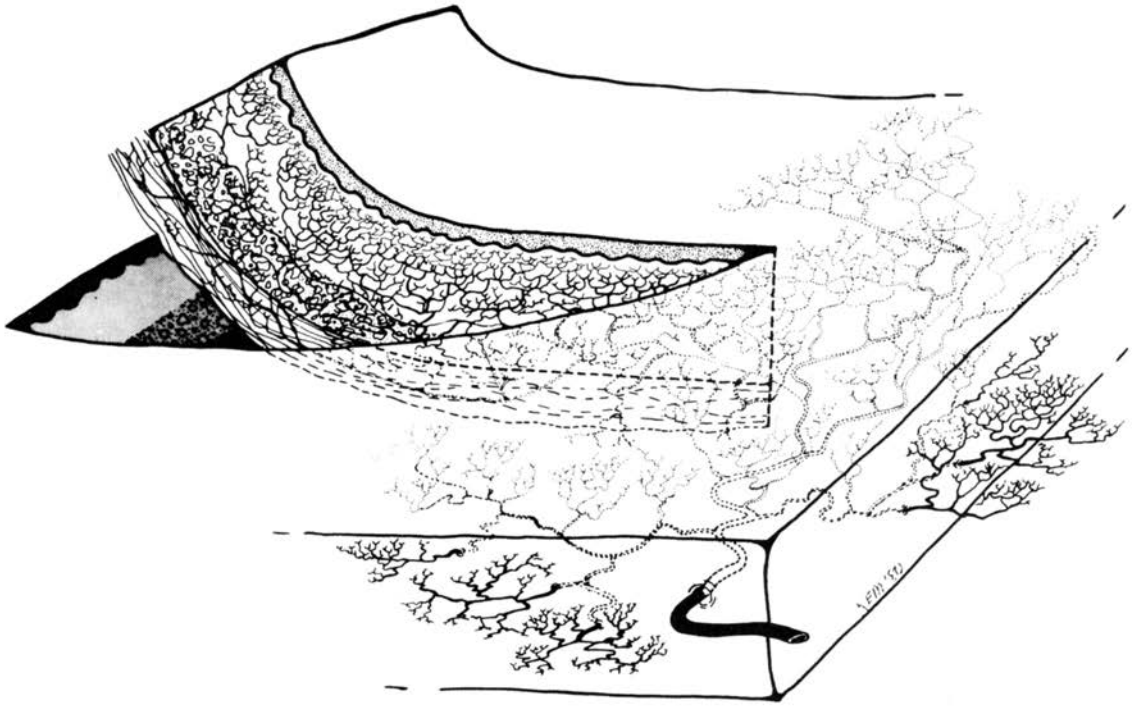

Figure 41-2. The subdermal plexus flap in the dog and cat. This flap is analogous to the random or cutaneous flap in human patients. The flap is nourished by the subdermal plexus and attenuated branches of the direct cutaneous vessels some distance away. (From Pavletic MM. Canine axial pattern flaps, using the omocervical, thoracodorsal, and deep circumflex iliac direct cutaneous arteries. Am J Vet Res I98I;42:39I.)

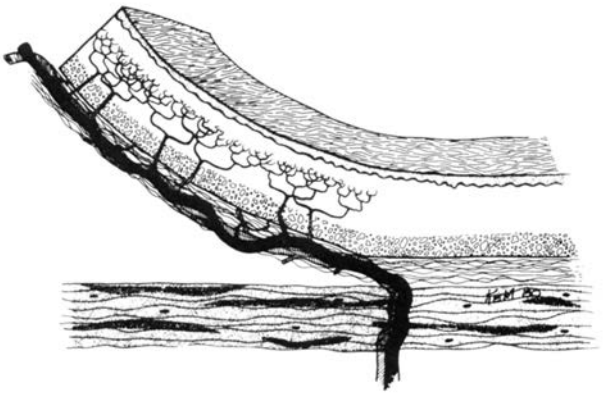

Figure 41-3. Axial pattern flap (arterial pedicle graft) in the dog and cat. A flap created over the direct cutaneous vessels has an intact blood supply capable of supporting a flap of considerable size. An axial pattern flap in humans is similar, with the exception of their poorly developed panniculus muscle. (From Pavletic MM. Canine axial pattern flaps, using the omocervical, thoracodorsal, and deep circumflex iliac direct cutaneous arteries. Am J Vet Res I98I;42:39I.)

flap); elevation of the affected limb beneath a flap created on the trunk (direct flap). Axial pattern flaps have largely precluded the routine use of these more labor-intensive distant flap techniques. Similarly, most distal extremity wounds are better managed with skin grafts.[3,5-9]

Flaps need not be exclusively comprised of skin or mucosa alone. As noted above, skin flaps also can be elevated with an underlying muscle segment, creating a myocutaneous flap (Figure 41-5). Flaps comprised of two or more tissues are called *compound* or *composite flaps*. Muscle, bone and cartilage also may be included in these flaps.[3,5,10] For example, a full-thickness labial flap is comprised of mucosa, skin, and a central musculofascial layer. Oral composite flaps are useful for oral and nasal reconstructive surgery. However, these more specialized flap techniques are less commonly used compared to skin flaps and grafts for wound closure.[5]

General Principles of Flap Development

The wound size, location, shape, and condition dictate the technique(s) required to close the defect. In general, surgeons try to used the simplest, most direct technique to close the wound and restore function to the area.[3,5]

The elastic properties of the skin are assessed adjacent to the wound. Ideal donor areas have ample skin available to elevate a flap and close the donor bed under minimal tension. The scrotum also has been used to close adjacent wounds by flap advancement or rotation into the wound.[11] There are occasions where wound closure to protect an important anatomic structure may take precedent over creating a donor defect that cannot be closed after transposing the flap.[5]

The size of the wound will dictate the size of the skin flap required to close most, if not all of the defect. In some cases, partial wound closure with a skin flap may be sufficient to successfully close the recipient bed, with the assistance of 2nd intention healing for the remaining portion of the area. If there is insufficient healthy skin available for local flap development, axial pattern flaps, skin grafts, and skin stretching options are considered.[5]

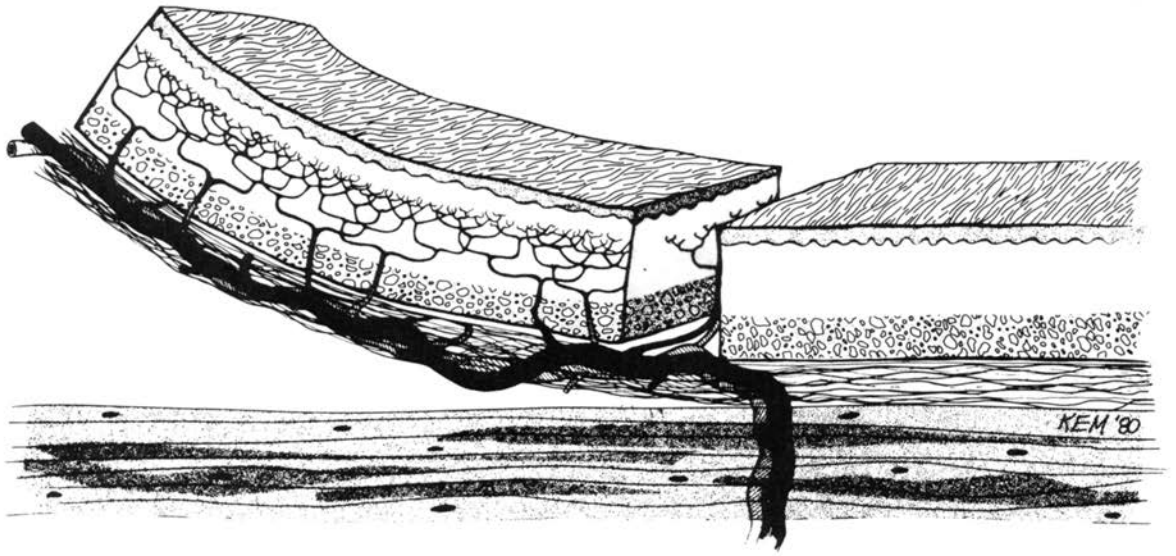

Figure 41-4. Island arterial flap (island axial pattern flap) in the dog. The graft is nourished solely by the direct cutaneous artery and vein. Island flaps have greater mobility than axial pattern flaps. Vessels have the potential to be severed and reanastomosed with microvascular surgery at a distant recipient site. (From Pavletic MM. Canine axial pattern flaps, using the omocervical, thoracodorsal, and deep circumflex iliac direct cutaneous arteries. Am J Vet Res 1981;42:391.)

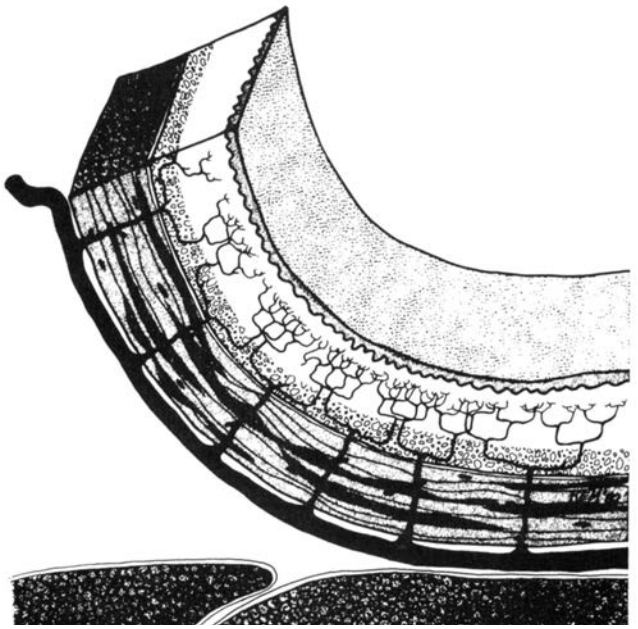

Figure 41-5. Myocutaneous flap in a human patient. The skin is nourished by musculocutaneous vessels, which receive circulation from the intact skeletal muscle vasculature. (From Pavletic MM. Canine axial pattern flaps, using the omocervical, thoracodorsal, and deep circumflex iliac direct cutaneous arteries. Am J Vet Res 1981:42:391.)

Flap orientation is considered both for the relative ease of transference and the positioning of the pedicle for optimal circulation. Factors that help preserve circulation to a flap include: (1) the base of the flap should be equal to or slightly wider than the uniform width of the flap (island arterial flaps are an exception); (2) the flap length should be kept to the *minimum* required to close the wound without undue tension. However, simply increasing the width of a flap does not increase the total length of survival, unless direct cutaneous vessels are incorporated into the pedicle.

It is preferable to orient a subdermal plexus flap's base in the direction of a direct cutaneous artery/vein if possible. With few exceptions, necrosis associated with a skin flap is the result of insufficient circulation to sustain the tissue.[3,5]

Wound (Recipient Bed) Preparation

The recipient bed should be free of debris, necrotic tissue, and infection prior to closure. Unlike free grafts, skin flaps can survive over defects which have little or no circulation. Chronic granulation tissue can be resected at the time of flap closure. In some cases, the fibrotic and contaminated tissue can be removed, allowing for a healthy granulation bed to form within 3 to 5 days, thereby creating a more suitable wound surface for flap application. The epithelialized wound borders also are removed, thereby enabling the surgeon to close the defect completely with the skin flap.[3,5] Chronic radiation beds can be problematic to close, as a result of a dramatic decline in circulation over time. Skin flaps, muscle flaps, and myocutaneous flaps are options to close these wounds, provided that the vascular pedicle is preserved.[5]

Surgical Techniques

Local Flaps

Local flaps remain as one of the most simple and practical methods of closing small to moderate sized problematic wounds. Their effective use requires loose, elastic skin adjacent to the wound as a donor source for flap development. Local flaps normally are based on the subdermal plexus circulation. As noted, flaps must be kept as short as possible to help assure that perfusion can reach the terminal end of the flap. Local flaps are broadly classified as advancement flaps or rotating flaps. Local flaps can be developed in most body regions, although their use is somewhat limited in the lower extremity regions. The axillary and inguinal skin folds can be used in a similar fashion.[12,13] The following are the most useful local flaps to consider on a routine basis.[3,5]

Single-Pedicle Advancement Flap

The single-pedicle advancement flap (sliding flap) is simple in design and execution. The width of the flap approximates the width of the defect. Their effective use requires the flap to advance or stretch directly into the defect. The advanced flap simultaneously closes both the donor and recipient beds.[3,5]

To create a single-pedicle advancement flap, two skin incisions equal to the width of the wound are made in a staged or incremental fashion. In general, it is useful to have the two incisions slightly diverge to assure that the base of the flap is not inadvertently created too narrow thereby compromising circulation. The distant edge of the flap, bordering the wound is gently grasped, elevated, and the flap undermined. The process is continued until the flap stretches (advances) over the recipient bed. In most dogs and cats, 3-0 monofilament suture material is used to secure the flap (Figure 41-6).[5]

As noted, the length of the flap should be kept to the minimum in order to close the wound without excessive tension. Two shorter single-pedicle advancement flaps, on opposing sides of the wound, can be used to close longer defects. Termed "H-Plasty" two shorter flaps may close the wound without resorting to a single, longer advancement flap (Figure 41-7).[5]

The primary problem associated with advancement flaps is their reliance on stretching over the wound. There is a tendency for elastic retraction by the collagen fibers in the flap's dermis. This can contribute to postoperative distortion in some clinical situations. For example, advancement flaps, used to close problematic eyelid wounds, occasionally will distort the lid margin resulting in an unsatisfactory result both cosmetically and functionally. Under these circumstances, a 90° transposition flap should be considered, since this rotating flap closes wounds by "donating" additional skin to the immediate area.[3,5]

Bipedicle Advancement Flap

A bipedicle advancement flap is created by making two parallel incisions and undermining the skin segment: the flap is advanced at a right angle to its long axis. Bipedicle flaps are usually considered for closing adjacent elongated wounds. Although circulation is derived from two pedicles, long release incisions may result in a more centrally located "ischemic zone" with necrosis. If sufficient skin is present, the donor area can be closed (Figure 41-8).[3,5]

The release or relaxing incision in design and execution is a bipedicle advancement flap. Release incisions are used to reduce tension on an adjacent incision. Used in this fashion, the release incision is left open to heal by second intention. Release incisions may be little more than 1 or 2 centimeter "stab wounds" or extended several centimeters to close a problematic skin wound. As a general rule release incisions are no closer than 3 to 5 centimeters from incision.[5]

Transposition Flap

A transposition flap is a rectangular pedicle graft that pivots into position. Normally transposition flaps are rotated at a 45° to 90° angle in relation to the long axis of the skin defect. Flaps can be transposed at an angle greater than 90° although the flap length will shorten with this greater arc of rotation. One border of the flap generally contacts the wound border (Figure 41-9). Transposition flaps can be developed in most body regions, although their size is somewhat limited in the mid- to lower extremities.[5]

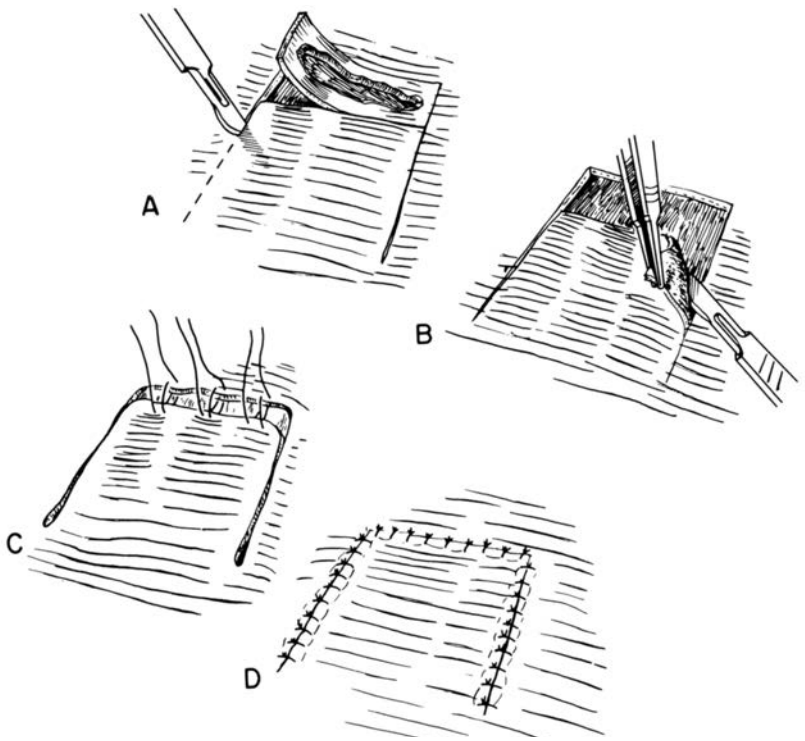

Figure 41-6. Single-pedicle advancement flap. **A.** Removal of skin lesions and outline of intended flap incisions. **B.** The flap is lengthened and undermined enough to allow for closure without excessive flap tension. **C.** Preplacement of tension sutures may aid in flap alignment. **D.** Closure.

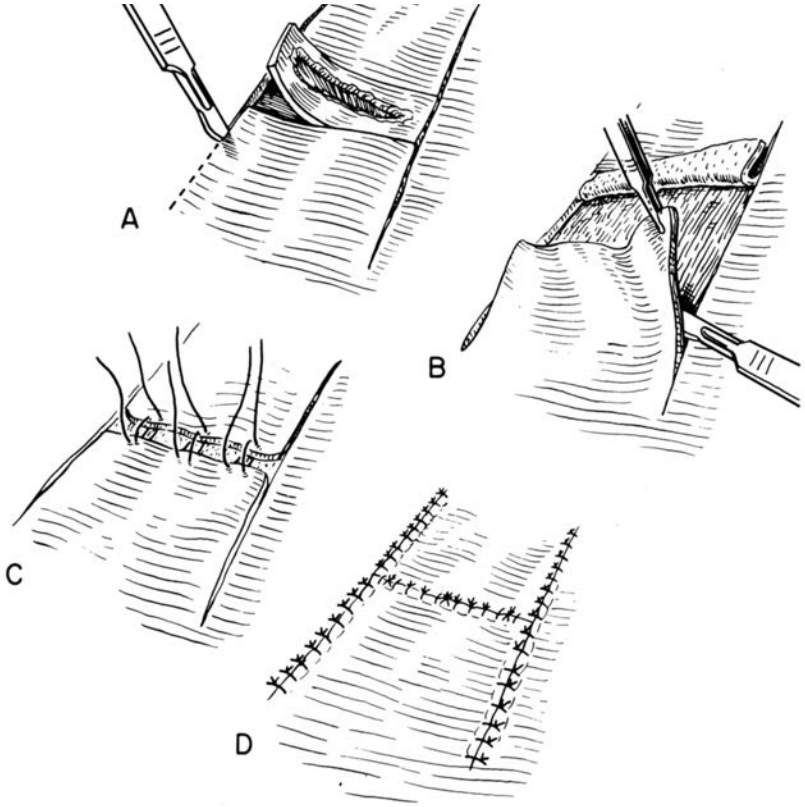

Figure 41-7. Sliding H-plasty. **A.** Removal of lesion and outline of the flaps on both sides of the defect. **B.** Undermining of both flaps. **C.** Alignment. **D**. Closure.

Figure 41-8. Bipedicle advancement flap. **A**. The flap width generally equals the width of the defect. **B.** The secondary defect (donor bed) is closed by direct apposition. (Redrawn from Grabb WC, Myers MB. Skin flaps. Boston: Little, Brown, 1975.)

Flap width approximates the width of the "rectangular" shaped defect; the flap length is measured from the *pivot point* of the flap base to the most distant point of the defect (Figure 41-10). To reduce tension, a stab or release incision may be created along the line of greatest tension. Alternatively, a release incision can be created in the skin adjacent to the defect, thereby eliminating the need to incise the flap. In practice, I will measure flaps with the above dimensions. In many cases, I will shorten the calculated length of the flap if possible, thereby improving the chance that reasonable perfusion can nourish the terminal flap border.[3,5]

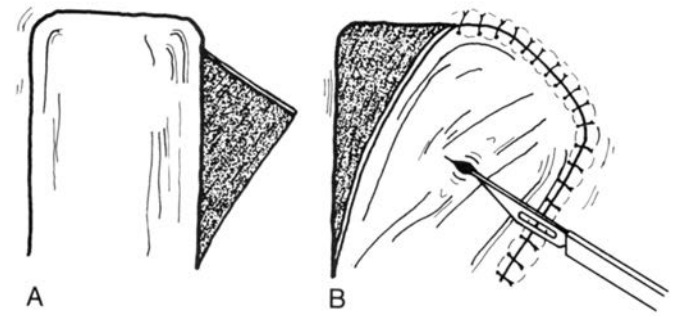

Figure 41-9. A and **B.** When creating a transposition flap, adjustment should be made to allow for the length loss caused by rotation of the flap. A stab incision made over the line of greatest tension can be used to relieve any excessive tension developed on transfer. The secondary defect can be closed by undermining and direct suture closure. (Redrawn from Grabb WC, Myers MB. Skin flaps. Boston: Little, Brown, 1975.)

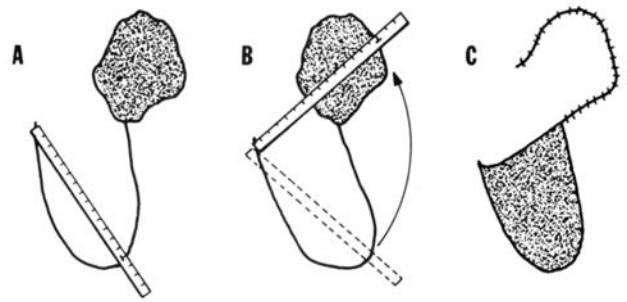

Figure 41-10. Transposition flap. **A.** Removal of defect and outline of the intended flap incision. **B.** Rotation and alignment of flap. **C.** Closure. The ruler measurement from the pivot point to the tip of the flap must equal the distance between the pivot point and the most distant point of the defect (recipient bed). The secondary defect is sutured closed after local undermining.

Z-Plasty

Z-plasty, by design, is a variation of the transposition skin flap. A "Z" shaped incision is created with the central limb of the "Z" placed parallel to, and overlying a problematic tension band. When each flap is transposed into their opposing donor beds, wound closure is achieved while modestly reducing tension in the immediate area. In veterinary medicine, Z-plasty is primarily used to reduce incisional tension or lengthen a restrictive scar band. In humans, Z-plasties (and its variation, W-Plasty) are used to cosmetically mask linear scars.[5] Use of multiple small z-plasties is not considered very effective for lengthening restrictive scars.

The basic design employed is creating a Z-shaped incision at 60° angles to the central limb of the "Z." Each incision is equal in length. The key to understanding Zplasty is the following: the central limb is aligned parallel to, and overlying the "line of tension." The net gain in length theoretically is 75% of the length of the central limb, after each triangular flap is transposed in opposite directions. In practice, the net gain is closer to 50%. In figure 41-11, z-plasty is employed to lengthen a restrictive scar.

Similarly, this Z-plasty technique can be used to lengthen a local area of skin tension to facilitate incisional closure (for example, a portion of a skin incision, after tumor removal, cannot be closed due to regional skin tension). The incisional gap is determined in centimeters. To lengthen this line of tension, a Z-plasty incision 5-10 centimeters from the incision with the central limb of the "Z" aligned over the tension "band." For example, to obtain a 3 centimeter gain, the Z-plasty central limb is aligned to this zone of tension with each incision 6 centimeters long. The Z-plasty is created, the problematic incision in closed, and each triangular flap is sutured into their transposed position}.[5]

The author prefers skin stretchers, the 90° transposition flap, and release incisions to relieve skin tension. However, some surgeons find the Z-plasty useful and effective for reducing incisional tension as described above.

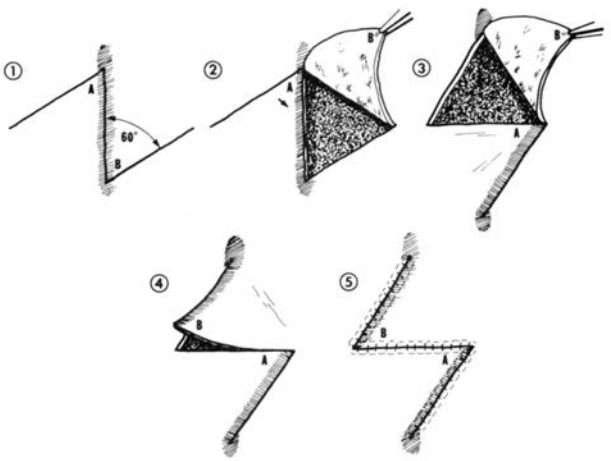

Figure 41-11. Z-plasty technique to lengthen a restrictive scar (shaded area): *(1)* a central incision is made over the scar, and two additional incisions equal in length to the central incision are created at a 60° angle forming a Z; *(2)* triangular flaps *A* and *B* are elevated and *(3, 4)* are transposed to their opposing bed; *(5)* the equilateral triangular flaps are sutured into place, resulting in a lengthening of the previously restricted area by 75%.

Axial Pattern Flaps

Axial pattern flaps receive a major source of their circulation by incorporating a direct cutaneous artery and vein into the flap's pedicle. As a result large skin flaps can be created with greater assurance of flap survival, provided the vessels are preserved.[3,5] There have been several papers describing the use of axial pattern flaps in the more recent veterinary literature describing the use of the lateral thoracic artery and superficial temporal artery in the dog and cat.[14-16] Other papers have described the use of various axial pattern flaps in wound closure with their clinical outcome.[17-20] Table 41-1, summarizes the major axial pattern flaps most commonly used in the dog and cat (Figures 41-12 and 41-13).[3,5,22-29]

Careful positioning of the patient is necessary for outlining each flap, using marking pens: skin distortion in relation to anatomic landmarks used for flap may result in failure to incorporate the vessels.[3,5] Axial pattern flaps can be rotated into a variety of wounds. On occasion the flap must cross over skin interposed between the donor and recipient sites. A "bridge incision" or partial tubing of the flap may be used to cross over this area. The flap may be shaped in the standard rectangular (peninsular design) shape or modified with a right angle (hockey-stick variation) for closure of wider or irregular problematic wounds.[5]

Axial pattern flaps may be converted to an island arterial flap, by cutting the cutanenous pedicle.[3,5] Tethered by the direct cutaneous artery and vein, the mobile island flap can be pivoted 180° into a defect. This technique is normally reserved to close large skin wounds that encroach on the normal base of the flap, thereby creating an island arterial flap by "default." Surprisingly, the survival area of island arterial flaps and axial pattern flaps is nearly identical.[24,30] A variation of this technique, the neovascular island flap has been reported in the dog for closure of small trophic ulcers of the paw.[31]

The thoracodorsal and caudal superficial epigastric axial pattern flaps are the most versatile in the dog and cat, based on their length and arc of rotation (See Figures 41-12 through 41-15). Nonetheless, the other axial pattern flaps provide a wide array of options for the veterinary surgeon to consider for closing wounds secondary to trauma or tumor removal.[5,26,32,33,34]

Compound and Composite Flaps

Although musculocutaneous (myocutaneous) flaps can be used to close skin defects, they may be better suited for closure of problematic wounds where muscle "padding" may be beneficial. The latissimus dorsi muscle, alone or as a myocutaneous flap, can be used for thoracic wall reconstruction. It also can be used to cover problematic elbow ulcers, providing padding over this bony prominence (Figures 41-14 and 41-15). The cutaneous trunci myocutaneous flap is better suited to exclusive wound closure, although the adjacent thoracodorsal axial pattern flap is better suited to closing the larger wounds within their respective arcs of rotation.[5]

Secondary or revascularized myocutaneous flaps can be created by grafting skin onto a muscle; once healed, the muscle is elevated

Table 41-1. Summary of Guidelines for Axial Pattern Flap Development

Artery	Anatomic Landmarks
Cervical cutaneous branch of the omocervical artery	Spine of the scapula Cranial edge of the scapula (cranial shoulder depression) Dogs in lateral recumbency, skin in natural position, thoracic limb placed in relaxed extension Vessel originates at location of the prescapular lymph node
Thoracodorsal artery	Spine of the scapula Caudal edge of the scapula (caudal shoulder depression) Dog in lateral recumbency, skin in natural position, thoracic limb in relaxed extension Vessel originates at caudal shoulder depression at a level parallel to the dorsal point of the acromion
Superficial brachial artery	Flexor surface of elbow Humeral shift Greater tubercle
Caudal superficial epigastric artery	Midline of abdomen Mammary teats Base of prepuce
Cranial epigastric artery	Hypogastric region Abdominal midline Mammary teats Base of prepuce
Deep circumflex iliac artery (dorsal branch)	Cranial edge of wing of ilium Great trochanter Dog in lateral recumbency, skin in natural position, pelvic limb in relaxed extension Vessel originates at a point cranioventral to wing of the ilium
Deep circumflex iliac artery (ventral branch)	Anatomic landmarks of flap base same as dorsal branch of deep circumflex iliac artery Shaft of femur
Genicular artery	Patella Tibial tuberosity Greater trochanter
Lateral caudal arteries (left and right)	Proximal third of tail length Transverse processes of vertebrae
Caudal auricular artery	Wing of atlas Spine of the scapula
Reverse saphenous conduit flap[b]	Inner thigh Tibial shaft

[a]**Major defects only.** [b]**Axial pattern flap variation.**

Reference Incisions	Potential Uses[a]
Caudal incision: Spine of the scapula in a dorsal direction *Cranial incision:* Parallel to the caudal incision equal to the distance between the scapular spine and cranial scapular edge (cranial shoulder depression) *Flap length:* Variable; contralateral scapulohumeral joint	Facial defects Ear reconstruction Cervical defect Shoulder defect Axillary defects
Cranial incision: Spine of the scapula in a dorsal direction *Caudal incision:* Parallel to the cranial incision equal to the distance between the scapular spine and caudal scapular edge (caudal shoulder depression) *Flap length:* Variable; can survive ventral to contralateral scapulohumeral joint	Thoracic defects Shoulder defects Forelimb defects Axillary defects
Incision lines: Flap base includes flexor surface of elbow, anterior third; lateral and medial incisions parallel humeral shaft; flap progressively tapered approaching greater tubercle *Flap length:* Variable, flap ends at level of greater tubercle	Antebrachial defects Elbow defects
Medial incision: Abdominal midline; in the male dog, the base of the prepuce included in the midline incision to preserve adjacent epigastric vasculature *Lateral incision:* Parallel to medial incision at an equal distance from the mammary teats *Flap length:* Variable: may include last four glands and adjacent skin	Flank defects Inner thigh defects Stifle area Perineal area Preputial area
Base of flap: Location in hypogastric region *Medial incision:* Abdominal midline *Lateral incision:* Parallel to midline incision at an equal distance from mammary teats *Flap length:* Glands 2, 3, 4; anterior to prepuce	Closure of wounds overlying sternal region
Caudal incision: Midway between edge of wing of ilium and greater trochanter *Cranial incision:* Parallel to caudal incision equal to the distance between caudal incision and cranial edge of iliac wing *Flap length:* Dorsal to contralateral flank fold	Thoracic defects Lateral abdominal wall defects Flank defects Lateromedial thigh defects Defects over the greater trochanter
Caudal incision: Extending distally, anterior to cranial border of femoral shaft *Cranial incision:* Parallel to caudal incision *Flap length:* Proximal to patella	Lateral abdominal wall defects Pelvic defects Sacral defects, as an island arterial flap
Base of the flap: 1 cm proximal to patella and 1.5 cm distal to tibial tuberosity (laterally) *Flap borders:* Extending caudodorsally parallel to the femoral shaft; flap terminates at base of greater trochanter	Lateral or medial aspect of the lower limb, from the stifle to the tibiotarsal joint
Incision: Dorsal or ventral midline skin incision, depending on intended flap usage; careful dissection along deep caudal fascia of the tail; vessels located lateral and slightly ventral to transverse processes, in proximal tail region; amputation of tail at third to fourth intervertebral space, preserving skin *Flap length:* Proximal third of tail length	Perineum, caudodorsal trunk
Base of flap: Palpable depression between lateral aspect of wing of atlas and vertical ear canal *Width of flap:* Central "third" of lateral cervical area over lateral aspect of wing of atlas *Flap length:* Up to spine of scapula (survival length variability)	Facial area Dorsum of head Ear
Proximal incision: Central third of inner thigh at level of patella; ligate saphenous artery and vein at level of femoral artery and vein *Cranial and caudal incisions:* Skin incisions extended distally in converging fashion, 0.5-1.0 cm cranial and caudal to cranial and caudal saphenous artery and medial saphenous vein; flap undermined beneath saphenous vasculature; ligate and divide peroneal artery and vein *Flap length:* Variable, base of flap at level of anastomosis of cranial branches of medial and lateral saphenous veins	Defects of tarsometatarsal regions Note: Use of flap requires intact collateral blood supply to lower extremity

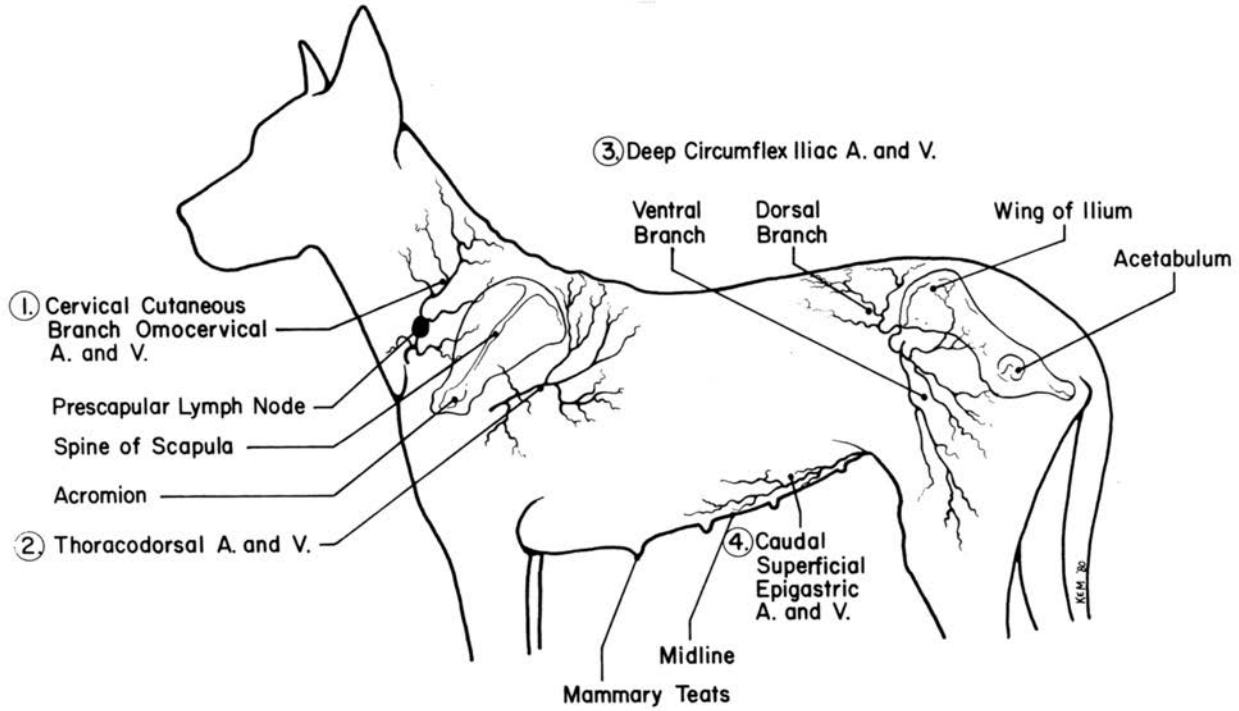

Figure 41-12. Four major cutaneous arteries are illustrated in relation to their anatomic landmarks *(1 to 4)*. (From Pavletic MM. Canine axial pattern flaps, using the omocervical, thoracodorsal, and deep circumflex iliac direct cutaneous arteries. Am J Vet Res 1981 ;42:391.)

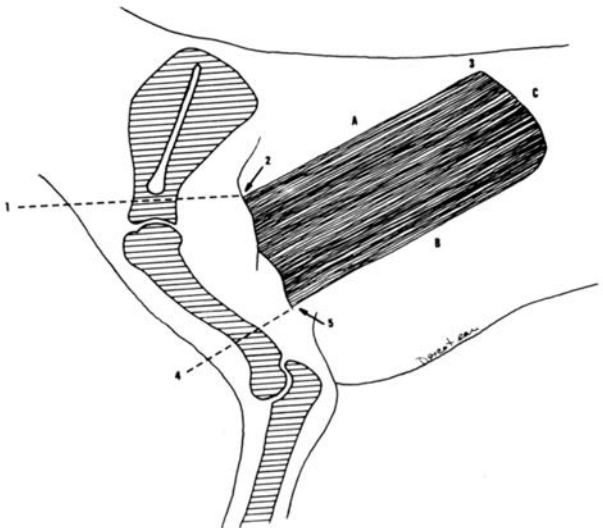

Figure 41-14. Anatomic landmarks for the latissimus dorsi and cutaneus trunci myocutaneous flaps: *(1)* ventral border of the acromion and *(2)* adjacent caudal border of the triceps muscle; *(3)* head of the last rib; *(4)* distal third of the humerus, which corresponds to the *(5)* axillary skin fold. The flap is drawn onto the skin with a marking pen by connecting landmarks *2* and *3* to form the dorsal flap border *(A)*. A second line is drawn from landmarks parallel to line A to the border of the last rib forming the lower flap border *(B)*. A third line *(C)* is drawn along the caudal border of the last rib, connecting lines *A* and *B*. (From Pavletic M, Kostolich M, Koblik P, et al. A comparison of the cutaneus trunci myocutaneous flap and latissimus dorsi myocutaneous flap in the dog. Vet Surg 1987; 16:283.)

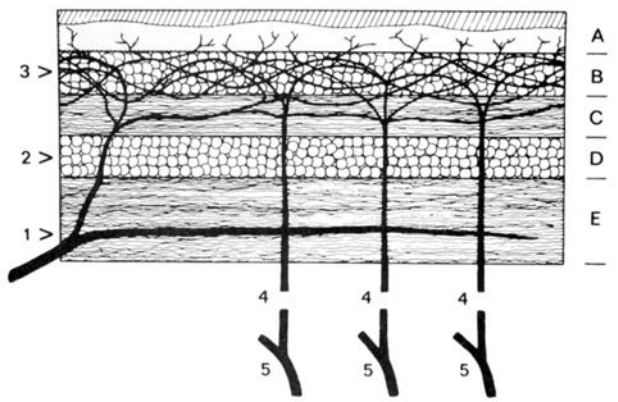

Figure 41-15. Vascular levels of the latissimus dorsi myocutaneous flap: (*A*) skin, (*B*) subcutaneous flap, (*C*) cutaneous trunci muscle, (*D*) fat, and (*E*) latissimus dorsi muscle. The vessels involved include: (*1*) the main branch of the thoracodorsal artery traveling within the latissimus dorsi muscle; (*2*) short perforating branches of the thoracodorsal artery to the cutaneus trunci muscle and overlying skin; (*3*) the subdermal (deep) plexus to the skin associated with the cutaneous trunci muscle; (*4*) the proximal lateral intercostal arteries divided during elevation of the latissimus dorsi muscle demonstrating anastomotic connections with the thoracodorsal artery intramuscularly; and (*5*) the intercostal arteries. (From Pavletic M, Kostolich M, Koblik P, et al. A comparison of the cutaneus trunci myocutaneous flap and latissimus dorsi myocutaneous flap in the dog. Vet Surg 1987; 16:283.)

and the composite flap transferred into a local defect as a flap or free flap [microvascular transfer].[35-40] Performed successfully under research conditions, they have limited clinical practicality over the flap and graft options already discussed.

Composite flaps have been successfully used for facial reconstruction, including the labial advancement flap, buccal rotation technique, labial lift-up bipedicled composite flap, and variations of these procedures.[5] In one case, a composite flap, using a damaged portion of the ear, was used to close a large adjacent defect.[41] A composite mucocutaneous subdermal plexus flap employing the upper lip ("lip to lid procedure") has been successfully used for full-thickness eyelid reconstruction in the dog and cat.[42,43] These compound or composite flaps are useful for specific body defects and are not routinely employed for skin defects alone.

Skin-Stretching Techniques

Skin is a nonhomogeneous viscoelastic tissue with the combined characteristics of a viscous fluid and elastic solid. Three factors account for skin extensibility as a stretching force is applied: (1) progressive straightening of dermal collagen convolutions; (2) Parallel alignment of dermal collagen fibers; (3) extension of fully aligned collagen fibers with increasing stretching force applied to the skin.[43]

Skin in various regions of the body has its own natural or "inherent extensibility". This is assessed by grasping and lifting the skin, a procedure **all** surgeons perform when assessing wound closure options. *Mechanical creep* is the biomechanical property that enables skin to extend or stretch beyond the limits of its inherent extensibility. As a stretching force is applied to the skin over time, collagen fibers align with the applied tension; collagen fibers compact and slowly displace interstitial fluid during the process. As the skin stretches beyond the limits of its natural extensibility over time, *stress relaxation* occurs. Stress relaxation refers to the progressive decrease in the force required to maintain the length of the stretched skin. For skin to stretch beyond the limits of its natural extensibility, the skin best deforms from the application of a constant load or force over time. Similarly intermittent application of force or "load cycling" also can assist in the process of skin stretching. A natural variation of this phenomenon is "biologic creep", or the progressive increase in cutaneous surface area noted as a result of expansile masses located beneath the skin.[44]

There are a few techniques that are currently used to stretch skin in humans and small animals, to facilitate wound closure. They include tissue expanders; presuturing; and an elastic cable system developed by the author, termed "skin stretchers."[5,44]

Skin Expanders

Skin expanders are inflatable devices composed of an expandable silicone elastomeric bag or reservoir; an attached silicone tube is connected to a self-sealing injection port. The entire device is placed beneath the skin. Controlled inflation of the device is accomplished by injecting sterile saline; a hypodermic

needle is inserted into the palpable injection port, through the overlying skin. The surface area of the overlying skin is gradually stretched, increasing its surface area by mechanical creep and stress relaxation. Once fully expanded, the skin is advanced or pivoted into a regional defect.[5,45-47]

Effective use of tissue expanders requires a reservoir of sufficient size to exert their stretching effect over on the overlying skin. However, they do require a degree of skin laxity for creating a pocket of sufficient size to accommodate the mass of the collapsed device. As a result, they are better suited for small to moderate sized problematic skin defects of the middle to distal aspects of the extremities. They may have limited use for closure of difficult wounds of the head. Many surgeons consider alternative means of closing extremity wounds, including skin grafts and select skin flap techniques. Veterinarians normally hesitate in purchasing a tissue expander for several hundred dollars with limited or no experience in their use. Properly handled, silicone tissue expanders can be autoclaved and reused.[5,45-47]

Implant size and shape is determined by the dimensions of the skin defect. Normally the surface area of the thick reservoir base corresponds to the surface area gain expected. Alternatively, slightly smaller reservoirs can be used, but hyperinflated 20- to 25% above the designated capacity of the device. Two smaller expanders also can be used in some situations. In one canine study, the rectangular 100 cc tissue expander appeared to be well suited for use in medium sized dogs.[5,45]

Variable rates of inflation have been used in human surgery. Although a somewhat slower rate of expansion may be reduce the risk of abrupt circulatory compromise to delicate skin, more rapid expansion rates may be preferable in other situations. Canine research demonstrated that 100 ml expanders can be inflated with minimal complications within 2 weeks, using an alternate-day injection schedule. A more cautious (3 week) rate may be advisable for delicate skin or tissues previously compromised by trauma. Use of expanders in previously irradiated tissues is best avoided.[5,45]

Outpatient visits enable the veterinarian to assess the skin during saline infusion. In human patients, the skin is assessed for color change (blanching, cyanosis) and patient discomfort. I have not noted these changes in the dog. During the later phase of expansion, skin tension can be pronounced immediately after the injection. When reassessed at the time of the following injection, skin tension has decreased. Viability of the skin is highlighted by the unimpeded growth of hair in the expanded skin.[5,45]

Upon completion of the expansion process, the expanded skin can be advanced or rotated into the recipient bed, usually in the form of a pedicle graft. This must be carefully planned in advance, since the initial access incision for implantation of the expander should not be incorporated into the base of the proposed flap (Figure 41-16).[5,45]

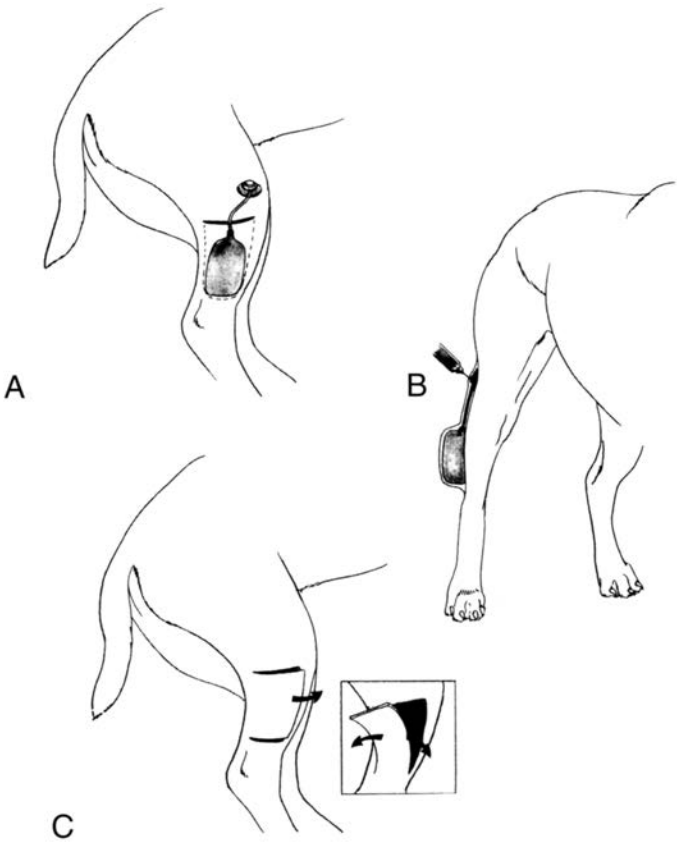

Figure 41-16. A-C. Tissue expander. In this illustration, a 100-ml tissue expander has been inserted into a subcutaneous pocket created by careful undermining of the skin. The access incision is closed with an intradermal suture pattern and skin sutures; 15 mL of saline is injected into the inflation reservoir, using a 23- to 25-gauge hypodermic needle, on alternate days after implant insertion. In approximately 2 weeks, the implant is deflated and removed; the expanded skin can be advanced or transposed into an adjacent detect. (From Pavletic MM. Atlas of small animal reconstructive surgery. Philadelphia: JB Lippincott, 1992.)

Skin Stretchers

Developed by the author, skin stretchers are an external device used to stretch skin rapidly, by the processes of mechanical creep and stress relaxation previously discussed. They are particularly effective for closing moderate to large wounds involving the trunk, neck and neighboring cranial area; they have limited use in the mid- to distal extremities. Skin stretchers enable the surgeon to close problematic wounds without the need for skin grafts or skin flaps.[5,34,44] They are my preferred method of choice to close most large skin wounds of the thoracic and abdominal areas.[5,44]

Skin stretchers have two components; skin pads to which elastic cables are affixed. The present design uses Velcro hook pads for the skin pads, and specially designed one inch elastic cable covered by Velcro "felt." Pads are placed on opposing sides of a wound and are secured to the skin with cyanoacrylate glue. Cables are applied to the opposing pads under moderate tension. Cable tension is gradually increased every 6 to 8 hours for 48 to 72 hours prior to surgical closure of the defect. At the time of surgery, pads can be pulled off the skin. Left in place, skin pads normally loosen within 7 to 10 days of application, as a result

of normal skin desquamation. Nail polish remover is a solvent for cyanoacrylate glue, although the author has not used it to facilitate skin pad removal (Figure 41-17).[5,44]

The primary complication is the occasional need to replace a skin pad that displaces as cable tension increases during their 48 to 72 hours of application. Pads are reglued or replaced until completion of the stretching procedure. Because the skin tension is applied over the wide footprint of the skin pads, patient comfort is maintained and allows for more forceful application of cable tension. The skin stretcher system can be used to prestretch skin prior to elective surgical procedures, including the surgical removal of problematic skin tumors. Skin stretchers are also very effective in minimizing incisional tension after wound closure; pads and cables can be used for 3 to 5 days to help prevent wound deshiscence.[5,44]

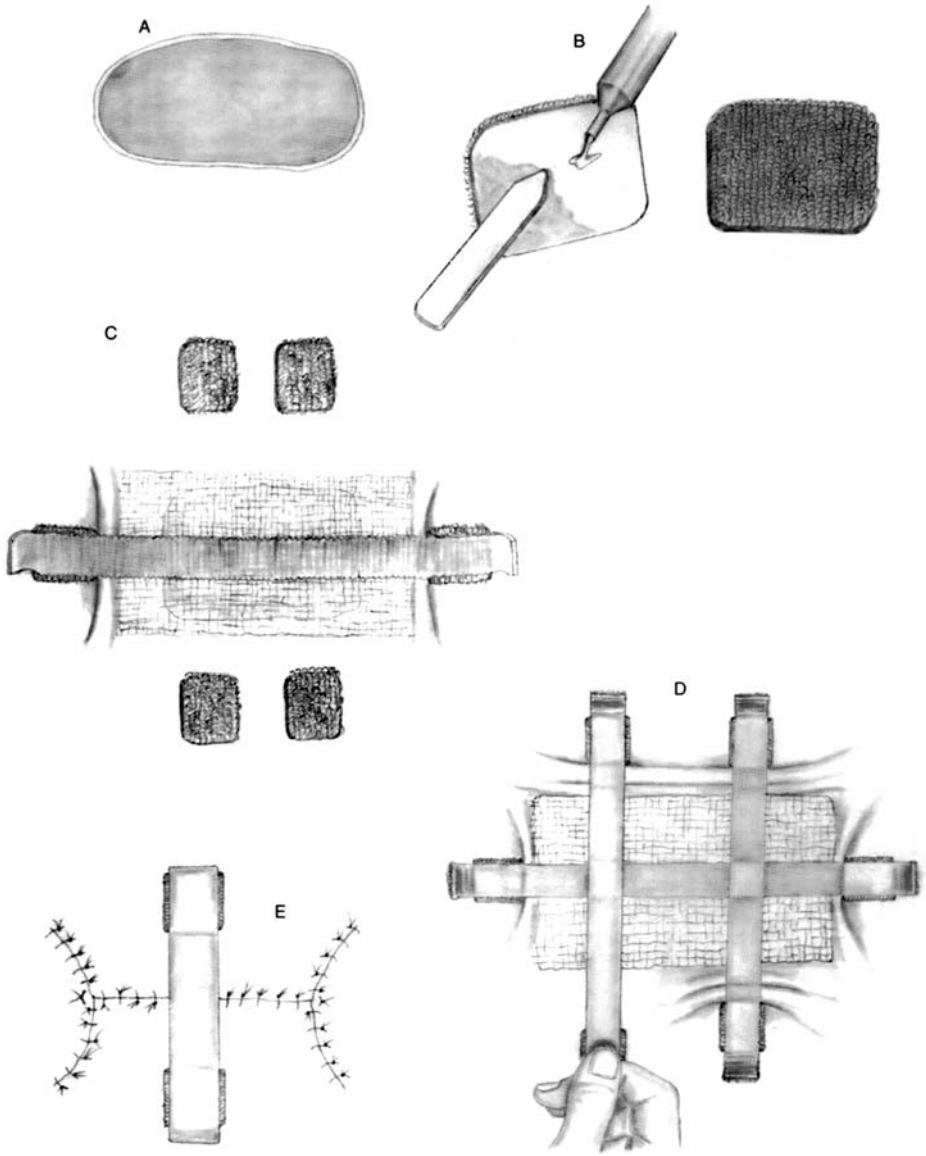

Figure 41-17. Illustration of a skin wound. The fur has been liberally clipped from around the area. Surgical soap and water are used to remove cutaneous oil and debris. Isopropyl alcohol swabs are then used to remove skin and residual skin oil. Excess alcohol is removed with gauze or towels and the skin allowed to completely dry before pad application. The hook pads can be applied to the skin after peeling off the protective tab or cover; cyanoacrylate glue is applied in a thin film to enhance pad adherence to the prepared skin surface. Note the long axes of the rectangular pads have been placed perpendicular to the wound borders, parallel to the tension cables to minimize the potential for pad displacement. Pads normally are placed 10-20 cm from the wound borders. An additional row (tier) of pads and cables can be applied outside this suggested zone, if further skin recruitment is required (and feasible) to recruit skin more distant to a large trunk defect. [Skin stretchers also can be effectively used to pre-stretch the skin prior to elective surgical removal of large tumors or diseased skin segments.] Completion of cable application. A mild amount of tension is initially applied to each cable. Cable tension is progressively increased every 6 hours as the skin stretches toward the defect. One end of the elastic cable is disengaged from a skin pad, stretched, and recoupled to the skin pad, as illustrated. **E.** In general skin is stretched for 48 to 96 hours prior to surgery. Pads are peeled off the anesthetized patient, the skin is prepared for surgery, and the recruited skin advanced over the wound. On occasion, the outer corneal layer will be stripped off during pad removal, but the surface rapidly reforms. [Nail polish remover can facilitate pad removal, but is unnecessary from the author's experience.] In this illustration, a second set of pads and a short cable segment are being used to offset postoperative wound tension upon completion of the surgery. Stretchers are very effective in reducing incisional tension; the author uses this device for 3-5 days.

Free Skin Grafts

Free skin grafts lack a vascular attachment on transfer to the recipient graft bed. As a result, their initial survival at the time of transplantation is by absorbing tissue fluid (plasmatic imbibition) from the recipient bed capillary circulation is established from the vascular wound bed. Initial reestablishment of circulation to the free graft is noted approximately 48 hours after application. During this period, capillaries from the recipient bed establish contact with the exposed vascular channels (exposed graft plexuses) to reestablish vital circulation. Termed "inosculation," reestablishment of vascular flow will give the skin graft a pink coloration. Grafts with a lavender color are the result of venous congestion; they assume a pink hue as circulation improves. The thickness of the graft will determine whether the superficial, middle or deep (subdermal) plexus is exposed to the underlying vascular bed. The finer vascular network of the superficial plexus has a greater chance at revascularization, a major reason why thin split-thickness skin grafts have a greater likelihood of vascularization. Similarly, a medium split-thickness skin graft has a greater likelihood of revascularization compared to a full-thickness graft. Despite these earlier research findings, properly prepared, full-thickness skin grafts have an excellent chance of surviving or "taking.[5,48]"

Once initial contact (inosculation) occurs between the capillary buds and exposed vascular channels of the skin graft, the capillaries grow into the graft and remodel the capillary network over the next several days. However, there are several factors that may delay or prevent revascularization of a skin graft, resulting in necrosis. Any accumulation of material between the graft and recipient bed can block inosculation, including pus, blood (hematoma), serum, or foreign material. Grafts techniques that provide effective drainage, can reduce the probability of graft loss from this potential complication.[5,48]

Subcutaneous fat must be removed from full-thickness skin grafts; presence of the fatty tissues will prevent revascularization of the free graft. The graft must conform to the contour of the wound bed: excessive stretching of the graft will create a "drum skin" over depressions in the recipent bed, preventing revascularization. Folds or wrinkles in the graft will have a similar effect. Lastly, grafts must be immobilized to prevent motion between the recipient bed and overlying graft: shearing forces will prevent revascularization.[5]

Skin staples or sutures are frequently used to secure skin grafts to the recipient area. Fibrin deposition between the graft and underlying recipient bed serves as a natural glue to help stabilize the graft. The fibrin serves as a scaffold for fibroblasts and subsequent collagen deposition. A protective bandage is required to prevent motion to the area during the healing process.[5]

As noted, a healthy vascular wound bed is required for graft survival. Healthy granulation tissue, viable muscle, and periosteum are capable of supporting a skin graft. Chronic granulation tissue is laden with collagen and has an unsatisfactory blood supply to support a graft. In many cases, this tissue may be excised, promoting reformation of a healthy granulation bed within 5 days. Chronic radiation ulcers lack the circulation to support a skin graft. In wounds lacking sufficient circulation to support a graft, a skin flap or muscle flap (covered with a skin graft) may be necessary.[5]

Skin Graft Classifications

Free grafts can be classified according to the source of the graft, its thickness, and its shape or design. Autogenous grafts are used exclusively for permanent coverage in dogs and cats. Allografts (homografts) and xenografts (heterografts) are rarely used in veterinary medicine as a temporary biologic dressing: left in place, these grafts are eventually rejected by the patient's immune system. Isografts, or the exchange of skin grafts between highly inbred strains of animals is usually limited to research rats and mice.[5,48]

Free grafts are commonly classified according to the thickness of the graft. Full- thickness skin grafts include the entire dermis, thereby retaining a large percentage of the compound hair follicles. Split-thickness skin grafts, harvested by a graft knife, razor blade, or dermatome include variable portions of the dermis. They are broadly classified as thin, medium, or thick split thickness skin grafts. Thinner grafts have relatively few hair follicles and are less cosmetic in fur-bearing animals, unlike the human. Although thin split thickness grafts reportedly survive or "take" more readily, they also lack the hair growth and overall durability of full-thickness skin grafts. Split-thickness grafts, harvested with a dermatome, normally are reserved for large wounds (especially large full-thickness bums) with more limited donor skin.[5,48,49]

Surgical Techniques

Free grafts are most commonly used for the more problematic defects involving the lower extremities. Most surgeons will use full thickness grafts when possible due to the superior hair growth, durability and relative ease of harvesting. Full thickness skin grafts can be harvested and applied as a "sheet" or cut into various shapes including punch-pinch grafts, strip grafts, stamp grafts, or mesh grafts (Figures 41-18 through 41-21).

Punch, pinch, strip, and stamp grafts afford partial coverage of a wound surface. The space between grafts provides drainage as their epithelial cells migrate over the exposed granulation tissue. Grafts that provide reasonable drainage are more likely to survive in the presence of a low-grade bacterial infection. Punch and pinch grafts are easy to perform and are used most commonly to promote epithelization of smaller, slow healing open wounds. However, depending on their numbers and spatial relationship, they do not provide a particularly durable epithelial surface for those body regions subject to periodic external trauma. Full-thickness mesh grafts are better suited for larger wounds.The techniques for punch, strip, and stamp grafts are described in (See Figures 41-18 through 41-21).[5]

Full-thickness mesh grafts are especially useful for coverage of larger wounds involving the distal extremities (See Figure 41-21). An impression template of the moist wound surface can be performed using gauze or absorbable paper [the paper packaging

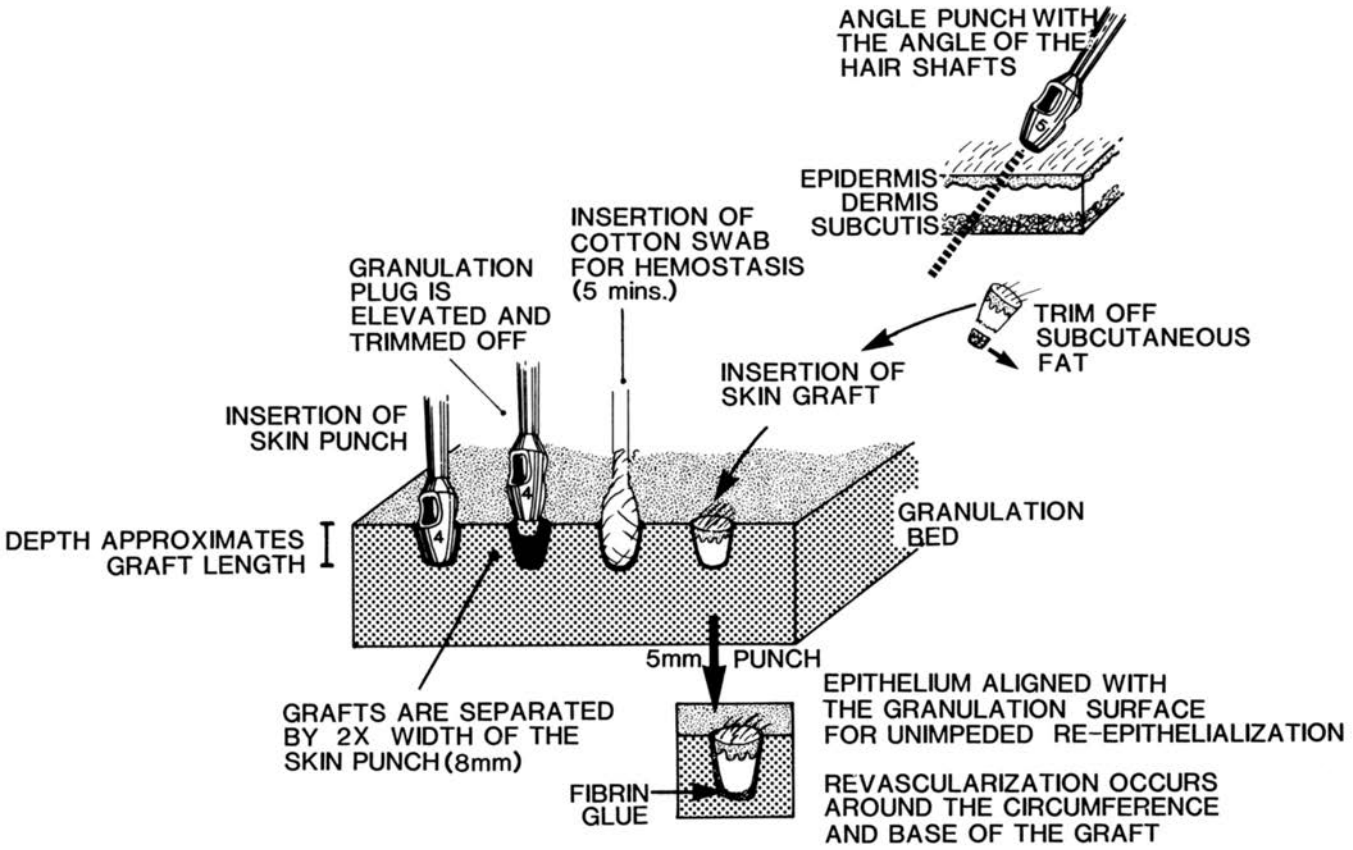

Figure 41-18. Punch graft technique (pinch grafts). A sharp 5- or 6-mm biopsy punch is used to harvest the graft plugs from a suitable donor site. The donor area is clipped, leaving the hair shafts exposed. Subcutaneous fat is trimmed off the graft base. A single stitch is used to close the donor bed. The grafts are placed between two moistened saline pads until needed. A 4-mm biopsy punch is used to remove cores of granulation tissue in the recipient bed. Holes are spaced 8 mm apart (twice the width of the biopsy punch). Fine scissors are required to remove the granulation core. A sterile cotton swab is inserted into each hole for 5 minutes. The graft plugs are then inserted in the direction of natural hair growth. A firm dressing is applied postsurgically to maintain the position of the grafts. This procedure has the following advantages: 1) 4-mm granulation holes compensate for graft shrinkage and allow the grafts to fit more snugly; 2) the epithelial surface of the graft is level with the granulation bed, and re-epithelialization is unimpeded; 3) as many hair follicles as possible are included into each graft to promote hair growth; 4) re-epithelialization is possible despite partial graft necrosis from surviving hair follicles and skin adnexa deep in the graft; and 5) graft revascularization occurs around the circumferences as well as through the base of the graft plug, a comparatively large surface area.

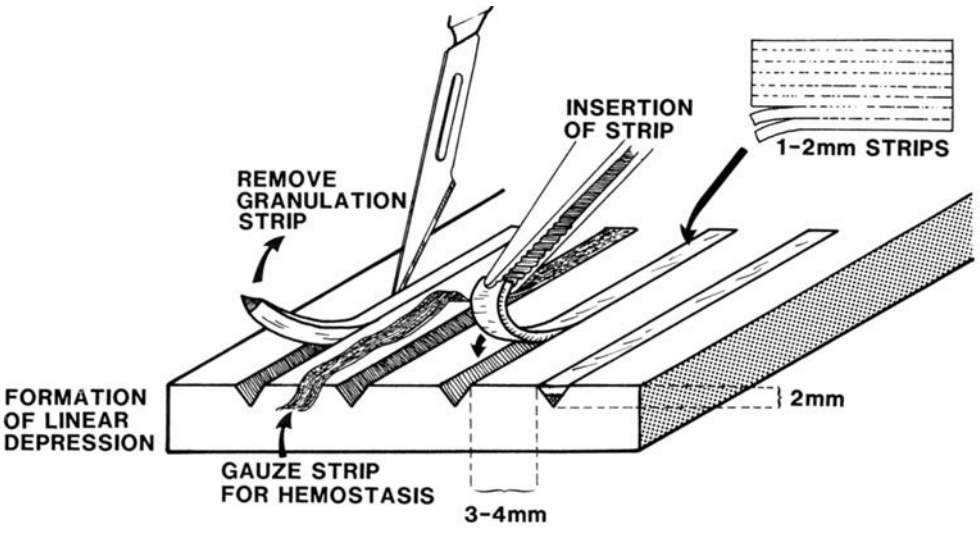

Figure 41-19. Strip grafts. Application of strip grafts is similar to that of punch grafts. Linear strips of skin are laid in granulation troughs cut with a special blade. Granulation tissue between the strips is eventually reepithelialized from the graft.

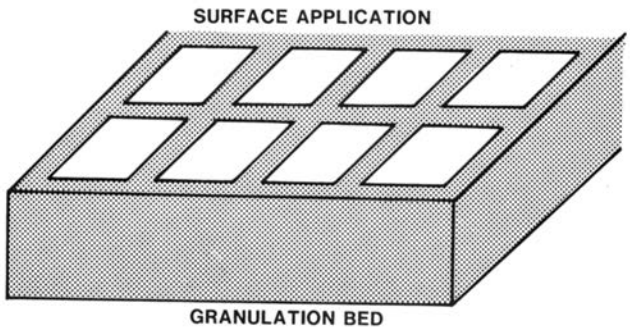

Figure 41-20. Stamp grafts. Full-thickness or split-thickness grafts are harvested and are divided into squares. Size can vary up to the size of postage stamps. Grafts are laid over the recipient bed a few to several millimeters apart. Square depressions may be cut into a granulation bed if necessary to improve graft immobilization.

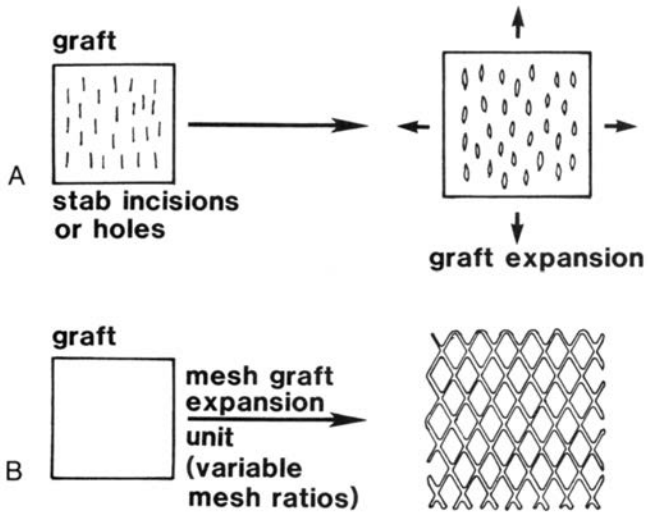

Figure 41-21. Mesh grafts. Both full-thickness and split-thickness grafts may be used. **A.** Multiple stab incisions or holes are cut into the graft to allow the graft to expand and to provide adequate drainage. The graft is sutured at the periphery. **B.** Mesh-graft expansion units have been developed to expand the graft into a uniform mesh. A graft can be expanded 1.5 to 9 times its original surface area to cover extensive skin defects.

for sterile gloves is an ideal material]. Using sterile materials, the template can be trimmed and directly applied to the donor area. In most cases, skin is simply harvested from the lateral thorax and abdomen. The template is placed on the donor area, ideally allowing for the graft to be harvested with the appropriate hair growth pattern of the recipient area. Normally, I will harvest an additional one centimeter around the circumference of the template. Harvesting of the graft as a simple geometric pattern that includes the footprint of the template [rectangular design is most commonly used] will facilitate closure of the donor area; the graft can be trimmed to the appropriate size at the time of application.[5]

A key step in full thickness graft preparation is the removal of all subcutaneous tissues (fat, panniculus muscle) down to the dermal surface of the graft. Unless removed, this layer of tissue will prevent revascularization of the graft. Properly "defatted", the dermal surface of the graft will have a "cobble stone" appearance: dermal collagen striations and the speckled appearance of compound hair follicles are identifiable on close inspection (Figure 41-22).[5]

Grafts can be directly abutted against the borders of the skin defect and sutured into position. Alternatively, the author prefers to slightly overlap the wound margins of the recipient bed with the graft. This facilitates securing the graft with sutures or skin staples while completely covering the wound. Skin staples facilitate graft application by rapidly securing the graft to the overlapped cutaneous borders. Graft tension is adjusted by stapling one side and slightly stretching the graft before stapling

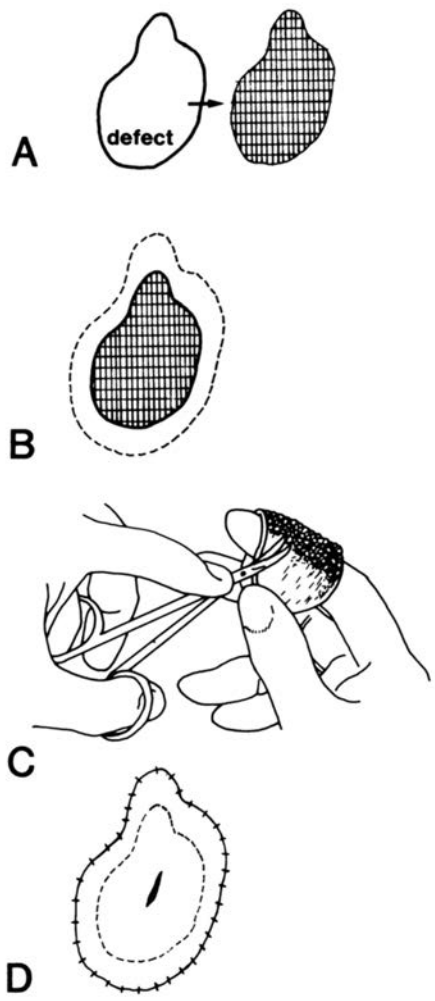

Figure 41-22. Free full-thickness graft. The recipient is prepared for operation, and any epithelialized areas are excised to accept full graft coverage (cross-hatching). **A.** A sterile gauze or paper template is made of the recipient bed. **B.** After the template is transferred to the prepared donor site, a sterile ink applicator is used to outline the template on the donor site I cm outside its border. **C.** The graft is removed, and the donor bed is closed. The graft is "defatted" by trimming away all subcutaneous tissue. The resultant graft appears opaque when held to a light source and must be kept moist at all times. **D.** The graft is laid over the wound. Stab incisions may be used to prevent fluid accumulation beneath the graft. The graft overlaps the recipient bed and is sutured into place with a simple interrupted or continuous pattern. The overlapped border eventually sloughs, leaving complete graft coverage over the recipient bed. The graft is dressed and bandaged postsurgically.

the opposing border. The process is repeated in the opposite plane. The graft is applied with sufficient tension to allow the graft to flatten and conform to all surface areas. Graft holes are stretched to allow a gap of a few to several millimeters to form, facilitating drainage. As a general rule, grafts are not sutured to the wound bed in order to avoid hemorrhage. If the graft is tenting over a depression, a fine suture can be used to assure proper graft to bed contact. Fibrin deposition occurs several hours after application, forming a natural glue to immobilize the graft. Skin sutures or staples can be removed in 7 to 10 days; the overlapped skin border will undergo necrosis and can be trimmed off at this time.[5]

Pad Grafting

There are several articles discussing the use of pad grafts to replace the loss of the metacarpal and metatarsal pads, with the simultaneous loss of the digital pads. With the presence of the adjacent toes, digital pad flaps can be used to reconstruct the metacarpal/metatarsal pads more effectively.[5,50-52]

Grafts: Postoperative Care

Proper protection and immobilization is essential to graft survival. It is preferable to confine the patient to a cage. Sedation may be advisable for hyperactive patients.

A nonadherent dressing covered with a thick layer of bland ointment [triple antibiotic ointment is economical to use] is applied to the grafted area.and stapled over the area to prevent displacement. This is followed by layers of sterile gauze pads, and self-adherent roll gauze alternated with cast padding. A firm, thick bandage is formed prior to application of an outer elastic wrap. To further immoblize the area, tongue depressors, aluminum bars, half casts, metasplints, slings, and Shroeder-Thomas splints may be employed. The Latter splint is especially useful for immobilizing the knee, elbow, and tibiotarsal joints. Spica splints/bandages are advisable to immobilize the upper extremity, especially in cats, whose reputation for extricating themselves from bandages is legendary.[5,48]

The author prefers to change the initial bandage 3 to 5 days postoperatively. Bandages can be changed 48 hours after surgery, but in this early period there is a risk of displacing the graft and damaging the fragile reestablished blood supply. Adherent dressings occasionally adhere to the grafted area. Saline can be applied to facilitate its removal, although it is more prudent to apply additional ointment to the area and rebandage the area. The exposed graft is inspected for viability and signs of infection. A culture can be taken if infection is suspected.[5]

Early signs of graft necrosis are discouraging but not always catastrophic: hair follicles in the deeper dermal layer of the graft may survive and serve as a source for epithelization. Subsequent bandage changes may be performed every 2 to 4 days, depending on the condition of the graft. This routine is continued for approximately 2 weeks or until epithelization is complete. This can be followed by application of a lighter bandage for an additional 10 to 14 days, if necessary. An Elizabethan collar is advisable to prevent self-mutilation of the graft site. Eventually, the owner can remove the collar temporarily with the pet under close supervision. If the patient does not rub or lick at the grafted area, the collar can be eliminated completely, usually within a month after the surgery.[5] Bandages can have adverse effects on the graft. Excessive bandage tension and pressure points from uneven bandage application can result in partial or complete graft failure. Bandages also can have an abrasive effect on the graft if immobilization of the affected area is inadequate.[5]

Mesh Skin Grafting

Eric R. Pope

Introduction

Skin grafting in dogs and cats is most commonly used for reconstructing degloving injuries on the extremities, but can also be used to cover skin defects on other areas of the body when simpler techniques may not be indicated or applicable. The use of both full-thickness and split-thickness grafts has been described but I have almost always used full-thickness grafts. Full-thickness grafts consist of the epidermis and entire dermis, whereas split-thickness grafts consist of the epidermis and variable portions of the dermis (Figure 41-23). Of the various types of skin grafts described in the literature, the mesh skin graft offers many advantages for the veterinary surgeon. A mesh graft is a full-thickness or split-thickness skin graft in which parallel rows of staggered slits have been cut either manually with a No. 11 scalpel blade or mechanically with a commercial mesh dermatome. Mesh grafts have the following advantages: 1) they can be expanded to cover large defects if donor sites are limited (e.g., burns); 2) they conform well to irregular surfaces; 3) the creation of numerous slits allows drainage from underneath the graft; and 4) they can be placed over areas that are difficult to immobilize. The primary disadvantage of mesh grafts is that when they are expanded and the interstices heal by epithelialization, resulting in islands of nonhaired epithelium throughout the graft. For this reason, a nonexpanded or minimally expanded graft is preferred.

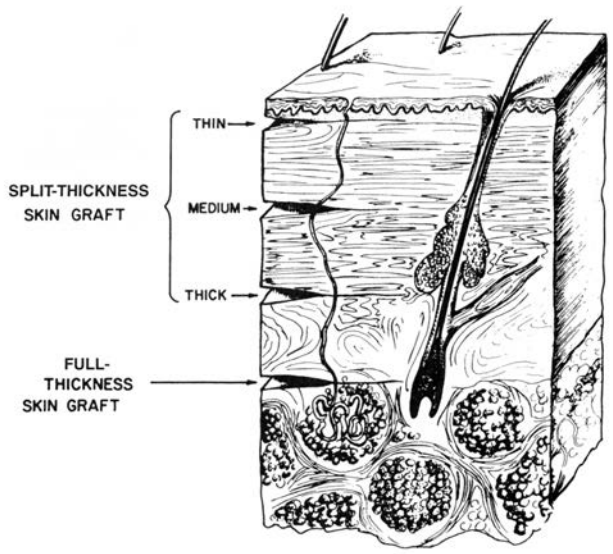

Figure 41-23. Full-thickness skin grafts consist of the epidermis and entire dermis. Split-thickness grafts consist of the epidermis and variable portions of the dermis. (Courtesy of Swaim SF, DVM, Auburn University, Auburn, AL.)

Preoperative Considerations

Recipient Bed

Skin grafts can be successfully placed on freshly created surgical wounds or on healthy granulation beds. A freshly created wound can be grafted immediately if the surface of the wound has a blood supply sufficient enough to produce granulation tissue if left ungrafted. Muscle and fascia generally support grafts well. Bone, cartilage, and tendon covered by their supporting structures also support grafts. Grafts placed over avascular areas less than 1cm in width (0.5cm from each margin) generally survive because of the extensive interconnection of blood vessels within the dermis; this is referred to as the bridging phenomenon.

Although fresh wounds can be successfully grafted, I prefer to allow a healthy granulation bed to form before grafting. A granulation bed should be sufficiently formed within 5 to 7 days. A healthy granulation bed is smooth and pink; the migration of epithelium from the wound margin is also a good indicator that the granulation tissue is healthy. Chronic granulation tissue is rough and dark red and may be infected. Chronic granulation tissue should be excised to its base and a fresh granulation bed allowed to form before any skin-grafting procedure is performed. Culture and sensitivity testing should be considered if infection is suspected. In most instances, traumatic wounds are best managed conservatively initially, followed by grafting after a healthy granulation bed has formed. Obviously, devitalized tissue should be debrided from the wound, and open wound management performed (e.g. moisture retentive wound dressings, wet-to-dry dressings, vacuum-assisted wound therapy) until a granulation bed forms. Once a granulation bed forms, the wound surface should be protected with nonadherent dressings until grafting is performed.

Donor Sites

Important criteria in selecting a donor site are the color and length of hair with respect to that surrounding the recipient site and also the ability to close the donor site after harvesting the graft. Because abundant skin generally is present on the thorax and neck, large grafts can be harvested from these areas, and primary closure of the donor site is possible.

Split-Thickness Versus Full-Thickness Graft

Split-thickness grafts can be classified as thin (less than 0.008-inch thick), intermediate (0.010 to 0.015-inch thick), or thick (0.015 to 0.025-inch thick), depending on the amount of dermis included. Thin and intermediate-thickness grafts generally do not grow hair well and may have a scaly appearance because of the lack of glandular structures. Thick split-thickness grafts approach full-thickness grafts in depth and therefore grow hair more successfully and result in a more normal appearance than thinner grafts. If thick grafts are harvested, the donor site should be excised and closed primarily, if possible, because healing is usually prolonged, and hair growth may be poor.

Full-thickness grafts have several advantages over split-thickness grafts. Because full-thickness grafts contain all the adnexal components, they are more likely to resemble normal skin than split-thickness grafts. They also generally grow hair well and are able to withstand trauma as well as the surrounding normal skin. In contrast to split-thickness grafts, no specialized equipment is required to harvest full-thickness grafts. Finally, the success rate with full-thickness grafts is at least as good as that obtained with split-thickness grafts. For these various reasons, I recommend using full-thickness grafts unless donor skin is limited (e.g., large burn wounds or multiple degloving injuries). Therefore, the remainder of this chapter describes a practical full-thickness mesh grafting technique that I use almost exclusively when grafting is indicated.

Surgical Technique

The mesh grafting procedure involves four basic steps: 1) preparing the donor and recipient sites; 2) harvesting and preparing the graft; 3) meshing the graft; and 4) applying the graft.

Preparing Donor and Recipient Site

The patient is anesthetized following a standard protocol, and the donor and recipient sites are prepared for aseptic surgery. The donor site should be widely clipped in case a plasty procedure is required for closure. The recipient bed is prepared first, so hemorrhage can be controlled before the graft is applied. Strong antiseptic solution should be avoided, but a dilute solution of chlorhexidine (0.05%) does not affect graft "take" and is used routinely.

Lightly scrape the surface of the granulation bed with a scalpel blade to remove any surface debris and to expose capillary ends. Hold the blade at a 90° angle to the surface to avoid removing too much tissue. At this point, a blood imprint of the recipient site can be made if a full-thickness nonexpanded graft is to be used (see next paragraph). Finally, saline-moistened sponges are applied

to the surface of the recipient bed, and digital pressure is used to control hemorrhage. Excessive use of cautery or ligatures should be avoided.

Donor sites for full-thickness grafts usually are abundant. Large grafts can be harvested by the technique described here, and the donor site can be closed primarily. The first step is to make a pattern of the defect if a nonexpanded technique is to be used, especially if the edges of the defect are very irregular. A pattern can be made by obtaining a blood imprint of the recipient site after it is prepared as described previously. After the pattern is made, it is placed on the donor site, with care taken not to reverse the pattern (i.e., turning the pattern over so the dermal side is up and a mirror image of the needed graft is harvested). The pattern should also be placed so the direction of hair growth of the graft matches that of the skin surrounding the wound. An arrow is drawn on the imprint indicating the direction of hair growth on the pattern before removing it from the defect. A skin scribe, sterile new methylene blue, or a scalpel blade can be used to transfer the pattern to the skin before cutting the graft. This is performed so the borders of the pattern can still be followed if the skin is distorted while the graft is being cut.

If the wound edges are fairly regular (e.g., rectangular) or if the graft will be expanded, an exact pattern is not necessary. For nonexpanded grafts, the length and width of the defect are measured at their widest point, and a segment of skin of those dimensions is harvested. Excess skin is trimmed from the edge after the graft is placed on the recipient site. When expanded grafts are needed, the graft should be cut longer in the direction parallel with the mesh incisions to account for the loss of length that occurs as the graft is expanded.

Harvest the graft at the level of the superficial subcutaneous tissue or just deep to the cutaneous trunci muscle if it is present. After the graft is dissected free from the donor site, the subcutaneous tissue (and cutaneous trunci muscle if present) must be removed from the graft. Removal of the subcutaneous tissue is enhanced by suturing the graft, dermal side up, to a piece of sterile cardboard with sutures or hypodermic needles (Figure 41-24). Sharp scissors are then used to cut the subcutaneous tissue from the graft. The base of the hair follicles is visible when the subcutaneous tissue is removed, giving the graft a cobblestone appearance. Because the hair follicles extend into the subcutaneous tissue in part of the hair growth cycle, the hair follicles may be damaged and hair growth reduced. Failure to remove all the subcutaneous tissue impairs revascularization of the graft and is an important cause of graft loss.

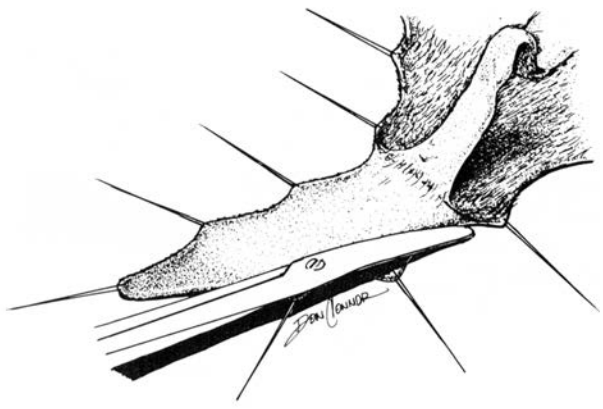

Figure 41-24. The graft is sutured, subcutaneous side up, to a piece of sterile cardboard, and the subcutaneous tissue is removed with sharp scissors. The base of the hair follicles should be visible in a properly prepared graft.

Meshing the Graft

Meshing can be accomplished with a No. 11 scalpel blade or a mesh dermatome but I typically use a scalpel blade because it is convenient and inexpensive. If a scalpel is used, the graft is left attached to the sterile cardboard, and staggered rows of parallel slits (approximately 0.5 to 1 cm in length) are cut in the graft (Figure 41-25). The degree of expansion achievable is influenced by the number of rows and length of the slits. Increasing the number of rows and the length of the slits increases the amount of expansion possible.

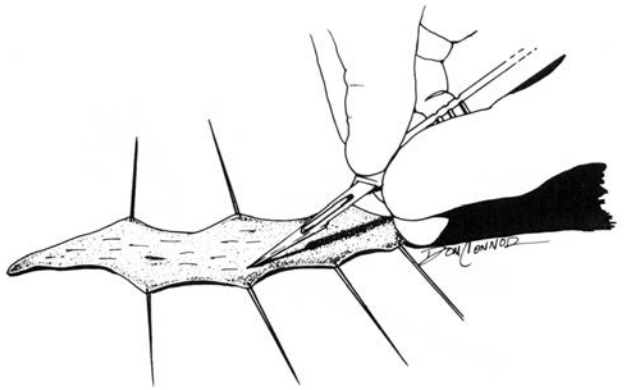

Figure 41-25. Meshing the graft with a number #11 scalpel blade. Increasing the number of rows and the length of the slits allows increased expansion of the graft and provides for more drainage of exudate from under the graft.

Application of the Graft

After the skin graft is harvested and prepared, it is placed on the recipient bed. To avoid disrupting the fibrin seal that begins to form soon after the graft is placed on the recipient bed, the graft should be manipulated as little as possible. The edge of the graft is sutured to the edge of the recipient bed using either nonabsorbable monofilament suture material or surgical staples. Alternatively, the graft is allowed to overlap the surrounding skin several millimeters and sutures are placed between the overlapped graft edge and skin below. The overlapped portion of graft will die and separate from the surviving graft, minimizing the risk of traumatizing the graft during suture removal. I have not noticed a significant difference using either technique but prefer suturing the graft to the skin edges of the recipient wound bed. Tacking sutures may be placed between the graft and graft bed on large grafts to help immobilize the graft.

Postoperative Care

Proper postoperative management is essential to successful skin grafting. Complete immobilization of a graft is necessary until a fibrous union occurs between the graft and recipient bed. Immediately after the surgical procedure, the graft is covered with a nonadherent pad. I apply an antibiotic ointment such as gentamycin ointment to the pad before placing it over the graft. A layer of absorbent material (e.g., Telfa WetPruf pads [Kendall Company Hospital Products] or cast padding is applied next and is covered with elastic gauze. Cast padding is easier to conform to the limb but is not as absorbent. If the graft crosses a joint, a splint is incorporated in the bandage to immobilize the limb. Finally, the entire bandage is covered with cohesive elastic bandage material or elastic tape. The bandage should provide moderate pressure. The dressing usually is changed in 48 hours but can be changed as early as 24 hours if drainage from the recipient bed soaks through the surface of the bandage. Care must be taken not to disturb the graft. Fractious animals should be sedated if necessary.

Because a moderate amount of drainage from the graft bed is common, waiting longer than 48 hours to change the bandage is not recommended. Bandages usually are changed every other day for the first 10 days and then as needed for 2 more weeks. Splinting usually can be discontinued after 10 days if the graft has healed normally. Healing grafts normally pass through a series of color changes during the healing process. Initially, many grafts appear pale because of the lack of blood supply. After 2 to 3 days, a graft normally develops a dark red or bruised appearance as the blood supply is reestablished. The graft may also appear edematous because of venous congestion. Graft areas that remain white or turn black will probably slough. Unless the entire graft is obviously nonviable, questionable areas are left until healing is complete. Attempts to remove small areas of nonviable graft may disrupt healing of surrounding areas. In some instances, partial thickness loss occurs leaving viable dermis in the deeper parts of the graft. The surface re-epithelializes from surrounding viable epidermal cells and from epidermal cells in the hair follicles.

Postoperative infection can have devastating results. Infection between the graft and the recipient bed may result in dissolution of the fibrin seal, or the graft may be physically elevated from the graft bed by the exudate produced. Care must be taken not to contaminate the graft when bandages are changed. Full-thickness skin grafts may develop a superficial infection, especially if revascularization is delayed. This generally is the result of the overgrowth of normal skin flora on abnormal skin and does not affect graft take. Infection usually is controlled by swabbing the graft lightly with an antiseptic solution when the bandages are changed and applying a topical antibiotic ointment. Sutures are removed 10 days postoperatively. The patient's owner should be cautioned to watch for developing paresthesia, as evidenced by constant licking and chewing at the graft. This problem is not common, but it is distressing if the patient chews off a successful graft. If this problem occurs, the graft should be protected with bandages for a longer period or a collar applied to prevent the animal from being able to traumatize the site.

Reconstructive Microsurgical Applications

J. David Fowler

Reconstructive microsurgery refers to the use of the operating microscope and microvascular technique in facilitating reconstruction of difficult or complex wounds. The premise of reconstructive microsurgery involves harvesting autogenous tissue from a body part distant to the wound, transferring that tissue into the wound bed for reconstruction, and reestablishing the transferred tissue's blood supply by microvascular anastomosis of vessels feeding the flap to vessels adjacent to the wound bed. Tissues transferred in this manner are most commonly termed "free flaps." Microvascular tissue transfer, free tissue transfer, and vascularized grafts are terms also used to refer to microsurgically transplanted tissue.

Free flaps are further described according to the tissue or tissues comprising the flap. Cutaneous free flaps refer to flaps incorporating skin and subcutaneous tissue. Free muscle flaps, omental flaps, jejunal flaps, and autogenous vascularized bone grafts are other examples of tissue transfers incorporating a single tissue type. Compound flaps incorporate more than one tissue type and are described accordingly. Myo-cutaneous flaps incorporate both muscle and skin; myo-osseous flaps incorporate muscle and bone; osteomusculocutaneous flaps incorporate bone, muscle, and skin.

Successful application of microvascular tissue transfer was first reported in human patients in the early 1960s. The development of instrumentation, suture, and needles appropriate to the repair of small vessels was a prerequisite. Throughout the 1970s and 1980s, a plethora of manuscripts detailing microvascular flaps and techniques in human patients appeared in the literature. Free tissue transfer is now strongly integrated into orthopedic and reconstructive surgery.

Veterinary reconstructive microsurgery is comparatively in its infancy. However, several microvascular flaps have been described experimentally and have been applied clinically to reconstructive problems in dogs. The purpose of this discussion is to detail the latest developments in veterinary reconstructive microsurgery and to provide the reader with some insight into future potential applications.

Recipient Site Requirements

Tissues used in free flaps vary according to the requirements of the recipient wound. A detailed assessment of the wound

bed should be performed to obtain an optimal outcome after reconstruction. One of the greatest advantages of microvascular tissue transfer is the ability to select from various tissues and donor sites to best suit the patient's specific reconstructive requirements. Timing of reconstruction may also vary according to the status of the wound or exposure of vital structures.

Vascular supply is paramount to successful wound healing. Complex and high-velocity impact wounds are often associated with extensive vascular disruption. Loss of blood supply delays wound healing and increases the incidence of complications, especially in instances of orthopedic injury with associated soft tissue disruption.[1] Adequate debridement of devitalized tissue, followed by vascular enhancement through early reconstruction, is beneficial in these patients. Muscle is most efficacious in the revascularization of ischemic wound beds.[2-6] Free microvascular transfer of muscle into the wound bed assists in neovascularization of the wound and provides a source of systemic factors reducing the incidence of wound sepsis.

Structural requirements of the recipient site must also be considered in selecting appropriate tissues for microvascular transfer. In the simplest of cases, the wound may simply require a volume of tissue to replace a tissue deficit. This may be accomplished using various tissues and flaps. The specific selection of donor site depends, in these instances, on ease of access and volume of tissue required. More complex wounds, such as segmental bone loss, may have specific structural requirements that are the major determining factors in selection of donor tissue.

Functional requirements of the recipient site frequently play a role in determining the optimal donor tissue. For example, little benefit results from reconstructing a wound with loss of a vital functional muscle group unless that function is restored. Functional muscle transfer has not been reported clinically in the dog, but is used in human patients for facial reanimation and restoration of flexor function after forearm trauma.[7,8] The functional requirements of weight-bearing surfaces are particularly problematic after extensive injury to the footpads. Reconstruction using "like tissue" is ideal in such circumstances. Sensory reinnervation, although not of certain necessity, may also be accomplished through the use of a neurovascular free flap that incorporates a sensory nerve as well as a vascular pedicle. Sensory nerve repair of the donor nerve to an appropriate recipient nerve may assist in the ultimate protection of the transferred tissue against ongoing weight-bearing stresses.

Donor Site Selection

Selection of an appropriate donor tissue depends on the requirements of the recipient site. Factors to consider in the specific selection of a donor site include ease of surgical dissection, morbidity associated with loss of the donor tissue, matching of donor tissue to recipient requirements, and the ability to access both donor and recipient sites simultaneously. Free tissue transfer has been described as the art of "robbing Peter to pay Paul." The surgeon must ensure that Peter does, in fact, have what Paul needs and that, by stealing it, Peter will not suffer undue consequences.

Technical Considerations

Successful free tissue transfer depends on detailed advance planning. Familiarity of the surgical team with the procedure, patient positioning, stability of the patient under anesthesia, and selection and preparation of recipient vessels all may affect outcome.

Angiosomes

An angiosome is defined as a region of tissue or tissues perfused by a single-source artery and vein (Figure 41-26).[9] Adjacent angiosomes are interconnected by vessels termed choke anastomoses. These communications are of obvious biologic advantage. After vascular injury, an angiosome normally dependent on the injured vessel generally receives adequate vascular supply from adjacent angiosomes. However, anatomic continuity of angiosomes does not necessarily ensure physiologic continuity of vascular supply in the event of vascular injury.

The concept of the angiosome is central to the development of free tissue flaps. Tissue incorporated in a free flap should lie, ideally, entirely within the primary angiosome of the source artery and vein, to ensure survival after revascularization. Demonstration of tissue survival beyond the primary angiosome has been demonstrated with cutaneous axial pattern pedicle flaps and with some pedicled muscle flaps.[10-12] As a general rule, a single, smaller angiosome adjacent to the primary angiosome survives when incorporated into the flap design. Dissection

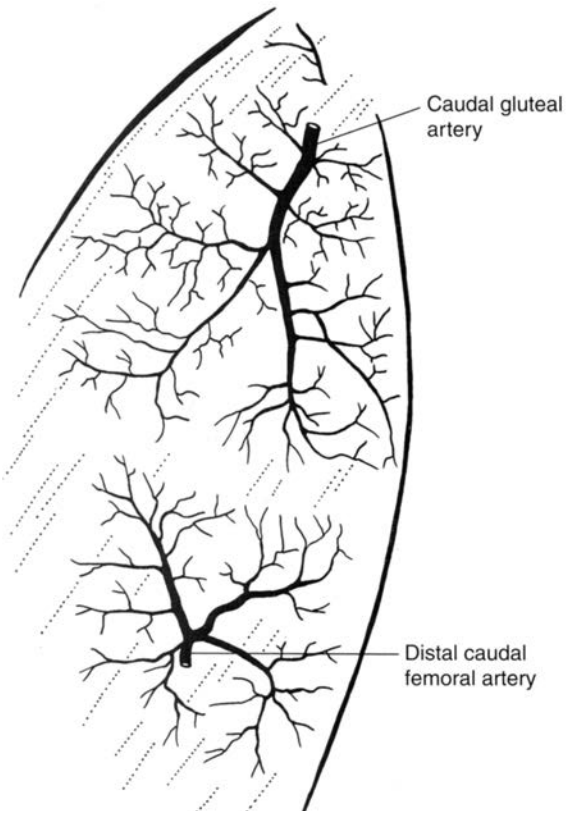

Figure 41-26. The biceps femoris muscle contains two distinct angiosomes. The proximal half of the muscle is vascularized by the caudal gluteal artery and vein, whereas the distal half of the muscle is vascularized by the distal caudal femoral artery and vein.

beyond the level of a single secondary angiosome should be considered tenuous and likely to lead to partial flap failure.

Anatomic descriptions of many cutaneous and muscle angiosomes have been provided for the dog, with few specific descriptions for the cat.[13-22] Based on this information, as well as on experimental data, several regional angiosomes and free flaps have been described. The importance of understanding the anatomy, consistency, and variability of regional vascular patterns cannot be overstated when undertaking microvascular tissue transfer.

Flap Dissection

The particular approach to flap dissection depends on the tissue harvested. Several guidelines and recommendations are common to dissecting all flaps for microvascular transfer. The tissue to be harvested must be isolated to the level of its source artery and vein. All supporting microvasculature must be preserved during this process. All underlying subcutaneous tissue should be incorporated with cutaneous flap dissections; underlying superficial cutaneous musculature should be incorporated in regions where such musculature exists. For example, the cutaneus trunci muscle should be incorporated with elevation of the thoracodorsal cutaneous flap. Muscle is readily dissected because of surrounding fascial sheaths. A soft tissue envelope is incorporated with dissection of vascularized bone grafts to preserve myoperiosteal vasculature. The reader should consult references pertaining to specific flaps, as well as the first section of this chapter, for details of surgical harvest.

Tissue is generally elevated beginning at a site distant to the vascular pedicle. Flap dissection is then continued until the source artery and vein are identified. Bleeding vessels encountered during this process should be meticulously controlled with bipolar electrocoagulation, suture ligation, or vascular clips. Once the vascular pedicle is identified, the artery and vein are skeletonized. Small branches encountered during vascular dissection may be electrocoagulated or clipped with vascular clips, depending on size. The surgeon must avoid damage to the intima of the parent vessel by excessive traction on small vascular branches or aggressive electrocautery. As much surrounding ad-ventitia as possible should be removed during initial dissection of the vascular pedicle. Surgical loupes providing a magnification of 3x to 4x facilitate identification of fine anatomic detail and atraumatic dissection of the vascular pedicle.

The length of vascular pedicle depends primarily on the anatomy of the donor flap. As a general rule, as much length as possible should be included with the initial vascular dissection. Excess length may be trimmed after transfer to the recipient site. A minimum vascular pedicle length of 1 cm is preferred, to allow manipulation of vessels during microanas-tomosis.

To minimize flap ischemia time, the vascular pedicle should not be ligated and divided before preparation of the recipient site. At that time, the artery and vein are independently ligated with vascular clips and are transected using fine vascular scissors.

Recipient Site Preparation

The recipient site should be free of devitalized tissue or active infection. Judicious debridement and lavage should be used to minimize contamination and necrotic tissue in open wounds. Early reconstruction of open wounds using vascularized tissues minimizes the risk of wound complications. In my experience, most open wounds can be converted to a state suitable for microvascular reconstruction within 48 hours of injury. Minimal debridement should be required at the time of microsurgical reconstruction. The wound bed may be lavaged preoperatively with an antibacterial solution, such as 0.05% chlorhexidine gluconate, to decrease bacterial contamination.

Recipient vessels, appropriate for anastomosis to the artery and vein of the flap to be transferred, must be identified and dissected. A knowledge of regional vascular anatomy is obviously a prerequisite. In patients with severe trauma, or a past history of trauma or surgery involving the affected area, preoperative angiography should be considered to identify variations in vascular anatomy. Recipient vessels should approximate the diameter of donor vessels, assuming end-to-end anastomosis. End-to-side technique is often used for arterial anastomosis, to preserve arterial supply distal to the wound. In this event, the recipient artery should be of larger diameter than the donor artery. Recipient vessels should be dissected beyond the wound's zone of trauma. The surgical approach used for vascular dissection should involve elevation of a skin flap such that the incision will not directly overlie the vascular anastomosis after skin closure.

The free flap is secured at the recipient site before initiating microvascular anastomosis. In the case of soft tissue flaps, this is accomplished using a few strategically placed simple interrupted sutures. Cutaneous flaps are sutured under minimal tension. Muscle flaps are sutured under sufficient tension to approximate their initial resting length at the donor site. Vascularized bone grafts are stabilized using suitable orthopedic fixation. Microvascular anastomosis of the donor and recipient artery and vein is then completed using an operating microscope and standard microvascular technique. Approximating clamps are not released until the completion of both artery and vein repair.

Pedicle length must be planned to avoid excessive length and redundancy of the pedicle or insufficient length resulting in tension or kinking. The vascular pedicle must be carefully positioned to avoid compression of the anastomosed vessels during closure. The venous pedicle is particularly sensitive to these effects. The vascular pedicle is assessed for patency, and remaining sutures are placed between the flap and the recipient wound bed. Patency should be reassessed before final skin closure. Total operative time is minimized by using two surgical teams. One team harvests the donor tissue while the second simultaneously prepares the recipient site.

Flap Perfusion and Anticoagulation

Uncomplicated free tissue transfer generally requires approximately 4 hours of general anesthesia. More complicated procedures, such as those requiring orthopedic fixation, may

necessitate 6 to 10 hours of general anesthesia. Adequate flap perfusion depends on maintaining the cardiovascular stability of the patient during the operative and postoperative periods. Intravenous fluid support during and after surgery is an absolute requirement.

Hypothermia must be controlled to avoid peripheral vasoconstriction and deleterious effects on flap perfusion. Patients are maintained on circulating water blankets, and temperature is monitored both during and after the surgical procedure. A heat lamp may be placed over the flap during the immediate postoperative period, before the patient's recovery from anesthesia. Bandaging of flaps using a lightly applied, heavily padded bandage protects the flap from trauma and assists in trapping body heat.

No consistent recommendation exists on the use of antithrombotic agents before, during, or after microvascular tissue transfer. The most critical factor in preventing thrombosis of the microvascular anastomosis is appropriate surgical technique, and no amount of antithrombotic therapy can salvage a poorly performed anastomosis. Heparin and saline (10 units heparin per 1 mL saline) are used topically at the anastomotic site to clear the lumen of vessels before anastomosis. Other antithrombotic therapy is determined by the preference of the surgeon and identified patient risk factors.

Aspirin may be used at a dose of 5 to 10 mg/kg body weight preoperatively, to inhibit platelet aggregation.[23] I routinely administer dextran 40 at a dose of 10 mL/kg body weight intraoperatively. Dextran administration expands the vascular space, thereby improving flap perfusion, and it may have an inhibitory effect on platelet function.[24] Anticoagulation using systemic heparin is rarely indicated.

Tolerated flap ischemia times vary according to the tissue transferred.[25-27] Skin is considered resistant to the detrimental effects of ischemia and reperfusion. Cutaneous free flaps tolerate 6 to 8 hours of warm (room temperature) ischemia before the onset of significant injury. Muscle is sensitive to ischemia and reperfusion and may demonstrate detrimental effects after 2 to 4 hours of warm ischemia. Total ischemia times in clinical free tissue transfer rarely exceed these time frames. In my experience, flap ischemia times have varied from 60 to 180 minutes.

Occasionally, a flap fails to perfuse after an apparently successful microvascular anastomosis. This is termed a "no-reflow" phenomenon and may be attributed to many causes. In this event, the vascular pedicle extending from the anastomotic site to the flap should be inspected under the operating microscope. Active bleeding through any previously unidentified branches from the pedicle is controlled with vascular clips. Specific attention is paid to areas of potential vascular injury and vasospasm. If a region of vasospasm is identified, 2% lidocaine is placed topically on the vessel. If focal vasospasm persists, then damage to the vessel may be assumed, and microvascular anastomosis should be repeated distal to this site. No reflow may occasionally be caused by inappropriate or traumatic dissection of the flap, with subsequent injury to the supportive microvasculature. This problem is easily avoided through meticulous attention to flap dissection. Little can be done to rectify the situation after its occurrence. Extended ischemia time may lead to reperfusion injury and subsequent occlusion of venous microvasculature by neutrophil adhesion. Therapy aimed at alleviating ischemia-reperfusion injury is indicated, but it is of questionable benefit after the period of reperfusion.

Postoperative Monitoring

Free flaps entirely depend on the integrity of the microvascular anastomsoses. Free flap failure may be caused by venous or arterial thrombosis, either of which must be recognized early and investigated aggressively if the flap is to be salvaged. Venous failure of cutaneous flaps is most easily recognized by the onset of congestion in the flap (Figure 41-27). A purplish-blue discoloration is noted. Bandaged flaps may be assessed by creating a window in the bandage to allow visualization of a portion of the flap. Flaps tolerate venous outflow occlusion poorly. At the earliest indication of this problem, the patient should be returned to the operating room, and the vascular pedicle should be dissected using the operating microscope. Careful attention is paid during the approach to look for evidence of vessel compression or kinking caused by positioning of the vascular pedicle or restrictive skin closure. If this is the case, the anastomosis may actually be patent, and the problem is addressed by simple repositioning of the pedicle or release of the overlying skin incision. In the event of a thrombosed anastomosis, the

Figure 41-27. A latissimus dorsi myocutaneous flap has been used to reconstruct a large deficit over the rear quarters in this dog. Venous compromise of the flap is visually apparent because of the onset of congestion and purplish discoloration of the flap. Reexploration of the venous pedicle and, possibly, medicinal leech therapy are indicated.

region of thrombosis is excised, and venous effluent from the flap is documented. Once flow through the flap is established, venous anastomosis is repeated. Sluggish venous outflow may also be treated by application of medicinal leeches. Leeches reduce flap congestion by direct ingestion of blood and by promoting continued hemorrhage from bite wounds resulting from local infusion of hirudin.[28]

Arterial failure can be more difficult to diagnose because it is not associated initially with overt color change of the flap. Flap temperature can be monitored; a drop in temperature indicates arterial insufficiency. This method is unreliable in bandaged flaps, because the bandage traps body heat and artificially elevates flap temperature. Doppler flow probes may be used to monitor arterial patency more reliably in the postoperative period. A window is created in the bandage overlying the arterial pedicle distal to the anastomosis. A pencil Doppler probe is then easily inserted through the window to monitor arterial patency. Bleeding may be a useful indicator of flap perfusion. Cutaneous flaps are punctured with a 20- or 22-gauge hypodermic needle and are monitored for active bleeding from the site. More specialized monitoring techniques such as laser Doppler flowmetry or fluorescein clearance have been described, but they are usually beyond the realm of clinical necessity.

Monitoring of flaps that do not incorporate a cutaneous component is more difficult. Doppler techniques are useful for monitoring arterial adequacy in such flaps. Venous monitoring is difficult or impossible. Vascularized bone grafts should be assessed using [^{99m}] technetium scintigraphy within 5 days of operation.

Free Flaps in the Dog and Cat

Several free flaps have been described experimentally, clinically, or both in the dog and cat. Other flaps have been described as pedicled flaps, maintaining a vascular attachment to the donor site. These flaps may be used reliably for free transfer as well, assuming adequate dimensions of the vascular pedicle. Vessel diameters for most described flaps in the dog approximate 1 to 2 mm. Vessel diameters of less than 0.5 mm are associated with increased rates of anastomotic thrombosis.

Cutaneous Flaps

Cutaneous angiosomes have been described extensively, and anatomic landmarks for dissection of pedicled cutaneous axial pattern flaps are well documented. Axial pattern skin flaps may be used for free transfer as well.

The superficial cervical axial pattern flap, based on the direct cutaneous pedicle of the prescapular branch of the superficial cervical artery and vein, has been documented as a free flap in a series of cases (Figure 41-28).[29,30] The vascular pedicle perforates the septum formed by the omotransversarius, cleidocervicalis, and trapezius muscles. The cutaneous angiosome extends dorsally from the point of origin to the midline and roughly incorporates the caudal two-thirds of the cervical skin in a cranio-

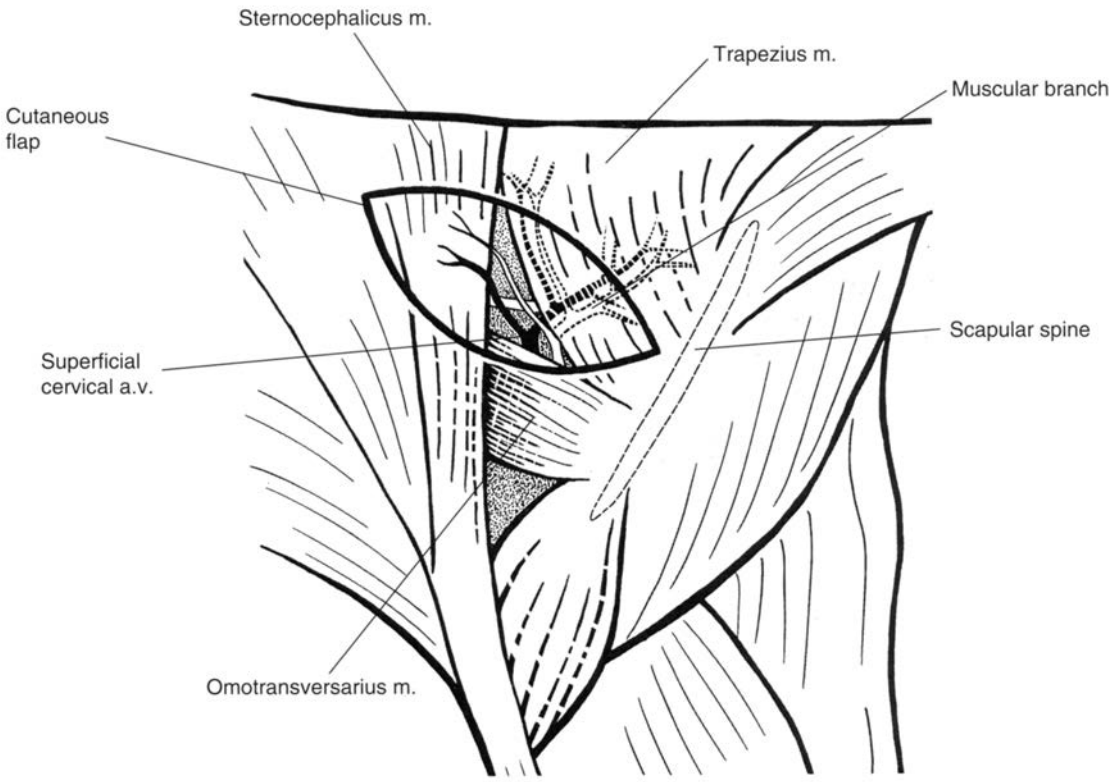

Figure 41-28. The anatomy of the superficial cervical cutaneous free flap is indicated. The direct cutaneous artery arises from a septum formed by the trapezius, omotransversarius, and sternocephalicus muscles. The muscular branch to the cervical portion of the trapezius muscle also arises from the superficial cervical artery.

caudal direction. The amount of skin harvested for transfer is determined, first, by the requirements of the recipient site and, second, by the ability to close the donor site primarily.

I have also used the caudal superficial epigastric axial pattern flap sporadically for microvascular transfer. The primary advantage of selecting an axial pattern skin flap for microvascular transfer is ease of dissection. Disadvantages include excessive bulk from inclusion of associated subcutaneous tissue and poor cosmetic result caused by differential hair growth characteristics between donor and recipient sites.

The saphenous fasciocutaneous free flap has been documented in experimental and clinical cases.[28,31] The flap is based on the medial saphenous artery and vein and includes the skin overlying the medial aspect of the thigh (Figure 41-29). Flap dissection includes the superficial fascia of the medial gastrocnemius muscle, giving the flap its designation as fasciocutaneous. Numerous small direct cutaneous vessels arise from the saphenous vessels as they course through the flap. The saphenous fasciocutaneous flap has the advantage of less bulk and improved cosmetic results compared with other free axial pattern skin flaps. The width of the flap is limited by the ability to close the donor site primarily.

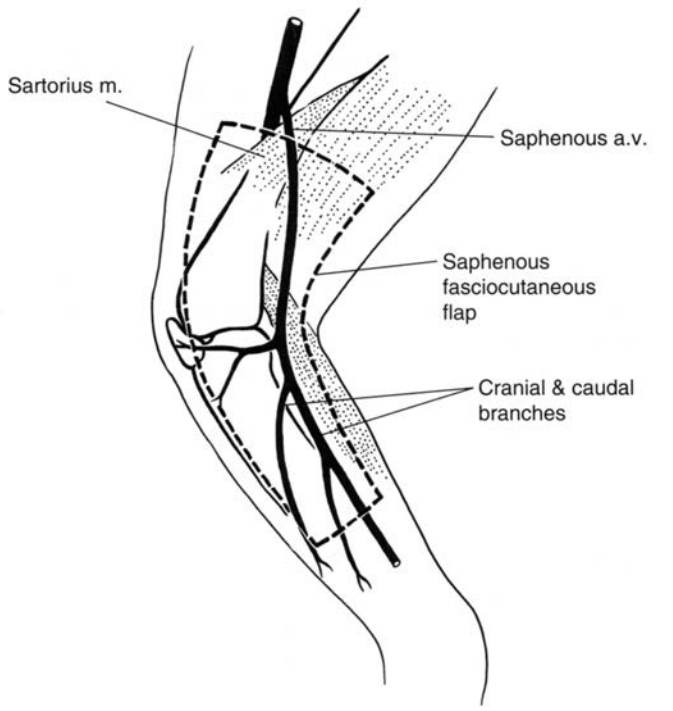

Figure 41-29. The saphenous fasciocutaneous flap is composed of skin and underlying fascia overlying the medial aspect of the thigh and tibia. The flap is based on the medial saphenous artery and vein. Inclusion of the caudal sartorius muscle is possible, by preservation of muscular branches from the saphenous vessels.

Muscle Flaps

Muscle probably has the greatest utility of any tissue used for microsurgical reconstruction. Muscle flaps are, for the most part, easily dissected. Most muscles may be harvested with minimal donor site morbidity because of the function of synergic muscle groups. Neovascularization of compromised wound beds is facilitated to a greater degree by muscle than by other tissues. Finally, donor muscles may be selected that closely match the dimensional and functional requirements of nearly any wound reconstruction.

The angiosomes of muscles may be classified into one of five types (Figure 41-30). Type I muscles have a single dominant vascular pedicle. Type II muscles have a single dominant pedicle and one or more minor pedicles. Type III muscles contain two dominant vascular pedicles, each of which has an approximately equal contribution to the muscle's blood supply. Type IV muscles have a segmental blood supply formed by numerous small pedicles of approximately equal contribution. Type V muscles have a single dominant vascular pedicle near their insertion and a segmental system near the origin of the muscle. Based on assumptions of physiologic blood supply through angiosomes, one can surmise that any type I muscle will survive entirely after free transfer based on the single dominant pedicle. Most type II muscles willl survive based on the dominant pedicle, depending on the number and relative contribution of the minor pedicles. Type III muscles are expected to survive after free transfer based on either dominant pedicle system. Type V muscles generally will survive based only on the single dominant pedicle. Type IV muscles are generally poor candidates for microvascular transfer because of the large number and small contribution of each pedicle system to the muscle's blood supply. Detailed descriptions of the vascular supply to muscles of the dog have been published.[21,22] The foregoing assumptions given serve as guidelines only. The ultimate reliability of any muscle in reconstructive microsurgery is proved only through experimental or clinical trials that establish its utility. If at all possible, muscle transfers should be limited to single angiosomes or previously documented free flaps.

Trapezius Muscle Flap

The vascular supply of the cervical portion of the trapezius muscle has been thoroughly described, as has the entire angiosome of the prescapular branch of the superficial cervical artery and vein (Figure 41-31).[32] The cervical portion of the trapezius muscle has a type II vascular supply, with the prescapular branch of the superficial cervical artery forming the dominant pedicle. Experimentally and clinically, survival of the entire cervical portion of the muscle has been consistently documented based solely on this dominant pedicle.

Dissection of the trapezius muscle flap is through a curvilinear incision beginning approximately 2 to 3 cm cranial to the point of the shoulder, extending dorsally parallel to the scapular spine and curving cranially below the dorsal midline.[33] Skin and subcutaneous tissue are dissected from the superficial fascia of the muscle, with care taken to identify and ligate the direct cutaneous branch as it exits the septum formed by the trapezius, omotransversarius, and cleidocervicalis muscles. The cervical portion of the trapezius muscle is sharply incised from its attachment to the scapular spine. Fascial attachments dorsally are incised, and the muscle is elevated carefully. Several muscle branches extending into deep musculature of the neck are identified and are ligated with vascular clips. At this point, the vascular pedicle should be located. The location of the pedicle is variable as it courses deep

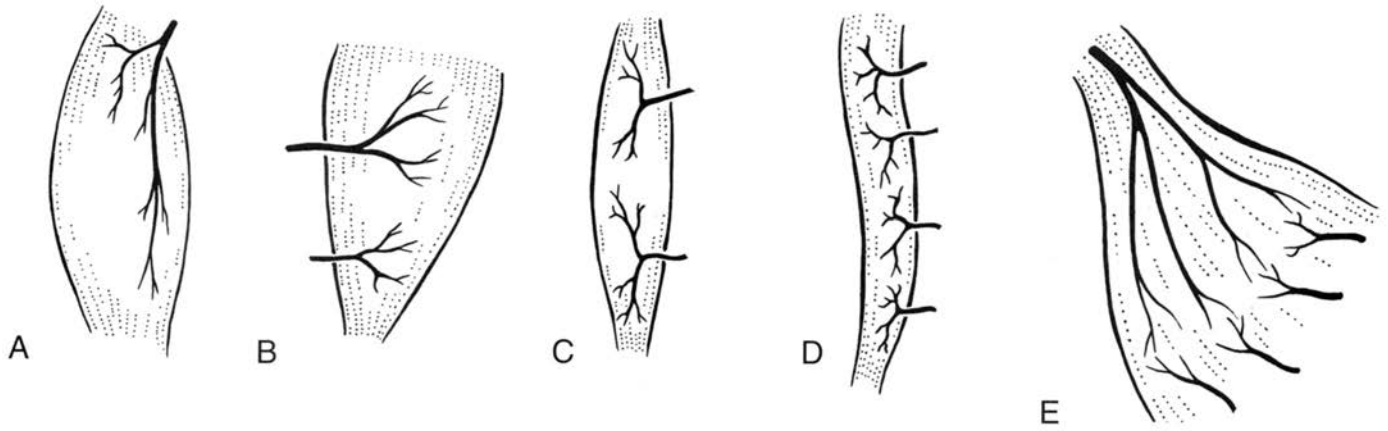

Figure 41-30. Diagrammatic representation of the five basic vascular patterns to skeletal muscles. **A.** Type I muscles have a single vascular supply. **B.** Type II muscles have one dominant pedicle and one or more minor pedicles. **C.** Type III muscles contain two equally dominant pedicles. **D.** Type IV muscles have a segmental blood supply derived from numerous small pedicles. **E.** Type V muscles have a single dominant pedicle near their insertion and a second segmental system near their origin. Type IV muscles are the least suitable for microvascular application.

to the trapezius muscle. It is most commonly located immediately beneath the cranial border of the muscle coursing from ventral to dorsal. In a few instances, the vascular pedicle lies immediately cranial to the cranial border of the trapezius muscle and gives off several smaller muscular branches to the muscle as it extends dorsally. Dissection in these patients must be performed with caution, to preserve the integrity of the vascular pedicle. After identification of the prescapular branch of the superficial cervical artery and vein, remaining muscle attachments are dissected. One or two small muscular branches to the omotransversarius muscle are identified and clipped, and the artery and vein are skeletonized and dissected for a length of at least 2 to 3 cm. The prescapular lymph node is intimately associated with the vascular pedicle and may either be included with the pedicle or carefully excised.

I used the trapezius muscle free flap for distal extremity reconstruction in a series of 20 cases. The trapezius muscle is broad and flat, lending itself well to conformation to many wound beds. Bulk of the flap is minimal and decreases dramatically over the course of several weeks because of denervation atrophy. Despite denervation atrophy, transferred muscle maintains a constant vascular density beneficial to the wound bed. The trapezius muscle is resurfaced using a full-thickness skin graft harvested from a donor site with hair growth characteristics similar to those of the recipient

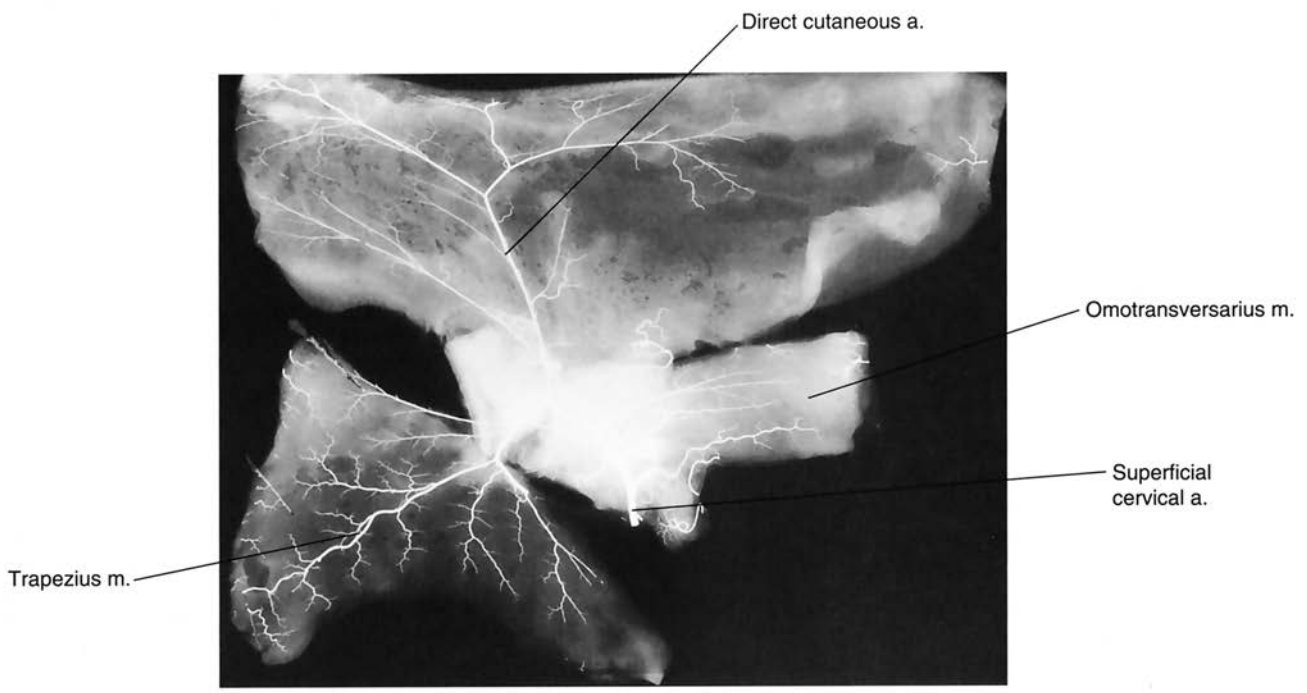

Figure 41-31. Barium has been infused into the superficial cervical artery to demonstrate the regional angiosome of this vessel. The superficial cervical artery gives rise to the dominant pedicle of the cervical portion of the trapezius muscle, the superficial cervical direct cutaneous artery, and a minor pedicle to the omotransversarius muscle. Any or all of these tissues may be included in a microvascular flap based on this vascular pedicle.

Figure 41-32. A. Cosmetic results are less than optimal after reconstruction using the trapezius myocutaneous flap because of the excessive subcutaneous bulk and poor match of hair characteristics. **B.** Contour and hair characteristics are much more closely matched by using the trapezius muscle flap and resurfacing with a full-thickness skin graft.

site. This technique has resulted in improved cosmetic results, compared with cutaneous or musculocutaneous free flaps (Figure 41-32). Seroma formation at the donor site is common and should be managed with drain placement for 5 to 7 days.

Latissimus Dorsi Muscle Flap

The latissimus dorsi muscle has, historically, been the workhorse for microsurgical reconstruction of complex distal extremity wounds in human patients. Pedicled latissimus dorsi muscle flaps have been used for chest wall reconstruction and experimental cardiomyoplasty in the dog and have been described experimentally for microsurgical transfer in the cat.[34] The latissimus dorsi muscle reliably survives in its entirety based solely on the dominant thoracodorsal artery and vein, which enter the deep surface of the muscle near its insertion (Figure 41-33). The muscle is approached through a curvilinear skin incision beginning at the axilla and extending dorsally and caudally to the level of the muscle's origin. Skin and subcutaneous tissues are dissected from the superficial muscle fascia, with care taken to identify and ligate the direct cutaneous branch of the vascular pedicle, located near the caudal shoulder depression. The origin of the latissimus muscle is identified and is sharply incised. Muscle elevation reveals numerous small muscular branches ex tending from the intercostal arteries. Segmental pedicles are cauterized or ligated and are transected as they are encountered. Dissection continues toward the muscle's insertion, and the dominant thoracodorsal artery and vein are identified on the deep surface of the muscle. After identification of the vascular pedicle, the muscle's tendon of insertion is transected, and the thoracodorsal artery and vein are skeletonized for a length of at least 2 to 3 cm. The cat occasionally has a minor pedicle originating from the lateral thoracic artery and vein, which enter

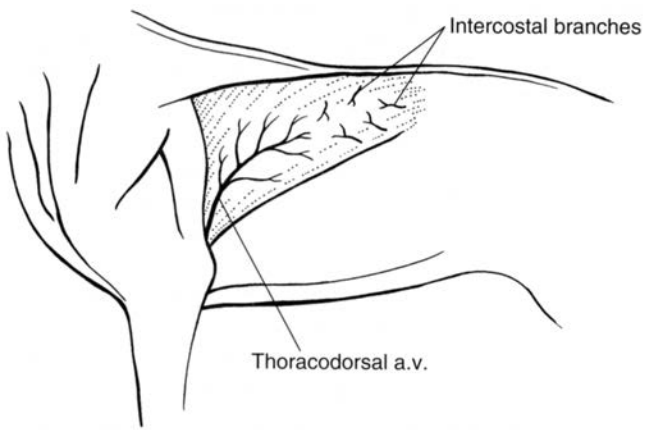

Figure 41-33. The latissimus dorsi flap is based on the dominant thoracodorsal vascular pedicle. The entire muscle survives based on this dominant pedicle.

the deep surface of the muscle ventrally near its tendon of insertion. This pedicle must be identified and ligated. The thoracodorsal pedicle in the cat has a diameter of approximately 0.4 mm, making microvascular anastomosis difficult. Dissection in the cat is therefore continued to the level of the origin of the subscapular artery and vein from the axillary vessels to facilitate subsequent anastomosis.

The dimensions of the latissimus dorsi muscle exceed the requirements of most wound beds in the dog. Its clinical use therefore has been sporadic. The latissimus dorsi muscle is useful as a free flap in patients with massive soft tissue loss secondary to trauma or ablative cancer surgery. I have used the latissimus dorsi free flap for cranial reconstruction after partial

craniectomy and orbitectomy for a sebaceous adenocarcinoma in a dog and for reconstruction of a massive rear limb degloving injury with associated orthopedic trauma. Clinical experience with this flap, however, is limited.

Vascularized Bone Grafts

The veterinary literature has no clinical reports, and few experimental descriptions, of autogenous vascularized bone grafts. Numerous reports of vascularized canine bone grafts appear as experimental models in the human literature. The indications, contraindications, and clinical utility of nonvascularized cortical bone grafts are well established. Nonvascularized cortical bone grafts provide immediate structural support in orthopedic reconstruction. Ultimate success depends on revascularization of the cortical graft from the wound bed, followed by gradual resorption and new bone deposition. This process requires years to complete and depends on a favorable wound environment. Osteomyelitis, structural weakening of the graft, and delayed healing of graft-bone interfaces are common complications.

Autogenous vascularized bone grafts are advantageous in that they maintain a vascular supply and, therefore, viability of cellular elements within the graft. Graft bone actively contributes to bone healing and remodeling. Vascularized grafts are more resistant to infection than nonvascularized grafts, lending themselves to the reconstruction of large segmental defects or vascularly compromised wound beds. Vascularized bone grafts described in the dog include rib, fibula, proximal ulna, and distal ulna.[35]

Vascularized Fibula Graft

The canine fibula graft has been used as an experimental model for the study of vascularized bone graft biology (Figure 41-34).[36] The popliteal artery branches into a larger cranial tibial and a smaller caudal tibial artery. The caudal tibial artery enters the interosseous space between the fibula and tibia and is intimately associated with the flexor hallucis longus muscle. The nutrient artery of the fibula arises from the caudal tibial artery and enters the fibula medially in its central third. Dissection of the fibula is performed to maintain a surrounding muscle cuff. Particular care is taken to preserve the flexor hallucis longus muscle with the graft. Subperiosteal dissection of the tibia is required to preserve vasculature within the interosseous space. The fibula may be transferred based either on the caudal tibial artery or on the popliteal artery. Dissection to the level of the popliteal artery necessitates ligation and transection of the cranial tibial artery. Use of the caudal tibial artery as a pedicle may be limited by the diameter of these vessels. Iatrogenic damage to the peroneal nerve must be avoided during proximal dissection of the graft and vascular pedicle. The vascularized fibula graft has not been used clinically in the dog and likely has limited utility for segmental long bone reconstruction because of its poor structural integrity.

Vascularized Rib Graft

Microsurgical transfer of the rib has been used in the dog as an experimental model for bone transfer.[37] Either the dorsal or the ventral part of the intercostal vascular system may be used as a vascular pedicle for rib transfer. Inclusion of the nutrient artery with the transfer mandates dorsal dissection.

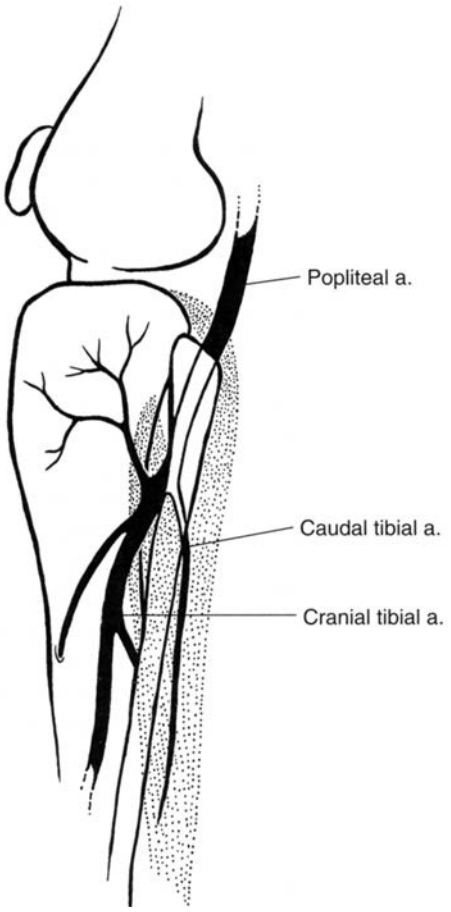

Figure 41-34. The anatomy of the vascularized fibula graft is demonstrated. The fibula may be harvested based on the caudal tibial artery. Dissection to the level of the popliteal artery gives rise to a more manageable pedicle for microvascular anastomosis, but it necessitates ligation of the cranial tibial artery.

Ventrally dissected grafts survive based on an intact musculoperios-teal vascular supply. The dorsal intercostal arteries arise from the thoracic aorta. Immediately before entering the intercostal space, a dorsal branch supplying the spinal cord and epaxial muscles is given off. The nutrient artery branches from the dorsal intercostal artery just distal to the tubercle of the rib and extends dorsally to enter the nutrient foramen. The dorsal intercostal artery continues distally in the costal groove on the caudal aspect of the rib, giving off numerous periosteal branches. A lateral cutaneous branch is formed from the dorsal intercostal artery before its anastomosis with the ventral intercostal artery. Intercostal veins parallel the arterial supply, with eventual drainage into the azygous vein. Clinical utility of the rib graft likely will be limited by its curvature and weak structural characteristics. Vascularized rib grafts may prove to have some usefulness in mandibular reconstruction, although this remains to be documented.

Vascularized Proximal Ulna Graft

The canine ulna may be harvested with little resulting functional impairment to limb use. This fact, along with the obvious structural integrity of the ulna, makes it a logical choice for segmental long bone reconstruction. The proximal ulna bone graft is harvested based on the common interosseous vascular

pedicle.[38] The common interosseous artery arises from the median artery at the level of the proximal radius, immediately enters the interosseous space from the medial side, and bifurcates into caudal and cranial interosseous branches. The caudal interosseous artery continues distally in the interosseous space, where it gives rise to the nutrient arteries of the radius and ulna, as well as to multiple periosteal branches. The nutrient artery of the ulna enters near the junction of the proximal and central thirds of the bone. The cranial interosseous artery emerges from the interosseous space laterally, where it gives rise to muscular branches to the extensor carpi ulnaris and the lateral and common digital extensor muscles.

Dissection of the proximal ulna graft is performed through a curvilinear caudolateral skin incision. Fasciotomy of the flexor and extensor muscle groups facilitates muscle dissection and identification of vascular structures. Separation between the extensor carpi ulnaris and the lateral digital extensor muscles proximally reveals vascular branches to these muscles. These muscular branches serve as a consistent landmark indicating the level of the vascular pedicle of the flap (Figure 41-35). The lateral radial periosteum is incised along the cranial surface of the abductor pollicis longus muscle, and subperiosteal dissection of the radius is continued into the interosseous space. The medial radial periosteum is similarly incised and elevated. Distal osteotomy of the ulna is then performed using an oscillating bone saw. The caudal interosseous artery and vein are identified within the interosseous space, ligated, and divided. Proximal osteotomy of the ulna is performed proximal to the level of the vascular pedicle. Circumferential subperiosteal dissection of the ulna is performed at this level, and the ulna is osteotomized. Muscular branches to the extensor muscles are ligated and divided. Cautious elevation of the os-teotomized ulna reveals the common interosseous pedicle on the medial aspect of the graft. The common interosseous artery and vein are dissected to their point of origin from the median artery and vein.

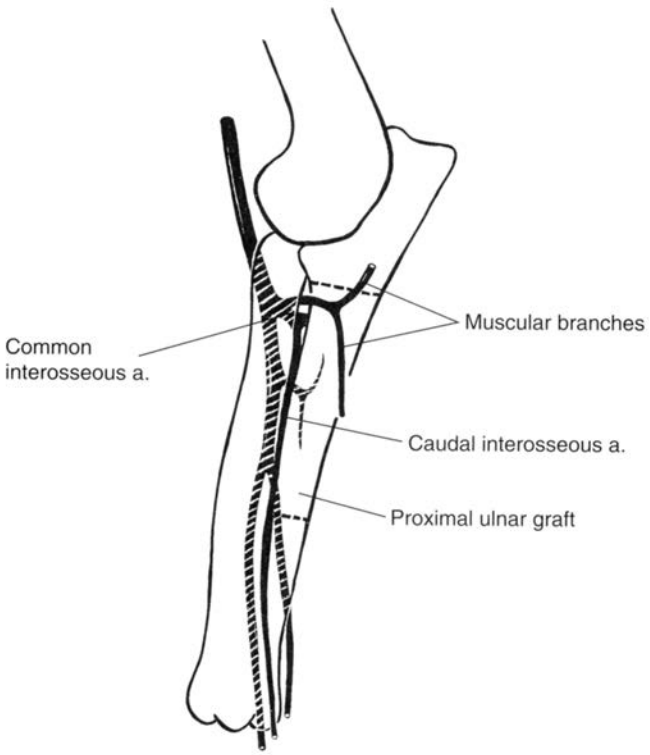

Figure 41-35. The proximal ulna vascularized bone graft is based on the common interosseous pedicle and preserves both the periosteal and nutrient vascular systems. Muscular branches to extensor muscles indicate the approximate level of the common interosseous pedicle.

Advantages of the proximal ulna graft include structural integrity and provision of a nutrient blood supply. Primary disadvantages include the necessity of proximal osteotomy adjacent to the elbow joint, difficult dissection of the vascular pedicle because of its medial location, and limited length of the vascular pedicle. The proximal ulna graft has been documented experimentally, but it has not yet been used clinically in the dog.

Vascularized Distal Ulna Graft

The distal ulna graft has great potential for clinical use in the dog.[39] The approach to initial dissection of the graft is identical to that described for the proximal ulna graft. After fasciotomy of the flexor and extensor muscle groups, the caudal interosseous artery and vein are identified as they exit the interosseous space caudomedially at the level of the distal ulna. These vessels are ligated and transected. The ulna is circumferentially dissected immediately distal to this level and is osteotomized using an oscillating bone saw. Dissection of the medial and lateral radial periosteum is performed as described for the proximal ulna transfer and is continued proximally. Subperiosteal dissection of the radius must be performed with great caution to avoid damage to the caudal interosseous vessels as they course through the interosseous space. The length of graft required for recipient site reconstruction is calculated. Proximal osteotomy is performed after circumferential subperiosteal dissection of the ulna. The proximal osteotomy should be performed such that the resulting length of bone graft is 2 to 3 cm longer than that required for the reconstructive procedure (Figure 41-36). The caudal interosseous artery and vein are located within the interosseous space, ligated with vascular clips, and transected. Once harvested, the interosseous artery and vein are dissected for a length of approximately 3 cm. The bone graft is then shortened to its required length by osteotomizing that portion of proximal ulna from which the vascular pedicle has been dissected.

The distal ulna graft depends entirely on an intact musculoperiosteal circulation for survival. An intact musculoperiosteal cuff must be included with the dissection, to include the ulnar head of the deep digital flexor, the pronator quadratus, and the abductor pollicis longus muscles. External skeletal fixation is recommended to minimize implant-associated embarrassment of the periosteal vasculature.

The utility of the vascularized distal ulna graft has been demonstrated experimentally.[40] I have used the distal ulna graft for reconstruction of the distal radius after limb-sparing surgery for osteosarcoma and for reconstruction of a mandibular nonunion and segmental defect caused by a gunshot injury.

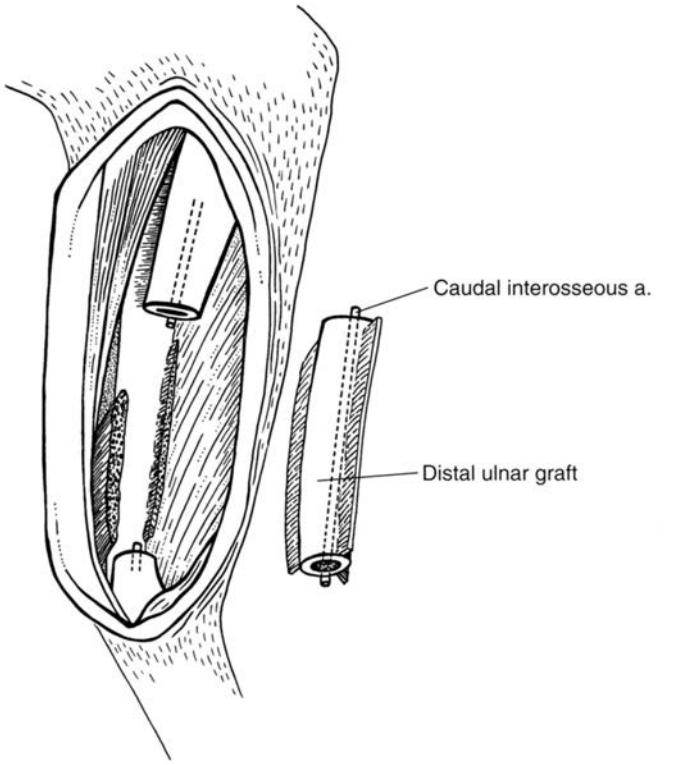

Figure 41-36. The distal ulna vascularized bone graft is based on the caudal interosseous artery and vein. Dissection preserves only the periosteal vascular supply. Inclusion of a surrounding muscle cuff is required to preserve this blood supply.

Compound Flaps

Compound free flaps incorporate tissues of more than one type. They may be useful for the reconstruction of complex trauma involving loss of multiple tissue types. A detailed knowledge of vascular anatomy allows the surgeon the flexibility of designing many compound flaps.

Musculocutaneous flaps combine both muscle and skin in the transfer. The superficial cervical axial pattern skin flap may easily be included with the cervical portion of the trapezius muscle by maintaining the direct cutaneous branch rather than by ligating it during dissection. The vascular supply to both muscle and skin is based on the prescapular branch of the superficial cervical artery and vein. Similarly, the thoracodorsal axial pattern skin flap may be incorporated with the latissimus dorsi muscle flap. Dissection of musculocutaneous free flaps must be carefully planned to include appropriate dimensions of the cutaneous component. With inclusion of an axial pattern skin flap, the cutaneous component may be used to overlie the transferred muscle directly and to reconstruct an associated cutaneous defect. The axial pattern skin flap may also be dissected free of the muscle flap, with care taken to maintain the direct cutaneous artery and vein. This allows use of both the muscle and cutaneous components for reconstruction of adjacent portions of large wound beds (Figure 41-37).

Myo-osseous flaps incorporate both muscle and bone. By strict definition, all vascularized bone grafts may be considered myo-osseous because of the preservation of an intact musculo-

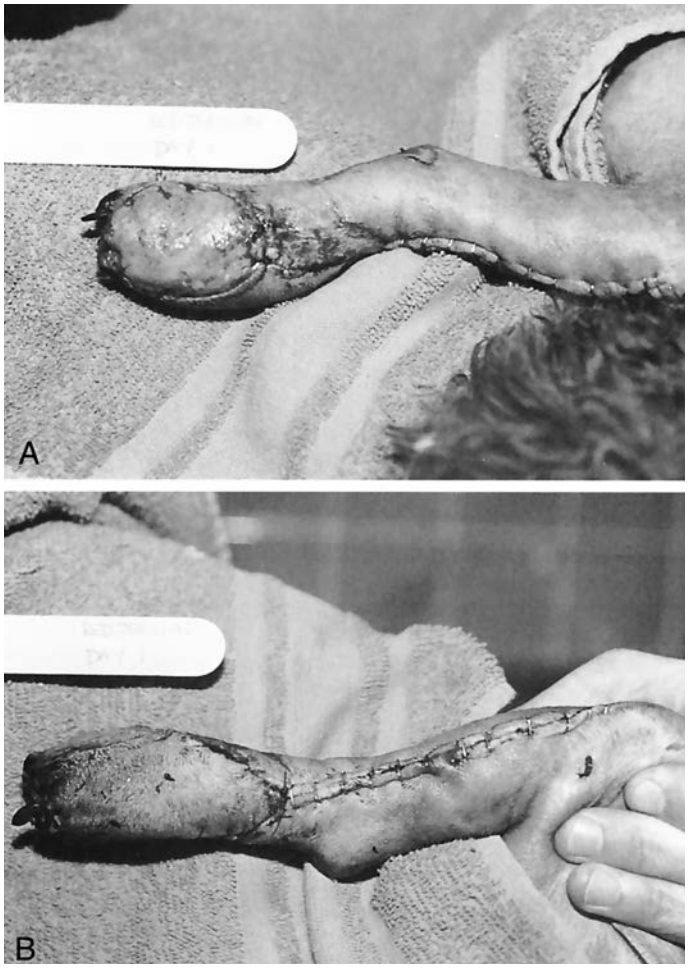

Figure 41-37. The cutaneous portion of myocutaneous flaps incorporating a direct cutaneous artery may be dissected independent of the underlying muscle. In this dog, the trapezius muscle was used to reconstruct the lateral aspect of a large degloving injury **A.** while the cutaneous portion of the flap was rotated to cover the defect medially **B.** The muscle was subsequently resurfaced with a full-thickness skin graft. Both components of the flap are based on the superficial cervical artery and vein.

periosteal cuff. However, the term is recognized to designate the inclusion of a significant muscle component used in the reconstruction. The successful inclusion of the scapular spine with the cervical trapezius muscle flap has been demonstrated experimentally (Figure 41-38).[41] Survival of the scapular spine depends on its periosteal vascular supply. Unfortunately, the scapular spine lies outside the primary angiosome of the prescapular branch of the superficial cervical artery, and this causes some concern relative to the reliability of its vascular integrity after transfer. I have used the cervical trapezius myo-osseous flap for reconstruction of metatarsal segmental defects and overlying soft tissue loss caused by a gunshot injury in a Chesapeake Bay retriever. Survival of the muscle flap and its overlying free skin graft was evident. However, postoperative [^{99m}]technetium scintigraphy of the bone graft was negative. This bone graft proceeded to rapid incorporation and healing, a finding suggesting either an intact vascular supply or rapid revascularization. Based on the negative scintigraphy results in this dog and the tenuous vascular integrity of the flap design, the cervical trapezius myo-osseous flap should be used with caution.

Figure 41-38. The trapezius flap may be extended to include the scapular spine, to form an osteomusculocutaneous flap. The scapular spine lies outside the primary angiosome of the flap, but experimentally it has been shown to survive based on perfusion through "choke" anastomoses from the trapezius muscle. Elevation of the flap based on the superficial cervical vessels is demonstrated.

The vascularized rib graft may be harvested as an osteocutaneous flap by preserving the cutaneous branch of the dorsal intercostal artery and its associated skin paddle. Maintenance of the skin paddle facilitates postoperative monitoring of vascular integrity of the flap. This flap may also be of benefit in mandibular reconstruction with associated skin loss.

Reconstruction of Weight-Bearing Surfaces

Reconstruction of weight-bearing surfaces poses a particular problem because of the stresses placed on the repair. Tissue used for such reconstruction must be durable and resilient. Local footpad transposition techniques and free pad grafts have been described for footpad reconstruction.[42-45] Marginal recipient beds may compromise the success of free grafts, and extensive trauma may preclude local transposition techniques. Free vascularized transfer of footpads may be used for reconstruction in such cases.

A microvascular transfer of the fifth digital footpad was described previously (Figure 41-39).[46] This procedure involves a digital fillet of the fifth rear digit. All phalangeal bones are dissected extraperiosteally and are excised through a dorsal skin incision. The digital pad and surrounding skin are then harvested, based on the deep plantar metatarsal artery IV and the superficial dorsal metatarsal vein IV. Sensory innervation is provided by the deep plantar metatarsal nerve IV and parallels the arterial supply to the footpad. Transfer may be accomplished as a microvascular free flap or as a neuromicrovascular free flap with repair of the donor nerve to a sensory nerve branch at the recipient site. The absolute necessity of sensory reinnervation in such flaps is not established.

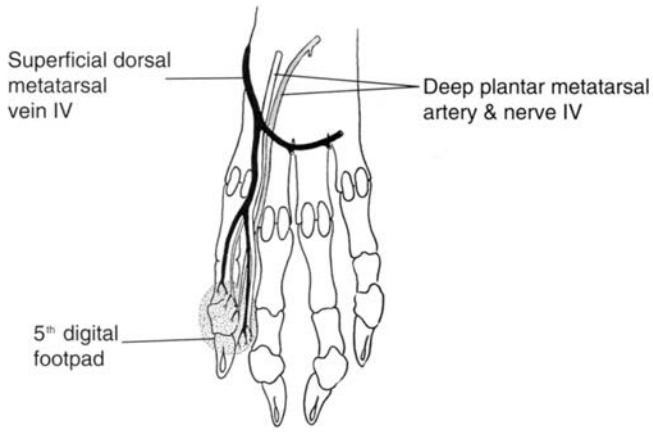

Figure 41-39. The fifth digital footpad may be harvested as a microvascular free flap for reconstruction of weight-bearing surfaces. Elevation of the flap involves a fillet of the digit through a dorsal incision. The vascular pedicle consists of the deep plantar metatarsal artery IV and the superficial dorsal metatarsal vein IV. Sensory innervation may be provided by including the deep plantar metatarsal nerve IV with subsequent repair of the nerve to an appropriate sensory recipient nerve.

The carpal pad may also be transferred as a microvascular free flap. This flap is advantageous in that a larger area of surrounding skin may be included with the flap, and harvest does not necessitate digital amputation. The smaller size and conical shape of the carpal pad make initial resurfacing of the weight-bearing surface more difficult compared with the digital pad flap. The carpal pad flap is dissected based on the caudal interosseous artery as it courses through the carpal tunnel. Two to three small venous branches from the medial aspect of the flap drain into the cephalic vein, which serves as the venous pedicle.

Both the digital pad flap and the carpal pad flap have been used for reconstruction of severely traumatized feet in dogs. The transferred pads have proved resilient to weight-bearing stresses and have undergone hypertrophic change in response to continued weight bearing. Precise positioning of the pad is essential to avoid trauma to surrounding hirsute skin. The most common complication of microvascular footpad transfer has been chronic incisional breakdown at the junction of donor and recipient skin caused by repeated tensile stresses placed on the wound. Functional reconstruction of weight-bearing surfaces is difficult. Further research and experience are needed before firm recommendations can be made regarding optimal techniques.

Complications of Free Flaps

Complications associated with microvascular tissue transfer may be divided into recipient site and donor site problems. Donor site complications are site specific, depending on the tissue harvested. Difficulties arising from loss of the donor tissue should not be seen if appropriate consideration has been given to selection of a donor site. Seroma formation is common after harvest of soft tissue flaps, particularly muscle flaps. The large amount of dead space and inherent movement between tissue planes in these instances makes prevention of seromas difficult. Tacking or walking sutures are not recommended for dead space management after dissection of muscle flaps because they restrict movement and increase postoperative discomfort. Dead space is managed by provision of surgical drainage; drainage for 5 to 7 days is adequate in most instances.

Cross-contamination from the recipient site to the donor site may result in donor site infection. Care should be taken to use separate instrumentation in each surgical field. The surgical team responsible for dissection of the donor site should avoid contact with the recipient site, and vice versa.

Recipient site complications may be caused by inappropriate preparation of the recipient wound bed or by flap-related complications. Microsurgically transferred flaps are excellent sources of vascularized tissue for reconstruction, but they should not be viewed as a panacea for a poorly prepared wound bed. Necrotic tissue and debris must be surgically removed from the wound before transfer. In the case of osteomyelitis, infected bone must be thoroughly debrided. Free flaps should not be placed onto heavily contaminated or overtly infected wound beds. Such wounds should be aggressively converted to a clean contaminated state and subsequently reconstructed.

Flap-related complications may be specific to the tissue transferred, such as loss of orthopedic fixation in vascularized bone grafts or incisional dehiscence of transferred footpads. Complications common to all flaps relate to the integrity of the microvascular anastomosis. Meticulous attention to anastomotic technique, astute postoperative monitoring and early surgical re-exploration of compromised flaps are mandatory.

The relative advantages and disadvantages of microsurgical reconstruction are well documented in the human literature. Our understanding of the potential of these techniques in veterinary surgery is expanding. Successful use of microsurgical tissue transfer requires appropriate instrumentation and a familiarity with microvascular technique, both of which are increasingly available at larger veterinary referral centers. Further experience with, and definition of, these techniques will inevitably lead to increased veterinary clinical application.

Paw and Distal Limb Salvage and Reconstructive Techniques

Mark W. Bohling and Steven F. Swaim

Indications

The paws of a dog and cat play a significant role in their ambulatory abilities; thus, when an animal has paw skin defects, some form of reconstruction or salvage surgery is necessary to preserve normal ambulation. Minor paw defects may only require a simple reconstructive surgical technique, such as suture of a pad laceration. Conversely, major defects may require a more involved reconstruction or salvage surgical technique as with a skin graft to reconstruct a massive skin defect. With severe paw trauma, limb amputation is often performed, whereas if paw salvage techniques are available, limb amputation may possibly be avoided. In other instances of severe paw trauma, limb amputation is not an option, and reconstruction or salvage becomes necessary, as in the instance of a cat with bilateral avascular necrosis of the forepaws caused by excessively tight bandages following onychectomy. In the working dog and canine athlete, in which limb and paw functions are essential for performance, strong functional reconstruction and salvage procedures are especially important.

Defects of the paws can involve the dorsal surface, palmar or plantar surface (pads), interdigital surfaces, or interpad surfaces. Certain larger wounds on the dorsum of the paw and distal limb can be managed by techniques such as skin grafts and flaps, which are described in earlier sections of this chapter. This discussion describes some of the techniques that have particular application for reconstruction and salvage of the unique injuries of the specialized structures of the paws.

A unique wound affecting greyhounds is the digital pad callus/corn. These are painful lesions in need of a technique to resolve the condition.

Dorsal Paw Wounds

Some dorsal paw wounds may be such that the wound edges can be easily apposed after debridement and lavage. In other instances, tension in wound closure may need to be overcome by using some type of tension suture pattern, such as vertical mattress sutures, horizontal mattress sutures, or far near near far sutures. Other sutures can be used to relieve tension by gradually stretching the periwound skin so that it can be apposed or nearly so. Examples of these latter sutures are presutures and adjustable horizontal mattress sutures.

When wound tension is too great to be overcome by undermining, tension sutures, or skin stretching sutures, relaxing incisions can be considered when wound size permits. These are used in lieu of skin grafts or flaps. Simple relaxing incision(s) made adjacent to the wound can be used; however, such incisions commonly result in wounds about as large as the one that is closed as a result of their use. Multiple punctate relaxing incisions provide cosmetic and quickly healing small wounds while providing skin relaxation.

Although other familiar tension suture patterns and simple relaxing incisions can be used to aid in closure of dorsal paw wounds, this section describes presutures, adjustable horizontal mattress sutures, and multiple punctate relaxing incisions. These techniques have been found especially useful in closure of distal limb and dorsal paw wounds.

Presutures

Presutures are particularly useful in the distal limb and paws, in which "walking" sutures can encroach on vessels, nerves, and tendons. Presutures are thus termed because they are placed before excision or debridement of a lesion. They stretch the surrounding skin so that it can be used to close a distal limb or paw defect. Presutures are placed with interrupted Lembert bites, using 2-0 or 3-0 polypropylene or nylon suture (Figure 41-40A and B). They are placed under tension, usually 24 hours before excision or debridement. Presutures are placed while the animal is under the effects of a tranquilizer or neuroleptanalgesia and local analgesic agent in the skin to be sutured. Following presuturing, the area is bandaged until lesion excision or debridement.

At the time of definitive surgery, the presutures are removed. The lesion is removed or debrided, and the skin, which has been stretched gradually by stress relaxation, is used to close the defect (Figure 41-40C and D).

An advantage of presutures is that they can be used in conjunction with other tension relieving techniques to provide wound closure. Between the time they are placed and the time of removal, the limb should be observed for any swelling distal to the sutures. This swelling indicates the possibility of a biologic tourniquet developing at the time of definitive surgery, and another form of reconstruction may be considered.

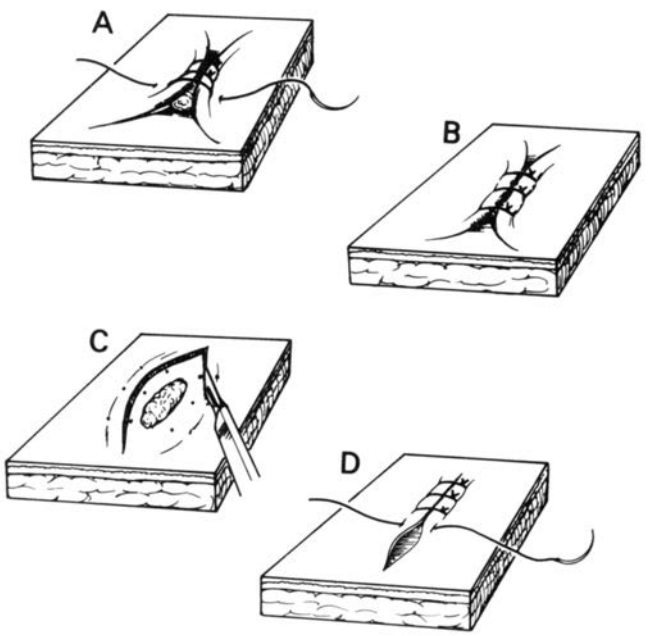

Figure 41-40. Presutures. **A** and **B.** The day before definitive surgical treatment, skin adjacent to the lesion is sutured over the lesion using a Lembert suture pattern. **C.** The next day, the presutures are removed, and the lesion is excised. **D.** The resulting defect or wound is closed using the stretched skin made available by the presuture. (From Scardino MS, Swaim SF, Henderson RA, Wilson ER. Enhancing wound closure on the limbs. Compend. Contin Educ Pract Vet 1996; 18:919.)

Adjustable Horizontal Mattress Sutures

A continuous adjustable horizontal mattress suture may be used to aid wound contraction by applying continuous tension to the skin edges of a wound that cannot be closed initially because of tension. The suture may be placed early in wound management or after granulation tissue has formed.

Synthetic 2-0 monofilament suture (nylon or polypropylene) on a cutting needle is used to place a half buried horizontal mattress suture at one end of the defect. The suture is continued as an intradermal horizontal mattress suture along the length of the wound. Each suture bite is advanced slightly, so the suture passes at an angle across the wound. Thus, as the suture is tightened, it slides through the tissues more easily. Care is taken not to disturb the attachment of skin to any granulation tissue present in the wound. At the opposite end of the wound, the needle is passed through the entire skin thickness and through a hole in a sterile button. Traction on the suture moves the wound edges toward each other. The skin edge advancement is maintained by a small fishing weight ("split shot") placed on the suture adjacent to the button. (Note: due to environmental concerns from lead, non-toxic split shot made from bismuth, tin, or antimony are now widely available, and should be used, to prevent the possibility of toxic lead exposure in the event of patient ingestion.) To prevent slippage, a second split shot is placed against the first (Figure 41-41). Excess suture is cut off about 2 inches beyond the split shot, and a bandage is applied over the wound.

On succeeding days, suture beyond the split shot is grasped with forceps, and gentle traction is applied while the limb is steadied. The wound edges move closer together, and the original split shot are pulled away from the button. Two new split shot are placed against the button to maintain suture advancement. Because of inherent skin elasticity, skin advancement is greatest in the first 2 to 3 days. When the wound edges are apposed or when they have advanced to their limit and further tension does not result in wound edge advancement or movement of the suture, the suture is removed.

Modified placement can be performed by placing the split shot button apparatus at both ends of the suture to allow tightening from both ends. With longer wounds, this maneuver is helpful because, the further the button is from the center of the wound, the less suture slippage through the tissues occurs. Therefore, pulling at each end of the wound distributes tension more evenly along the wound. During the use of an adjustable horizontal mattress suture, wounds can be treated with a topical antimicrobial or wound healing stimulant in combination with a protective bandage.

Multiple Punctate Relaxing Incisions

Multiple punctate relaxing incisions are small, parallel staggered skin incisions made adjacent to a wound to release tension and

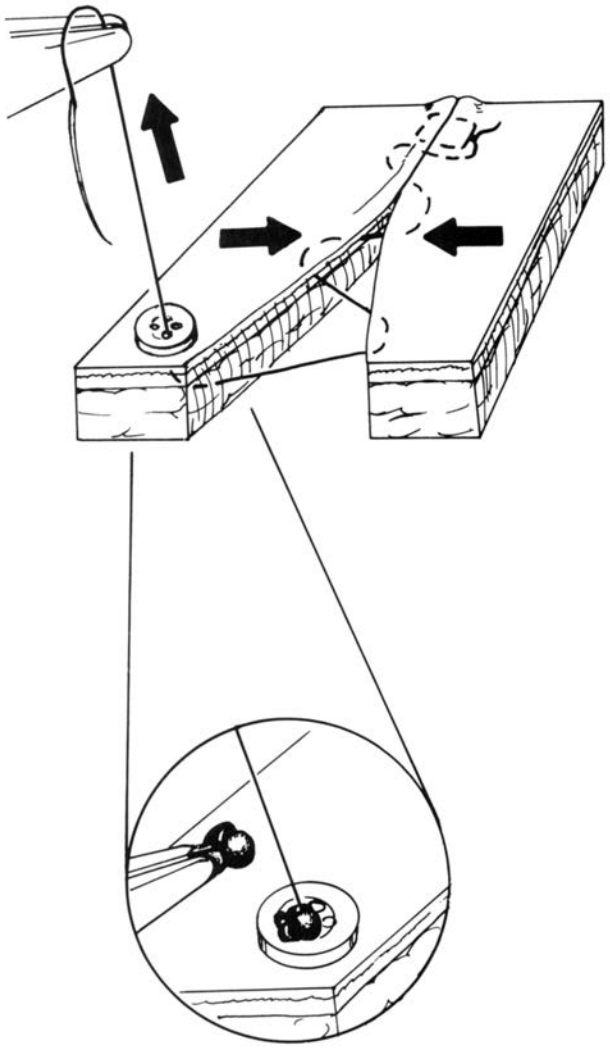

Figure 41-41. Adjustable horizontal mattress suture placement: A half buried horizontal mattress suture starts the suture at one end. The suture is advanced as an intradermal horizontal mattress suture with each bite slightly advanced (running suture). On the final bite, the needle is passed through the entire skin thickness and through a hole in a sterile button. Tension on the suture (vertical arrow) results in wound edge advancement toward the wound center (horizontal arrows). After wound edge advancement as far as possible, two split shot are used to secure the suture (inset). The suture is similarly tightened daily. (From Scardino MS, Swaim SF, Henderson RA, Wilson ER. Enhancing wound closure on the limbs. Compend. Contin Educ Pract Vet 1996; 18:919.)

to allow wound closure. The surgeon may want to use presutures or an adjustable horizontal mattress suture before making these relaxing incisions.

A continuous intradermal suture of 3-0 synthetic absorbable suture material, such as polyglyconate or polyglactin 910, is begun at one end of the wound. If the skin edges do not appose or appose with tension while placing and tightening this suture, punctate relaxing incisions are made in the skin adjacent to the wound edges on both sides of the wound. These incisions are usually 1 cm from the wound edge, 1 cm long, and 0.5 cm apart. They are made in parallel staggered rows (Figure 41-42A). After the skin edges are apposed, simple interrupted 2 0 or 3 0 polypropylene or nylon sutures are placed in the wound edges (Figure 41-42B).

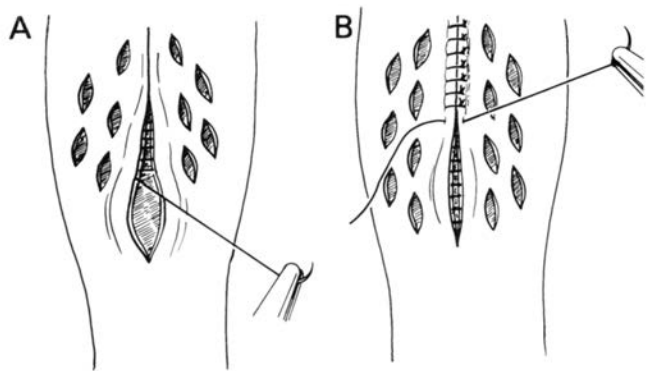

Figure 41-42. Multiple punctate relaxing incisions. **A.** As a continuous intradermal suture is placed, if wound edges do not appose, multiple punctate relaxing incisions are made bilaterally in parallel staggered rows. **B.** Once apposed, the skin edges are routinely sutured. (From Scardino MS, Swaim SF, Henderson RA, Wilson ER. Enhancing wound closure on the limbs. Compend. Contin Educ Pract Vet 1996; 18:919.)

An alternate method for performing the procedure entails placing the continuous intradermal absorbable suture along the length of the wound, but not tightening or tying it at one end. Tension is applied to the free end of the suture, and hemostats are placed under a loop of suture near its origin. If the skin edges do not appose when the hemostats are elevated, bilateral punctate incisions are made in the area of tension (Figure 41-43A and B). The procedure is repeated along the suture line to bring the wound edges into apposition (Figure 41-43C and D). Final closure is with simple interrupted 2-0 or 3-0 polypropylene or nylon sutures (Figure 41-43E).

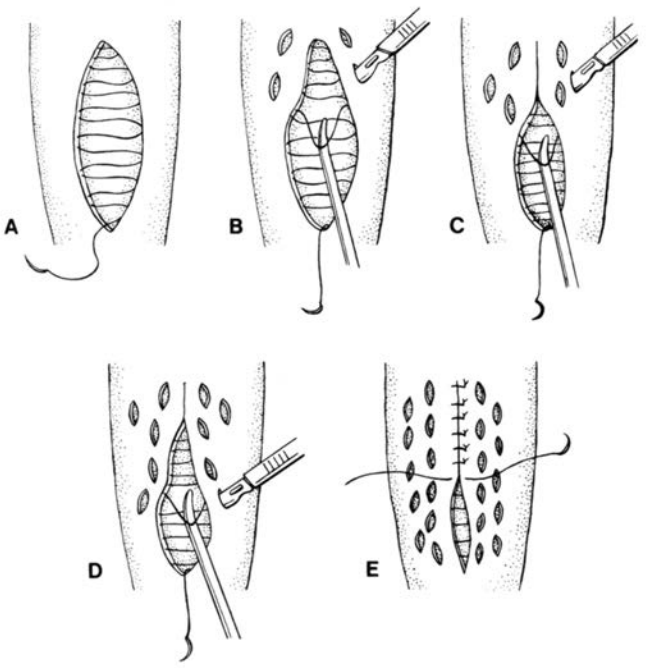

Figure 41-43. Alternate technique for multiple punctate relaxing incisions. **A.** A continuous intradermal suture is placed. **B.** If tightening a section of suture results in tension, multiple punctate relaxing incisions are made. **C** and **D.** The suture is progressively tightened, and incisions are made. **E.** Final closure is done with simple interrupted sutures. (From Swaim SF, Henderson RA. Small animal wound management, 2nd ed. Baltimore: Williams & Wilkins, 1997:189.)

The more punctate incisions that are made and the larger they are, the greater the tension relief. However, the opportunity to damage the cutaneous vasculature is increased, thus increasing the risk of necrosis. Therefore, no more punctate incisions should be made than are necessary to provide wound closure without excessive tension.

The sutured wound is routinely bandaged, with daily changes in the early postoperative period to remove drainage from the wound site that occurs through the punctate incisions. A nonadherent primary bandage layer facilitates atraumatic bandage changes. As healing occurs and drainage decreases, bandages are changed less frequently.

Multiple punctate relaxing incisions break up the relaxing incision in numerous small incisions that are more cosmetic, heal rapidly, and are more acceptable to the animal's owner. However, the amount of tension relief may not be as great as that attained by one large relaxing incision.

Pad Wounds

Wounds on the palmar or plantar surface of the paw often involve the digital, metacarpal or metatarsal pads. These wounds may be as simple as a minor laceration or as serious as the loss of an entire pad. Because the pads are subject to impact stress and frictional wear, surgical techniques and aftercare require some special features to ensure adequate healing.

Suturing Pad Lacerations

Suturing of pad lacerations is indicated when the edges of the traumatized pad can be apposed. Pad lacerations require special attention before closure, first to assess the depth of the laceration and second to determine the degree of contamination of the wound. These assessments may be facilitated by inserting the tips of a pair of hemostats into the wound and opening the jaws. Most wounds are partial thickness; however, some full thickness wounds of the metacarpal and metatarsal pads may expose the digital flexor tendons.

Because of the location and function of pads, they are subject to considerable contamination when weightbearing after injury forces contaminants into the tissues. Before suturing the pad, thorough debridement and lavage must be performed to remove dirt and other contaminants. If the laceration has extended through the entire metacapal or metatarsal pad, after lavage is completed, a small, soft, latex Penrose drain is placed under, not through, the pad.

Although the deep pad tissue may appear to be apposed, placement of deep simple interrupted sutures of 3 0 polydioxanone gives support to the tissues (Figure 41-44A). The superficial pad tissues are sutured with far near near far sutures of 3 0 nylon or polypropylene (Figure 41-44B).

A small amount of cotton is placed between the digits and in the space between the digits and the metacarpal or metatarsal pad to help keep these areas dry. A nonadherent bandage pad is placed over the suture line. The success of pad sutures in helping to provide early strong healing depends on proper bandaging to help prevent spreading of the pad during weight bearing. For a large dog where pad spreading with weight-bearing could cause significant tissue damage as sutures cut through the skin, the paw should be bandaged in a "clamshell" splint (see description in Chapter 2). The bandage is changed every 2 to 3 days unless a drain has been placed under the metacarpal or metatarsal pad. In this case, more frequent bandage changes are indicated to remove drainage fluid. Sutures are usually left in place for 10 to 14 days, depending on the severity of injury and the size of the animal; for example, a severe laceration on a large dog needs sutures and bandages longer than a minor laceration on a small dog.

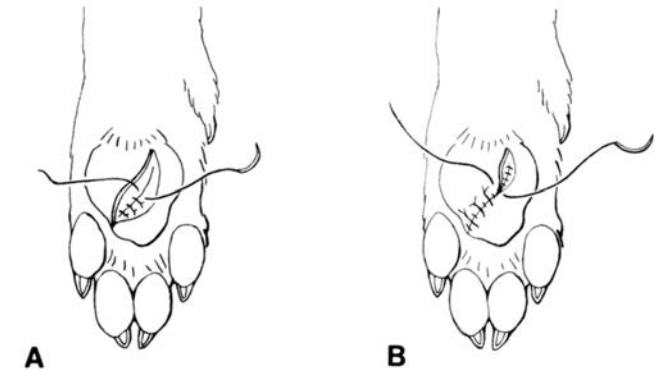

Figure 41-44. Suturing pad lacerations. **A.** Simple interrupted sutures are placed in deep pad tissue. **B.** Far near near far sutures are placed in superficial pad tissue. (From Swaim SF, Henderson RA. Small animal wound management, 2nd ed. Baltimore: Williams & Wilkins, 1997: 338.)

Phalangeal Fillet

The phalangeal fillet technique is the removal of the proximal, middle, and distal phalanges from a digit to free the pad so it can be used to replace or fill defects in a metacarpal or metatarsal pad. The technique is indicated when conservative therapy has not resulted in effective healing of the pad or when the entire pad is missing.

In patients with chronic nonhealing metacarpal or metatarsal pad wounds that have not resulted from trauma, a thorough examination should be performed preoperatively. This should include cytologic examination, fungal and bacterial culture and sensitivity testing, as well as histopathologic examination. Appropriate medical and/or surgical therapy should follow if cultures reveal fungal or neoplastic disease. Surgical therapy may range from limb amputation to pad amputation and replacement (phalangeal fillet), depending on test results. If histologic examination reveals chronic nonhealing tissue, the wound should be thoroughly debrided and lavaged because the granulation tissue may have embedded dirt and sand.

Phalangeal fillet may be performed from the palmar or plantar surface of the paw. The digit nearest the metacarpal or metatarsal pad defect is selected for filleting. This is usually the second or fifth digit. A rectangular skin segment is removed from the palmar or plantar skin between the digital pad and the edge of the metacarpal or metatarsal pad defect (Figure 41-45A). The proximal, middle, and distal phalanges of the digit are removed

by incising the joint capsules and ligamentous attachments to the bones (Figure 41-45B). The phalanges and nail are removed using blunt dissection as close to the bone as possible, thus leaving the blood and nerve supply intact in the digital flap. The edge and surface of the metacarpal or metatarsal pad defect are debrided, and the pad of the filleted digit is folded back on its pedicle of skin to fill the metacarpal or metatarsal pad defect (Figure 41-45C). The edges of the digital pad are sutured to the edges of the pad defect with simple interrupted or far near near far sutures of 3-0 polypropylene or nylon suture material (Figure 41-45D). The paw is bandaged as described for pad laceration repair.

A second technique for phalangeal fillet entails phalangeal removal through a single longitudinal incision on the dorsal surface of the digit (Figure 41-46A and B). The skin is then closed with simple interrupted sutures of 3 0 polypropylene or nylon suture material (Figure 41-46C). The area where the nail was removed is left open for drainage.

The paw is bandaged with periodic bandage changes, and it is allowed to heal for 14 days. At this time, the rectangle of palmar or plantar skin is removed, and the digital pad is folded back and is sutured into the defect as previously described (Figure 41-46D-F). Bandaging is as previously described.

Palmar or plantar filleting has the advantage of being a one step procedure; however, it is more difficult, and has greater potential

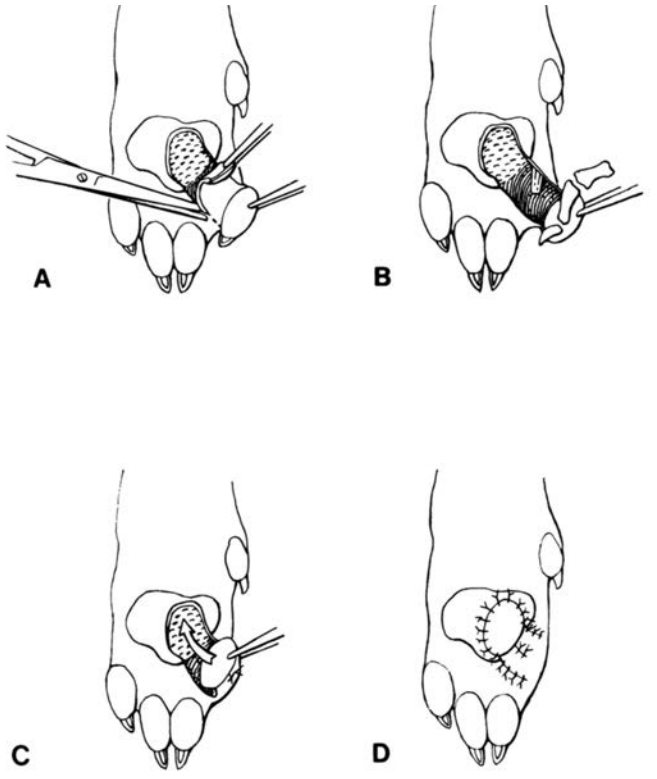

Figure 41-45. Palmar and plantar phalangeal fillet technique for pad replacement. **A.** A rectangle of skin is removed between the metacarpal and second digital pads. **B.** The proximal, middle, and distal phalanges and nail are removed. **C.** The second digital pad is folded back into the metacarpal pad defect (arrow). **D.** The second digital pad is sutured in place. (From Swaim SF, Henderson RA. Small animal wound management, 2nd ed. Baltimore: Williams & Wilkins, 1997: 345.)

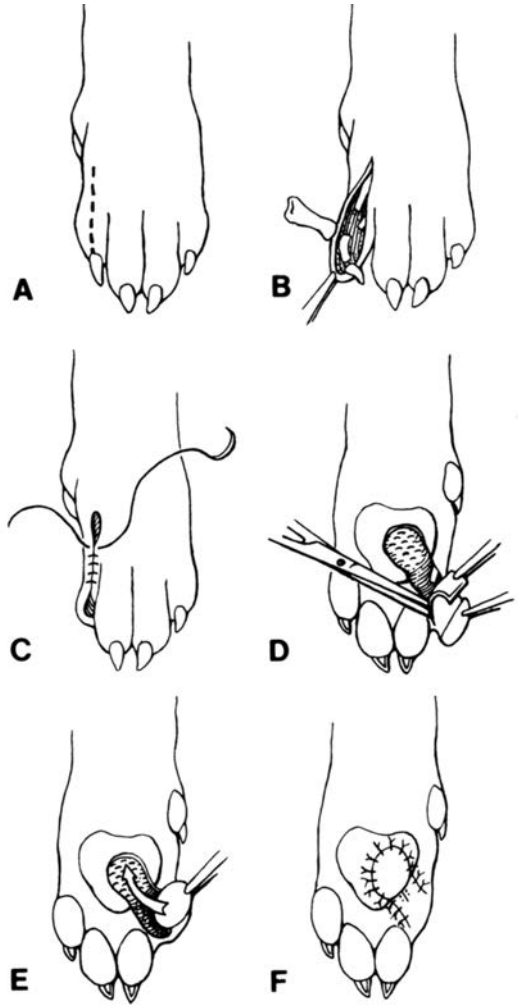

Figure 41-46. Dorsal phalangeal fillet technique for pad replacement. **A.** A longitudinal incision line is made on the dorsum of the second digit. **B.** The proximal, middle, and distal phalanges and nail are removed. **C.** The longitudinal incision is closed. **D.** Fourteen days later, a rectangle of skin is removed between the metacarpal and second digital pads. **E.** The second digital pad is folded back into the metacarpal pad defect (arrow). **F.** The second digital pad is sutured in place. (From Swaim SF, Henderson RA. Small animal wound management, 2nd ed. Baltimore: Williams & Wilkins, 1997: 346.)

for damage to the blood supply of the digital pad. Dorsal filleting is easier, but the technique takes longer because it is a two step procedure, with digital pad transposition performed 14 days after the phalanges have been removed.

In some instances, if a metacarpal or metatarsal pad wound has resulted from abnormal paw position because of tendon malfunction, bone misalignment or nerve damage, digital pad transposition may not be successful. Unless the underlying cause of abnormal pad wear is corrected, the new pad may wear through just as did the original pad.

Pad Grafts

Paw pad grafts are small full thickness segments of pad tissue that are placed in a granulation tissue bed around the edges of a wound where weight bearing pad tissue is missing. They are indicated in patients with loss of the metacarpal or metatarsal

pad as well as loss of some or all the digital pads, thus precluding phalangeal fillet.

After a paw wound has been managed to the point that it has healthy bed of granulation tissue, rectangular tissue segments measuring 6 x 8 mm are traced around the wound using a template of x-ray film with a hole in its center and a sterile skin marker or splintered applicator stick dipped in methylene blue (Figure 41-47A). The rectangles of tissue are incised with a number 11 scalpel blade, and the tissue is excised using iris scissors and thumb forceps, leaving a series of rectangular depressions about 2 mm deep around the wound (Figure 41-47B and C).

In the center of other digital pads on the same animal, possibly the same paw, the same template is used to trace the same number and size of rectangles (See Figure 41-47C). Again, a number 11 scalpel blade is used to incise the grafts, and iris scissors and thumb forceps are used to remove the grafts (Figure 41-47D). All subcutaneous tissue is removed from the grafts with iris scissors.

A graft is placed in each of the rectangular depressions and sutured in place. Two simple interrupted sutures of 5-0 polypropylene can be used, with one suture on each side of the graft on the long sides of the graft (Figure 41-48A). An alternative suture pattern, which the authors prefer, is a simple interrupted suture placed at each corner of the graft (Figure 41-48B).

A nonadherent bandage pad with a small amount of 0.1% gentamicin sulfate ointment is placed over the grafted site. The remainder of the bandage is as described for pad lacerations. The graft donor sites are allowed to heal by second intention and are bandaged in a similar manner. If remaining digital pad tissue is pliable enough to allow suture closure of the donor sites, these sites may be closed with 3-0 polypropylene or nylon far near near far sutures followed by bandaging. The initial bandage is usually left in place for 3 days, followed by bandage changes every other day until 21 days postoperatively. A bootie may be indicated for a transitional period between bandage and no bandage. Sutures in the grafts are removed between 10 and 14 days postoperatively.

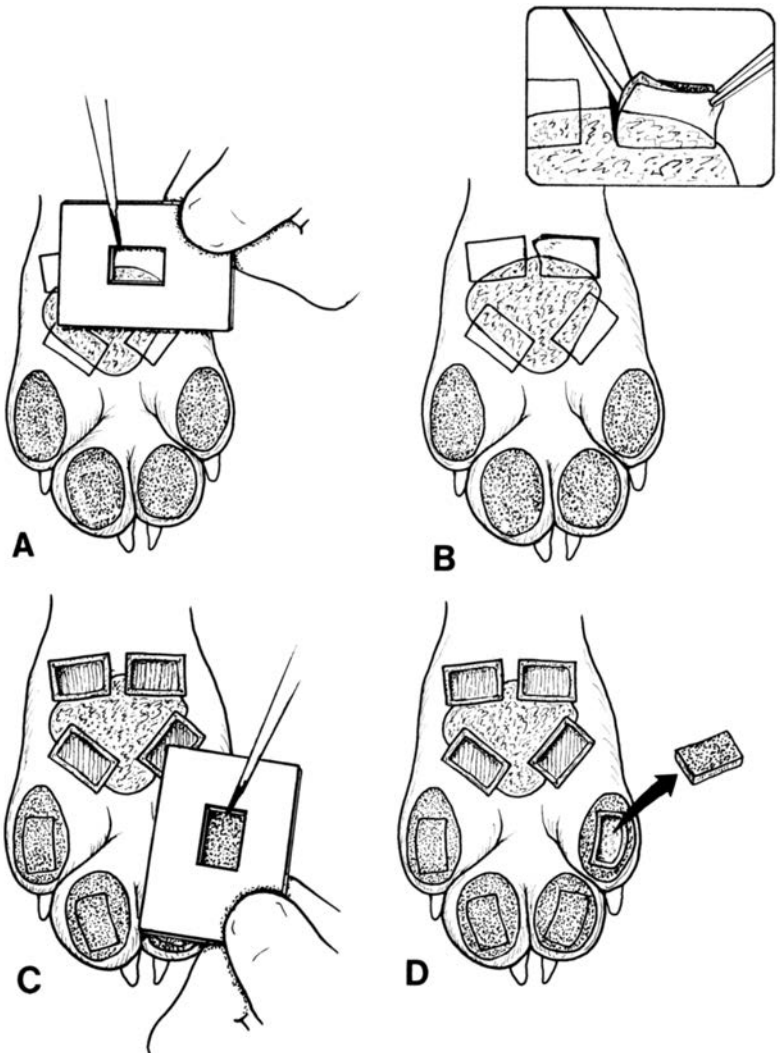

Figure 41-47. Pad grafts. **A.** A piece of x ray film with a 6 x 8 mm hole in its center is used with a splintered applicator stick dipped in methylene blue to trace graft recipient sites around the wound. **B.** After incision, thumb forceps and iris scissors are used to remove rectangles of tissue from recipient sites. **C.** With recipient sites prepared, the x ray film applicator stick and methylene blue are used to trace segmental grafts on digital pads. **D.** A segmental pad graft has been removed from a digit. (From Swaim SF, Bradley DM, Steiss, JE, et al. Free segmental paw pad grafts in dogs. Am J Vet Res 1993;54:2161-2170.)

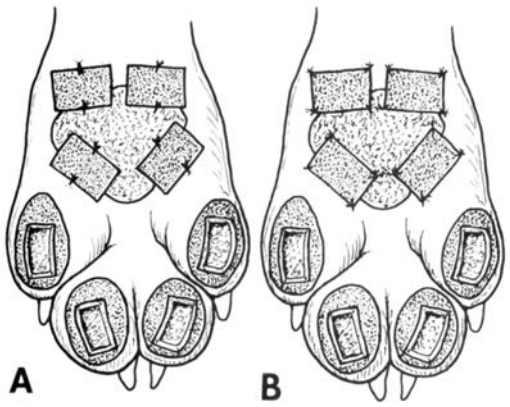

Figure 41-48. Pad graft sutures. **A.** Two simple interrupted sutures are used to suture each long side of the grafts into the recipient site. **B.** Simple interrupted sutures are used at each corner of the grafts to suture them into recipient sites, (From Swaim SF, Bradley DM, Steiss, JE, et al. Free segmental paw pad grafts in dogs. Am J Vet Res 1993;54:2161-2170.)

When sutures are removed from the grafts, the hard and dark stratum corneum usually lifts off of the graft to reveal underlying viable graft tissue that will form a new stratum corneum. As the grafts heal, two phenomena occur that provide a tough tissue on which the animal can ambulate. First, with wound contraction, the grafts coalesce toward the wound center. Second, the epithelial tissue that grows from the grafts to cover the remainder of the wound is tough keratinized epithelium that withstands the stress placed on pad tissue. If paw trauma has been severe enough so that bone is present directly under the healed pad grafts, weight bearing may cause pad trauma. Use of a pad toughening agent after the grafts are thoroughly healed has been found helpful in increasing pad durability.

Carpal Pad Flaps

Carpal pad flaps are flaps of skin on the distal forelimb that incorporate the carpal pad. They are used to provide a structure on which an animal can ambulate after amputation at the carpometacarpal articulation. These flaps may be single pedicle or bipedicle advancement flaps. Their successful use has been described in bilateral application on a small dog (single pedicle flap) and unilaterally on a cat (bipedicle flap).

Single Pedicle Carpal Pad Flaps

For a single pedicle advancement flap, a transverse skin incision is made over the cranial aspect of the limb at the carpometacarpal level. A proximally based single pedicle advancement flap is created on the palmar aspect of the limb such that it includes the carpal pad. The skin flap distal to the pad should extend to the mid-metacarpal level, to allow sufficient length for suturing the flap to the skin on the dorsum of the limb after advancement into position (Figure 41-49A).

After blunt dissection of the skin flap from underlying structures, the flexor carpi ulnaris tendon is transected, and the prominence of the accessory carpal bone is removed. The distal limb is then amputated at the carpometacarpal joint. The flap is advanced

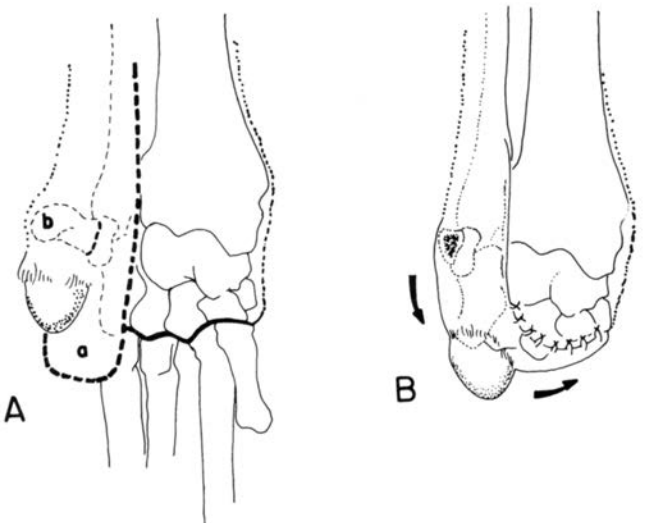

Figure 41-49. Single pedicle carpal pad flap. **A.** A dorsally based single pedicle advancement flap is designed to incorporate the carpal pad (a). The prominence of the accessory carpal bone (b) will be removed. **B.** After amputation at the carpometacarpal joint, the pad is advanced on the flap (arrows) and is sutured in position at the caudodistal end of the amputation stump. (From Barclay CG, Fowler JD, Basher AW. Use of the carpal pad to salvage the forelimb in a dog and cat: An alternative to total limb amputation. J Am Anim Hosp Assoc 1987; 23:527-532.)

distally until the carpal pad is located at the caudodistal end of the amputation stump. The pad is anchored in position with subcutaneous simple interrupted sutures of 3-0 synthetic absorbable material, and the skin is sutured with simple interrupted sutures of 3 0 nylon or polypropylene (Figure 41-49B).

The limb is immobilized in a soft padded bandage with a metal (e.g. "clamshell") splint. Sutures are removed and splinting is discontinued 2 weeks postoperatively.

Bipedicle Carpal Pad Flaps

For a bipedicle advancement flap, parallel horizontal skin incisions, one proximal to and one distal to the carpal pad, are made on the palmar aspect of the limb. The proximal incision is curved 2 to 3 mm proximally at each end to facilitate flap transposition (Figure 41-50A). After advancement of the flap under the end of the amputation stump, the flap is sutured in place with simple interrupted 3 0 nonabsorbable sutures. The palmar donor site is allowed to heal as an open wound (Figure 41-50B).

A padded splint is applied to the limb. A supplemental bar may be added to allow ambulation without disturbing the flap, or a "clamshell" bandage splint may be used. Periodic bandage or splint changes are performed until healing has occurred.

With successful carpal pad flap procedures, use by the patient results in thickening and enlargement of the pad. This provides functional weight bearing tissue.

Before performing carpometacarpal amputation and carpal pad flap repositioning, the animal's activity and intended use, and the owner's expectations after surgery should be considered. The technique has potential for use on larger dogs; however, accurate

placement of the pad may be more critical when considering the greater weight to be placed on it. Moreover, when the procedure is performed unilaterally, that limb is significantly shorter than the other limb, and the animal may tend to carry the limb or only use it intermittently.

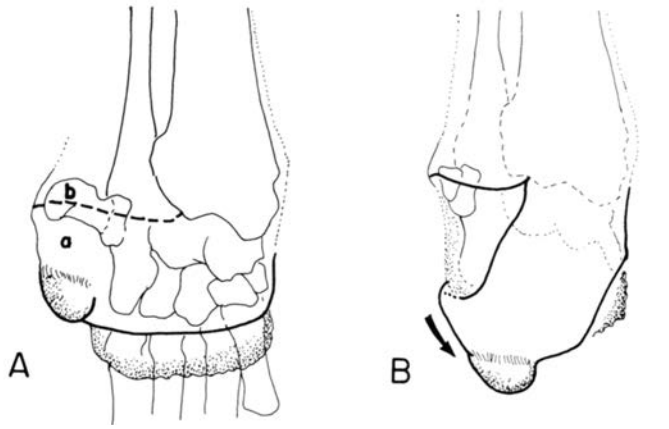

Figure 41-50. Bipedicle carpal pad flap. **A.** A bipedicle advancement flap is designed to incorporate the carpal pad and is undermined (a) The prominence of the accessory carpal bone (b) will be removed. **B.** After amputation at the proximal metacarpal area, the pad is advanced on the flap (arrow) and is sutured in position under the end of the amputation stump. (From Barclay CG, Fowler JD, Basher AW. Use of the carpal pad to salvage the forelimb in a dog and cat: an alternative to total limb amputation. J Am Anim Hosp Assoc 1987;23:521-532.)

Digital Pad Calluses/Corns

Greyhounds are subject to the development of painful fibrous scar tissue lesions on their digital pads. These callus-type lesions have been termed "corns." There are several theories as to their etiology. One theory is that of scar tissue accumulation, either from cuts and abrasions, or from a small foreign body in the pad with resulting scar tissue formation as the body attempts to isolate the foreign material. A second theory states that the lesion is caused by a papilloma virus infection, with the pressure and abrasion of walking forcing the lesion into a corn-type appearance. A third theory is that the phenotypic leanness of greyhounds is also manifested in their feet, by a lack of sufficient fibroadipose cushioning tissue in greyhound digital pads compared to other breeds of dogs. As a result, chronic low-grade pressure of the distal interphalangeal joint on the dermal pad surface results in a callus-like lesion.

Numerous treatments have been described for these lesions; the veterinary literature describes soaking of the paw and application of manual pressure to express the corn, sharp surgical excision of the corn, and partial or total amputation of the affected digit. A preliminary study has been performed to investigate the potential for placing silicone block gel particles subdermally under the digital pad skin to provide cushioning between the distal interphalangeal joint and the pad dermis, i.e., padding similar to the fibroadipose tissue of normal pads. Results of the study indicated a reduction in pad pressure at 3 months post-implantation.

Digital, Interdigital, and Interpad Wounds

Paw lesions may involve the interdigital skin or the interpad skin on the palmar or plantar surface of the paw. The lesions are usually traumatic or infectious. The phalangeal fillet technique and a fusion podoplasty technique may be used to reconstruct or to salvage paws thus involved.

Phalangeal Fillet for Digital and Dorsal Paw Resurfacing

The phalangeal fillet technique can be used as a salvage technique when patients have sustained considerable digital trauma to osseous structures of a digit with skin deficits of adjacent digits or the dorsum of the paw. If the digital and interdigital skin of the digit with osseous damage is viable, phalanges may be removed from the digit, and its skin and adjacent interdigital skin may be used to replace the skin deficit of the adjacent digits or dorsum of the paw.

The digits with severe osseous damage are carefully debrided, and the remaining proximal, middle, and distal phalanges and tendon fragments are removed (Figure 41-51A and Figure 41-52A). The skin of this digit and any available interdigital skin are cut and trimmed such that they can be used as a flap to resurface adjacent digits with large skin deficits or the dorsum of the paw (Figure 41-51B and C) and Figure 41-52B and C). The digital and interdigital skin should be cut and trimmed with care, to ensure

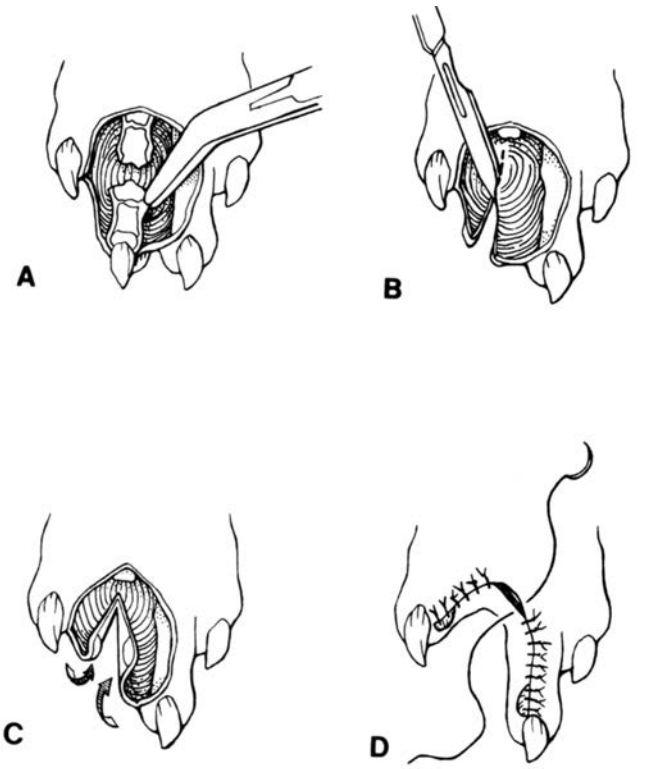

Figure 41-51. Phalangeal fillet for digital resurfacing: two flaps. **A.** The wound area is debrided, and bone and tendon fragments are removed. **B.** Digital and interdigital skin were used to create flaps. **C.** Flaps will be rotated to resurface adjacent digits (arrows). **D.** The flaps are sutured in place. (From Swaim SF, Henderson RA. Small animal wound management, 2nd ed. Baltimore: Williams & Wilkins, 1997: 354.)

that sufficient skin and subcutaneous tissue remain at the base of the flap to provide blood supply. The flap is sutured, to the remaining skin of the adjacent digits or dorsum of the paw with simple interrupted sutures of 2 0 or 3 0 polypropylene (Figure 41-51D) and Figure 41-52D).

Small amounts of cotton are placed between remaining digits and in the space between remaining digits and the metacarpal or metatarsal pad for dryness. A strip of nonadherent bandage pad is placed over suture lines. Absorbent secondary bandage and adhesive tape tertiary bandages are then applied. The cup of a metal splint may also be incorporated in the bandage. Clinical judgment should be used as to whether special considerations are needed in bandaging to relieve pressure on the area, i.e., "clamshell" bandage, foam sponge "donut" pad, or digit-elevating foam sponge pad (See Chapter 2). Bandages are changed periodically for 7 to 10 days. The length of time sutures should remain in place, the frequency of bandage changes, and the length of time bandages are needed are variable factors dependent on wound tension, wound healing rate, and amount of drainage.

The disadvantages of the procedure are that filleting of digit 3 or 4 leaves a cosmetic defect in the center of the paw, and a defect in this area can cause lameness. If digits 3 and 4 have been filleted to resurface digits 2 and 5 or the dorsum of the paw, the second and fifth digits protrude and may be subject to snagging on carpets or vegetation. If the pads of the filleted digits are needed for resurfacing procedures, they may be used; however, pad tissue in an abnormal location on the dorsum of the paw may be cosmetically unappealing.

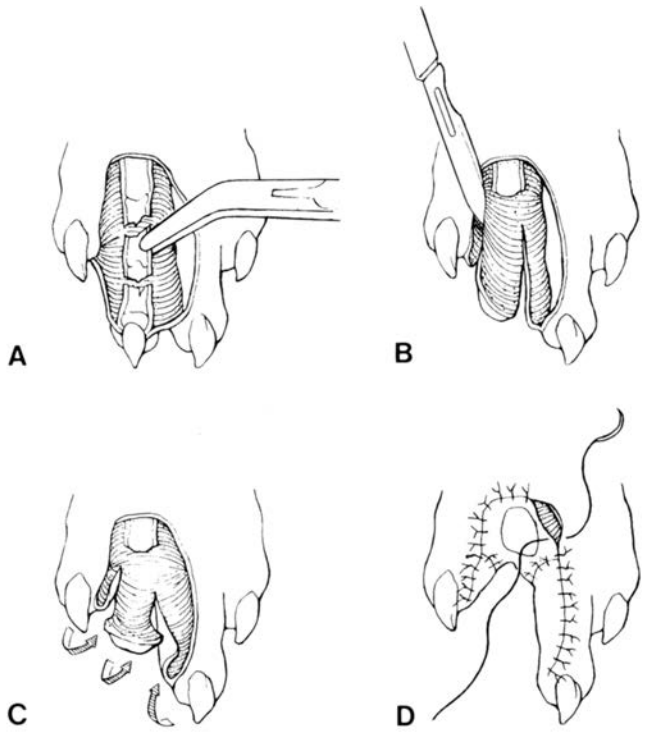

Figure 41-52. Phalangeal fillet for digital and dorsal paw resurfacing: three flaps. **A.** The wound area is debrided, and bone and tendon fragments are removed. **B.** Digital and intercligital skin are used to create flaps. **C.** Flaps will be rotated to resurface the dorsum of the paw and adjacent digits (arrows). **D.** Flaps are sutured in place. (From Swaim SF, Henderson RA. Small animal wound management, 2nd ed. Baltimore: Williams & Wilkins, 1997: 354.)

Fusion Podoplasty

Fusion podoplasty is a paw salvage technique whereby all interdigital and interpad skin is removed from a paw, and the remaining strips of skin on the dorsum of the digits are sutured together, as are the digital and metacarpal or metatarsal pads. The technique is indicated for the treatment of chronic fibrosing interdigital pyoderma in dogs when other forms of medical therapy or conservative surgical approaches have been unsuccessful. The procedure is usually performed on two paws at a time when all four paws are involved. The most severely involved paws (usually the fore paws) are operated on first, followed 1 month later by the hind paws. The technique has also been described for use in treating abnormalities associated with severed digital flexion tendons to fuse the digits against the metacarpal or metatarsal pad to provide a functional paw.

When this technique is used to treat chronic fibrosing interdigital pyoderma, the dog is given systemic antibiotics based on the results of culture and sensitivity testing before the surgical procedure. At the time of surgery, a sterile marking pen is used to outline the interdigital skin to be removed. On the dorsum of the paw, lines are drawn on the digits at the junction of normal and affected skin. Lines are drawn near the nails, so 2 to 3 mm of skin remains adjacent to the nail on the axial surfaces of the digits.

Because the third and fourth digits extend beyond the second and fifth, respectively, lines on the abaxial surfaces of the third and fourth digits are drawn so they intersect the digital pad midway between their cranial and caudal ends. The technique provides skin excisions on the abaxial surfaces of the third and fourth digits that match the axial surface excisions on digits 2 and 5, respectively (Figure 41-53). This method usually incorporates all affected skin between the fourth and fifth as well as between the second and third digits.

On the palmar or plantar paw surfaces, lines are drawn to enclose all interpad skin and the cranial portion of the metacarpal or metatarsal pad. Lines are drawn around the caudal aspects of the digital pads at the junction of pad and interpad skin. No lines are drawn around the cranial edge of the pads under the claws or around the abaxial surface of pads 2 and 5. From the caudoabaxial aspect of the second and fifth digital pads, lines are drawn along the skin fold that extends from this point to the base of the metacarpal or metatarsal pad. The line is continued across the cranial surface of the metacarpal or metatarsal pad. This line is 3 to 5 mm cranial to the level at which the caudal edges of the digital pads contact the metacarpal or metatarsal pad when the digits are flexed back against this pad (Figure 41-54).

A half inch Penrose drain is applied as a tourniquet around the limb just distal to the carpus or tarsus. The tourniquet is released for 1 minute after all skin incisions have been made, and again after the excision of all interdigital skin is completed. A scalpel blade is used to incise along all previously drawn lines.

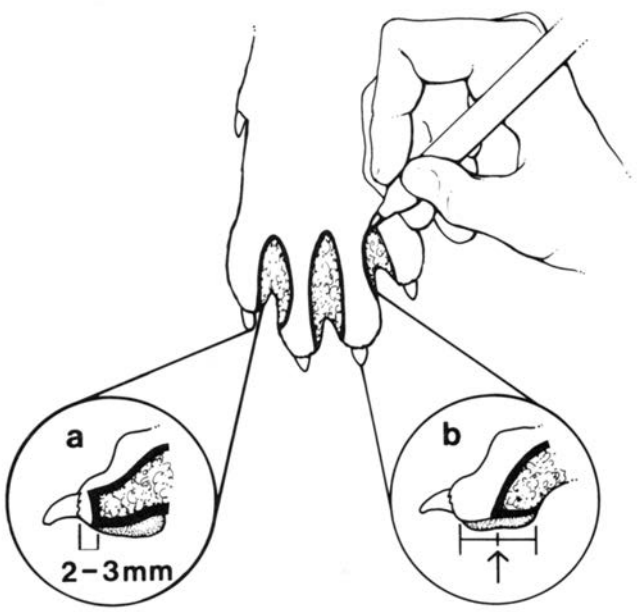

Figure 41-53. Fusion podoplasty. Interdigital skin to be removed from the dorsum of the paw is marked (bold lines). Inset: *(a)* 2 or 3 mm of skin is left near the nails on the axial surface of digits; *(b)* excision lines on the abaxial surfaces of digits 3 and 4 bisect the length of the pad (arrow). (After Swaim SF, Lee AH, MacDonald JM, et al. Fusion podoplasty for the treatment of chronic fibrosing interdigital pyoderma in the dog. J Am Anim Hosp Assoc 199 1;27:264-274.)

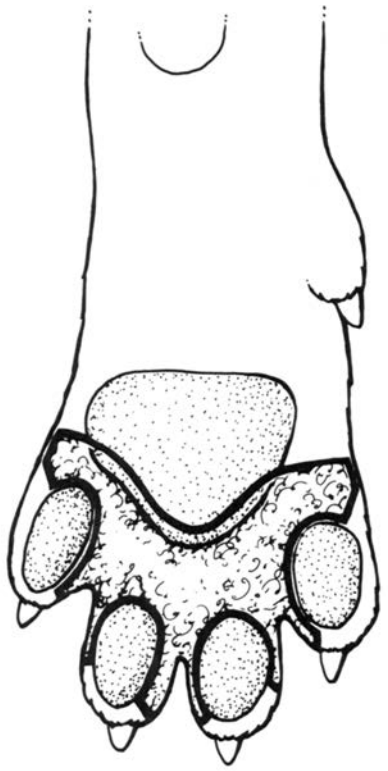

Figure 41-54. Fusion podoplasty. Interpad skin to be removed from the palmar or plantar surface of the paw is outlined (bold line) to include some skin from the cranial surface of the metacarpal or metatarsal pad. (After Swaim SF, Lee AH, MacDonald JM, et al. Fusion podoplasty for the treatment of chronic fibrosing interdigital pyoderma in the dog. J Am Anim Hosp Assoc 199 1;27:264-274.)

Starting at one dorsal interdigital cleft, interdigital skin is dissected from the cleft toward the cranial fold of this skin. Dissection is performed as close to the dermis as possible to avoid damage to the axial and abaxial dorsal and palmar or plantar proper digital vessels and nerves. When dissection becomes difficult near the fold of the web, dissection is discontinued and an adjacent interdigital space is dissected (Figure 41-55). After all interdigital spaces have been dissected, blunt and sharp dissection is done around the caudal aspects of the pads and along the palmar or plantar surface of each digit, again dissecting as close to the dermis as possible. At the base of the metacarpal or metatarsal pad, dissection of the dermis and epidermis is carried across the cranial surface of the pad from the lateral to the medial aspects of the pad. Underlying pad tissue is undisturbed (Figure 41-56). Deep connective tissue pockets containing exudate are carefully removed. After removal of the tourniquet, fine point electrocoagulation is used for hemostasis. The paw is soaked in a 0.05% chlorhexidine diacetate solution for 1 to 2 minutes. The paw is wrapped in a snug pressure bandage, and the procedure is repeated on the opposite paw.

After pressure wrapping the second paw, the pressure wrap is removed from the first paw. Adjacent digital pads are united with three simple interrupted 3-0 polypropylene sutures (Figure 41-57). The four united digital pads are flexed back against the cranial surface of the metacarpal or metatarsal pad. Simple interrupted 3-0 polypropylene sutures are placed alternately on either side of a central suture to affix the united digital pads to the metacarpal or metatarsal pad (Figure 41-58). The primary purpose of these sutures is to hold the digital pads in position against the metacarpal or metatarsal pad while the healing process begins in the deeper tissues.

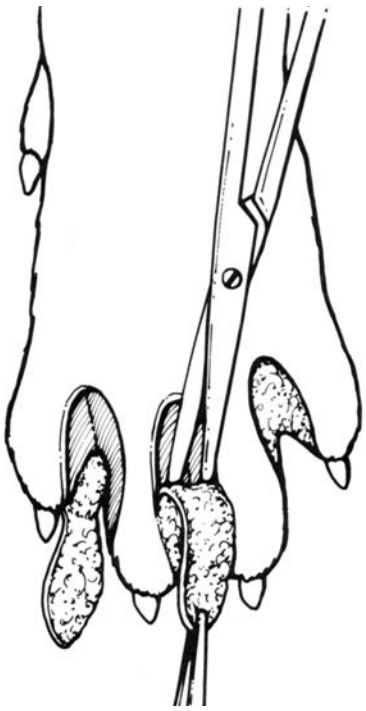

Figure 41-55. Fusion podoplasty. The dorsal interdigital skin is dissected from the interdigital spaces progressing from the digital cleft to the fold of the web. (After Swaim SF, Lee AH, MacDonald JM, et al. Fusion podoplasty for the treatment of chronic fibrosing interdigital pyoderma in the dog. J Am Anim Hosp Assoc 199 1;27:264-274.)

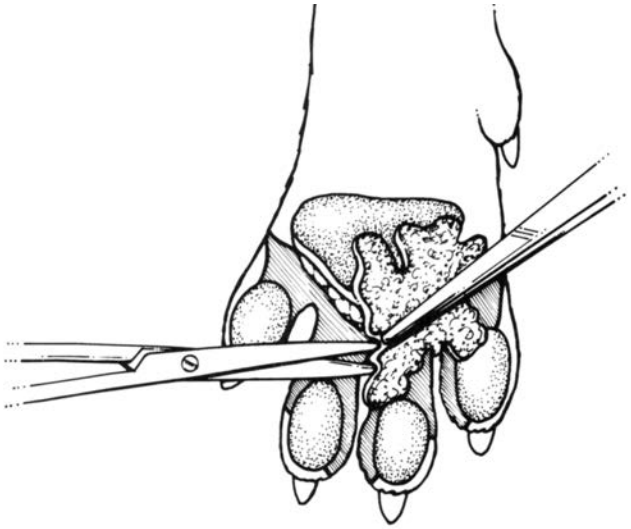

Figure 41-56. Fusion podoplasty. Interpad skin is dissected from the palmar or plantar surface of the paw. Dissection is done first along the palmar or plantar surface of the digits, then across the cranial surface of the metacarpal or metatarsal pad. (After Swaim SF, Lee AH, MacDonald JM, et al. Fusion podoplasty for the treatment of chronic fibrosing interdigital pyoderma in the dog. J Am Anim Hosp Assoc 1991 127:264-274.)

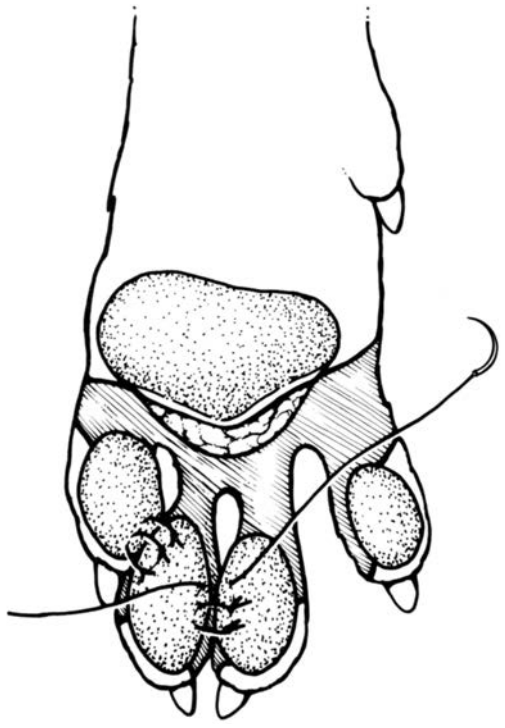

Figure 41-57. Fusion podoplasty. The digital pads are united with three simple interrupted sutures. (After Swaim SF, Lee AH, MacDonald JM, et al. Fusion podoplasty for the treatment of chronic fibrosing interdigital pyoderma in the dog. J Am Anim Hosp Assoc 199 1;27:264-274.)

Before placing the final two sutures on either side of the paw, the tips of a pair of curved Carmalt forceps are passed deep to the pad sutures across the cranial surface of the metacarpal or metatarsal pad. A quarter inch diameter Penrose drain is grasped and pulled through the wound. It is cut with a half inch protruding on each side of the paw. The drain is anchored in place by passing the final suture on each side through the skin and drain (Figure 41-59).

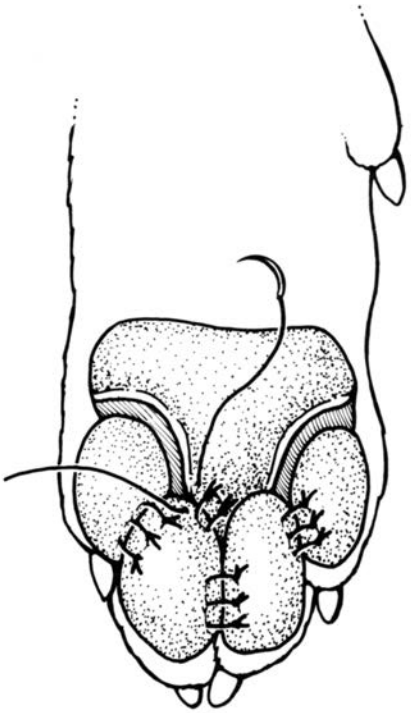

Figure 41-58. Fusion podoplasty. The united digital pads are flexed back against the metacarpal or metatarsal pad. Suturing progresses alternately to each side from a central suture using simple interrupted sutures. (After Swaim SF, Lee AH, MacDonald JM, et al. Fusion podoplasty for the treatment of chronic fibrosing interdigital pyoderma in the dog. J Am Anim Hosp Assoc 199 1;27:264-274.)

The skin strips on the dorsum of each digit are sutured together with three to four simple interrupted sutures of 3-0 polypropylene (Figure 41-60). Areas at the ends of the digits are not sutured, to allow for drainage. After suturing the first paw, the pressure wrap is removed from the second paw, and it is sutured in like manner.

Gauze sponges are placed on the dorsal and palmar or plantar surfaces of the paws. A thin layer of 0.1% gentamicin ointment may be spread on the gauze before it is applied. A "clamshell" splint bandage is applied over the paws (See Chapter 2). These splints go to the level of the elbow on the forelimbs, or to the hocks on the hind limbs. Bandages are changed daily as long as drainage is significant, usually 10 to 14 days. With decreased drainage, bandages are changed every second or third day until 21 days. A small amount of gentamicin sulfate ointment may be placed over the suture lines and at points allowed for drainage. When the bandage is changed, if the area has a characteristic odor of Pseudomonas, the paw may be soaked in 0.05% chlorhexidine solution before being rebandaged; a biguanide-impregnated gauze (Kerlix AMD, Kendall Healthcare, Tyco Healthcare Group, Mansfield, MA, USA) is also helpful for this.

Drain tubes are removed at 10 days. Sutures are removed from the dorsal paw skin and between the digital pads at 10 to 14 days. Sutures between the digital pads and the metacarpal or metatarsal pad are removed at variable times, depending on when the tissues appear healed or whether the sutures are still apposing tissues in patients with some tissue separation in this area. Generally, all sutures and splints are removed by 21 days. A

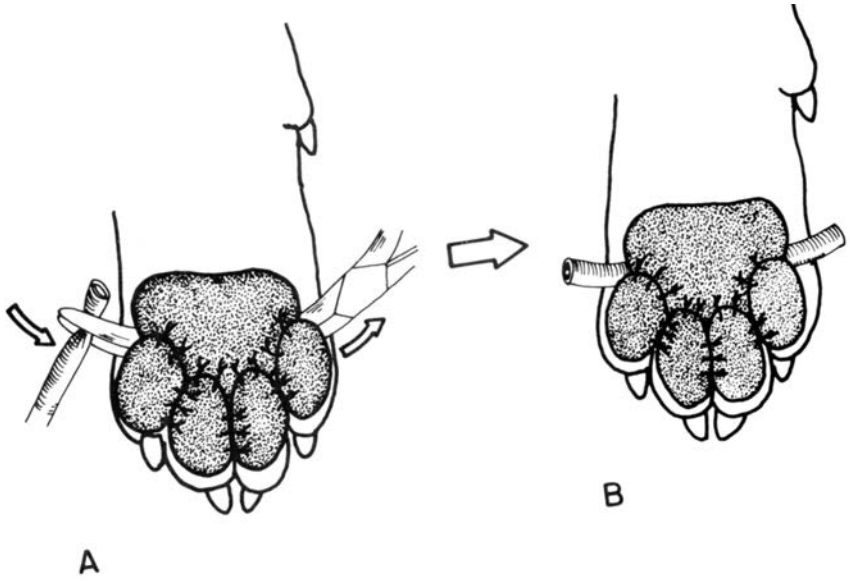

Figure 41-59. Fusion podoplasty. **A.** Curved Carmalt forceps are passed across the cranial surface of the metacarpal or metatarsal pad deep to the sutures to grasp a quarter inch Penrose drain to be pulled through the area. **B.** The drain is in place. (After Swaim SF, Lee AH, MacDonald JM, et al. Fusion podoplasty for the treatment of chronic fibrosing interdigital pyoderma in the dog. J Am Anim Hosp Assoc 199 1;27:264 274.)

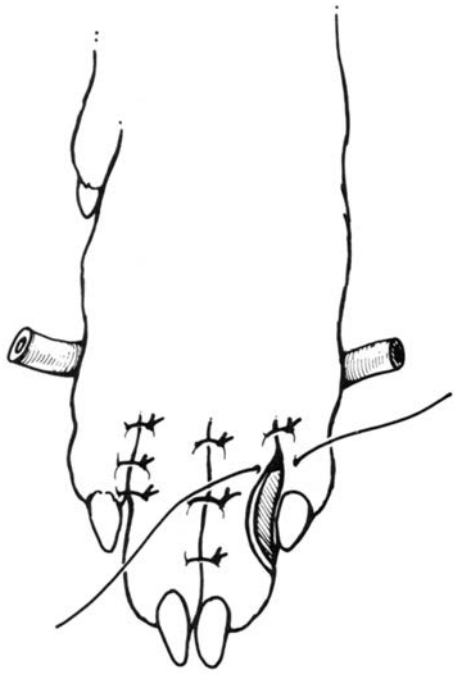

Figure 41-60. Fusion podoplasty. Simple interrupted sutures are used to suture the skin strips on the dorsum of each digit. (After Swaim SF, Lee AH, MacDonald JM, et al. Fusion podoplasty for the treatment of chronic fibrosing interdigital pyoderma in the dog. J Am Anim Hosp Assoc 199 1;27:264-274.)

light bandage or a protective bootie may be used for a period as a transition between full bandaging and no bandage.

The most common complication of the procedure is separation of the suture line between the digital pads and the metacarpal or metatarsal pad. The "clamshell" splint (See Chapter 2) helps to prevent this complication; however, separation may occur and can expose an area of granulation tissue. If it appears that individual sutures are not functioning to hold the digital pads against the metacarpal or metatarsal pad, these sutures are removed, and the area is allowed to heal as an open wound. A nonadherent bandage pad is used with the remainder of the bandage until the area has epithelialized, usually by 21 days.

Massive Digital Wounds – Pandigital Amputation

Pandigital amputation is a salvage operation in which all digits are amputated at the metacarpophalangeal or metatarsophalangeal level, and the metacarpal or metatarsal pad is positioned under the ends of metacarpal or metatarsal bones to provide a weight bearing tissue on which the animal can ambulate. The procedure is indicated in cases of severe damage to all digits as the result of pressure necrosis, phlebitis, trap injury, or other sources of trauma.

A transverse incision is made in the dorsal paw skin over the metacarpophalangeal or metatarsophalangeal articulation (Figure 41-61A). On the palmar or plantar surface of the paw, the incision is made at the junction of the metacarpal or metatarsal pad with the interpad skin (Figure 41-61B). If a line of demarcation is present between viable and nonviable skin on either surface of the paw, the incision should be made approximately 3 mm proximal to the line in viable tissue.

Working from the dorsum of the paw, the skin is reflected, and dorsal axial and abaxial common or proper digital vessels are ligated with 3-0 polydioxanone ligatures and are severed distal to the ligatures. Associated nerves, extensor tendons, collateral ligaments and metacarpophalangeal or metatarsophalangeal joint capsules are severed. The sesamoid ligaments are cut, and the sesamoid bones are removed on the palmar or plantar surface of the limb. The palmar or plantar common. or proper digital vessels are ligated and are severed along with associated nerves and flexion tendons. The digits are removed (Figure 41-61C). Bone rongeurs are used to remove the heads of the metacarpal or metatarsal bones if no infection is present.

Metacarpal or metatarsal bones, especially the third and fourth bones, are trimmed back until the metacarpal or metatarsal pad can be folded cranially and positioned such that the thickest part of the pad is directly beneath the ends of the metacarpal or metatarsal bones (Figure 41-61D). The skin edge on the dorsal surface of the metacarpal or metatarsal area may also have to be trimmed to get this positioning. If infection is present, the heads are not removed from these bones in an effort to avoid the possibility of ascending infection in the marrow cavities of the bones. After infection is controlled the area may undergo reoperation to remove the heads and trim the bones.

After the metacarpal or metatarsal pad has been folded cranially into position, a quarter inch diameter Penrose drain is placed between the pad and the ends of the bones. The pad is rotated under the ends of the bones. Interrupted horizontal mattress sutures of 2-0 or 3-0 polvglyconate or polyglactin 910 are used to suture the subcutaneous tissue on the cranial edge of the metacarpal or metatarsal pad to the subcutaneous tissue overlying the cranial aspect of the metacarpal or metatarsal bones after the pad is rotated into position (Figure 41-61E). Far near near far sutures of 2-0 or 3-0 polypropylene or nylon are used to complete the closure of the metacarpal or metatarsal pad to the skin on the cranial surface of the metacarpal or metatarsal bones. Simple interrupted tacking sutures are placed at each end of the drain to hold it in place (Figure 41-61F).

A "clamshell" splint is indicated when bandaging to keep pressure off of the newly positioned pad. The drain is removed in 4 to 5 days. Sutures are removed at 10 to 14 days, and bandage support is used for 21 days. These times are subject to variation, depending on healing and the size of the animal.

Pandigital amputation. **A.** A transverse incision is made on the dorsum of the paw proximal to the line of demarcation between viable and nonviable skin. **B.** A similar incision is made on the palmar or plantar surface of the paw cranial to the metacarpal or metatarsal pad. **C.** After severance of deep structures, the digits are removed. **D.** The distal heads of the metacarpal or metatarsal bones are removed, and the bones are trimmed to allow proper fit of the pad under their ends. **E.** A quarter inch Penrose drain is placed between the pad and the ends of the bones, and series of interrupted absorbable subcuticular horizontal mattress sutures are used to suture the pad under the metacarpal or metatarsal bones. **F.** Far near near far skin sutures are used to complete the closure. (From Swaim SF, Henderson RA. Small animal wound management, 2nd ed. Baltimore: Williams & Wilkins, 1997: 360.)

Occasionally, because of a combination of the way the animal bears weight and the lack of secure connective tissue fixation of the metacarpal or metatarsal pad to underlying structures, the pad may not remain in the desired position under the metacarpal or metatarsal bones, and ulceration may develop in an area adjacent to the pad. Repositioning of the pad and placement of fixation sutures under the pad may help to secure it in place. Placement of pad grafts in the area of wear may also be considered, and is preferred by the authors.

Heart and Great Vessels

Conventional Ligation of Patent Ductus Arteriosus in Dogs and Cats

Eric Monnet

Introduction

Patent ductus arteriosus is the most common congenital heart defect diagnosed in dogs. In cats, ventricular septal defects and pulmonic stenosis are more common cardiac defects. Physical findings include a continuous murmur auscultated at the left heart base and a hyperkinetic pulse. Thoracic radiographs show dilation of the descending aorta, the left atrium, and the pulmonary artery. Pulmonary overcirculation is also present. Surgical correction of the defect should be performed as soon as possible after diagnosis. Most animals with untreated patent ductus arteriosus will die within 1 year from congestive heart failure. Pulmonary hypertension may cause reversal of flow through the ductus arteriosus in a few cases. Dogs presenting with pulmonary edema should be treated with furosemide prior to surgery.

Surgical Technique

PDA ligation is accomplished through a left 4th intercostal thoracotomy in dogs, or a 4th or 5th left intercostal thoracotomy in cats. The left cranial lung lobe is reflected caudally and packed with a moistened laparotomy sponge or 4x4 gauze in smaller animals. The vagus nerve courses over the ductus arteriosus and can be used as a landmark to locate the ductus arteriosus. The vagus nerve is elevated from the mediastinum by sharp dissection and retracted gently with a suture. The recurrent laryngeal nerve should be identified as it passes caudal to the ductus. Dissection of the vagus nerve should be performed outside of the pericardial sac with a right angle forceps. Dissection of the patent ductus arteriosus starts on its caudal aspect (Figure 42-1). The forceps should be kept parallel to the transverse plane during this part of the dissection. Dissection of the cranial portion of the ductus is performed at an angle of approximately 45° to the transverse plane in a triangle delineated by the aortic arch, pulmonary artery, and patent ductus arteriosus (See Figure 42-1). Careful sharp dissection with scissors is sometimes necessary to reflect

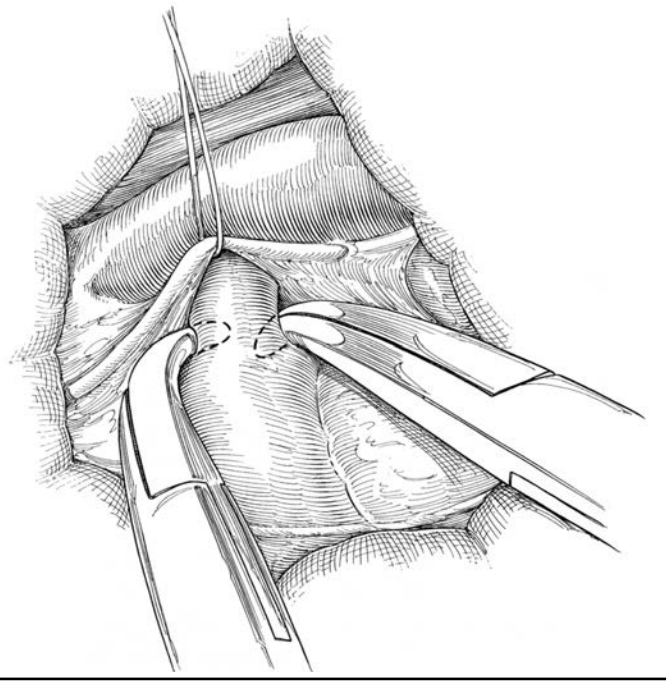

Figure 42-1. PDA ligation: The patent ductus arteriosus is isolated by blunt dissection without opening the pericardial sac. The right angle forceps is parallel to the transverse plane for the caudal dissection of the ductus. The right angle forceps is angle caudally 45° for the cranial dissection of the ductus. The ligature closest to the aorta is slowly tightened and tied first.: From E.C.Orton: Congenital Heart Defect, in Small Animal Thoracic Surgery, Williams & Wilkins, 1995, Chapt 19, p205.

the attachment of the pericardium ventrally from the aorta to expose this triangle. The dissection of the medial aspect of the patent ductus arteriosus is performed by passing the right angle forceps from caudal to cranial (Figure 42-2). Dissection should be as gentle as possible with small movements of the right angle forceps to avoid tearing the medial wall of the ductus. When the tip of the right angle forceps is clear of tissue, a #1 or 0 silk suture is grasped by the forceps and passed around the ductus. A second suture is passed around the ductus in the same manner. Alternatively, some surgeons pass a doubled strand of suture and cut the suture in the middle thus reducing the number of passes on the medial aspect of the ductus. The ligature closest to the aorta is slowly tightened and tied first (Figure 42-3). The second ligature is then tightened and tied. The palpable thrill in the pulmonary artery present prior to ligation should be completely eliminated after ligation. If the medial wall of the ductus is ruptured during dissection light pressure should be applied to control the bleeding. If the tear is not too large the bleeding will stop. However, continuing the dissection may worsen the tear and lead to uncontrollable hemorrhage. At this point, the options depend on the experience of the surgeon and on the availability of vascular instruments. One option is to abort the surgery and refer the case to a surgeon experienced in cardiovascular surgery for latter closure. Another option is to divide the ductus between two vascular forceps and close both ends with 4-0 polypropylene suture using a continuous mattress pattern. Intravenous injection of nitroprusside has been recommended to decrease arterial pressure after tearing a ductus arteriosus. Clamping of the aorta and the pulmonary artery to control bleeding has also been recommended. At

the conclusion of intrathoracic surgery, the cranial lung lobe is unpacked, replaced in its normal position, and reinflated. A thoracostomy tube is placed and the thoracotomy is closed in a routine fashion. The thoracostomy tube is usually removed in the immediate postoperative period after negative intrathoracic pressure is attained.

Surgical Management of Pulmonic Stenosis

Jill E. Sackman and D.J. Krahwinkel, Jr.

Introduction

Pulmonic stenosis is reported to be the third most common congenital heart disease in the dog with patent ductus arteriosus and aortic stenosis being first and second, respectively.[1] The English bulldog is the most common breed represented, however, other dogs at risk include the beagle, Samoyed, Chihuahua, schnauzer, Boykin spaniel, mastiff, and various terrier breeds.[2] The disease occurs equally between male and female except in the bulldog where the incidence in males predominates. The disease is rare in cats. Pulmonic stenosis has a genetic basis in dogs, although this is uncertain in the cat.[3]

The lesion may occur as a supravalvular, valvular, or subvalvular stenosis. With any of the three, an infundibular stenosis may occur in which the hypertrophied musculature obstructs the right ventricular outflow tract. The valvular site is by far the most common and is manifested by thickening, fibrosis, and hypoplasia of the valve leading to outflow obstruction.

Diagnosis

Many cases of pulmonic stenosis are asymptomatic early in their life; some remain asymptomatic indefinitely. More severe cases display exertional fatigue, dyspnea, and syncope. Signs of right heart failure including ascites, hepatomegaly, and arrhythmia may be present in advanced cases.[4] Physical examination reveals a systolic ejection murmur heard over the pulmonic valve that often radiates along the sternum to both sides of the thorax. A holosystolic murmur of tricuspid insufficiency may sometimes be auscultated over the right hemithorax.

The ECG usually indicates right ventricular hypertrophy, including right axial deviation, S waves in leads I, II, III, and aVF. Thoracic radiographs reveal varying degrees of cardiomegaly. The right side of the heart predominates in the enlargement. A

poststenotic dilatation of the main pulmonary artery is seen on the dorsoventral view. The pulmonary vessels appear normal or somewhat underperfused. Cardiac catheterization helps to locate the specific site of the stenosis and to measure pressure gradients for prognosis. Measuring gradients under anesthesia gives pressure readings that are usually much lower than actually exist. Angiographic features of pulmonic stenosis include thickened and dysplastic valve leaflets, narrowing of the outflow tract and valve orifice, poststenotic pulmonary artery dilatation, and right ventricular hypertrophy. In English bulldogs an anomalous left coronary artery may be seen crossing the ventricle at the level of the stenosis.

In many cases echocardiography and color flow Doppler echocardiography examination provide sufficient data making cardiac catheterization unnecessary. Typical findings are hypertrophy of the right ventricle, muscular narrowing of the right ventricular outflow tract, deformity and narrowing of the pulmonic valve, and post stenotic dilatation of the pulmonary artery. Pressure gradients measured by color flow Doppler echocardiography are more likely than catheterization to give an accurate assessment of the severity of disease because the examination does not require general anesthesia. Echocardiography and/or cardiac catheterization can usually determine the severity of the disease and locate the stenosis at the supravalvular, valvular, subvalvular, or infundibular site. This information is crucial in determining surgical candidates, selecting the correct surgical procedure, and giving prognosis. In some patients it is very difficult to delineate between a pure valvular stenosis and one that is both valvular and subvalvular. This makes selecting the proper surgical technique more difficult.

Surgical Guidelines

Nonanesthetized pressure gradients that are less than 50 mmHg are generally considered mild and do not require surgical intervention. Severe gradients exceeding 80 mmHg place the patient at risk of heart failure and death. These should have surgical intervention.[3,4] Dogs with moderate disease (gradients of 50 to 80 mmHg) may or may not require surgical correction depending on the progression of the disease. One author has recommended surgery when: 1) the right ventricular pressure exceeds 120 mmHg or a gradient exceeds 100 mmHg in a mature dog, or 2) the right ventricular pressure is 90 to 120 or a gradient of 70 to 100 in an immature dog.[5] Others recommend surgery any time the gradient exceeds 50 mmHg and right ventricular hypertrophy is significant.[6]

Any animal not undergoing surgery should be re-evaluated at three month intervals to determine if the disease is progressing. Symptomatic animals should have surgical intervention regardless of their pressure gradients. A problem of waiting to see if a patient's disease is progressive based on pressure measurements or disease signs is that they may become poorer surgical candidates with time. These animals may develop secondary infundibular muscular stenosis, worsening right ventricular hypertrophy, right ventricular fibrosis, and right heart failure. If possible surgery should be delayed until the animal is mature so the procedure is done on a fully developed heart that will not outgrow the correction.

Even though various authors have stated guidelines for surgical intervention, most of these are based upon personal observations. There have been no clinical trials in dogs with long-term follow-up to validate criteria for surgical intervention or to determine which corrective procedure gives the best results; however in a series of 72 cases of congenital pulmonic stenosis left untreated, only 65% of patients were alive after two years.[7] Unfortunately in this series, the severity of the stenosis was not described.

Anesthesia for Pulmonic Stenosis

Nearly all anesthetic agents depress cardiopulmonary function directly or alter reflex regulatory mechanisms.[8] Patients with cardiac disease may have little to no reserve for compensation; therefore, anesthetic agents must be administered carefully and in reduced dosages. Preanesthetic agents should be administered to relieve anxiety and to reduce the amount of depressant general anesthetic required. A combination of a benzodiazepine and an opioid are used for sedation. Opioid-induced respiratory depression may occur, therefore oxygen by mask should be provided during the induction process. Anticholinergics, especially atropine, are not used unless bradycardia occurs because of their propensity to induce tachycardia.

Administering low concentration isoflurane in oxygen until tracheal intubation can be accomplished completes anesthetic induction. Anesthetic maintenance is by continued low concentration of isoflurane supplemented with intermittent doses of an opioid. Intermittent positive-pressure ventilation is provided either manually or mechanically. Profound muscle relaxation can be produced by intravenous administration of atracurium, a nondepolarizing muscle relaxant.

Pulmonic stenosis patients must be closely monitored for cardiopulmonary function. Monitoring parameters should include heart rate, ECG, pulse quality, direct or indirect blood pressure, pulse oximetry, and central venous pressure. Assessment of blood volume and hemodilution is by serial determinations of packed cell volume and total plasma proteins. Measuring urine production assesses renal function. Blood pressure is maintained by a maintenance flow of intravenous crystalloids supplemented with colloids. Cross-matched whole blood must be available should major hemorrhage occur.

Surgical Procedures for Pulmonic Stenosis

Various surgical procedures have been described for correction of pulmonic stenosis.[9] These include balloon dilatation, open valvulotomy/valvulectomy, closed valvulotomy/dilatation, open and closed patch grafting, by-pass conduit, and open-heart repair with cardiopulmonary bypass. The specific procedure depends upon the location of the stenosis, size of the patient, severity of the disease, expertise of the surgeon, and equipment available. Many of the procedures have been adapted from techniques used to correct pulmonic stenosis in children although direct application to animals may be erroneous. For example, valvular stenosis in children is commonly a fusion of the valve leaflets, whereas in dogs it is usually a fibrotic, thickened, dysplastic valve. Direct comparison of the techniques or the expected results between children and dogs should not be made.

Open Valvulotomy/Valvulectomy

This procedure is a modification of the technique developed by Swan[10] using transient venous inflow occlusion and a pulmonary arteriotomy. The technique is used in patients with a valvular stenosis and minimal to no subvalvular component. The thorax is opened by a thoracotomy at the left fourth intercostal space. Dissecting between the thymus and the cranial aspect of the pericardial sac isolates the cranial vena cava. The cava is located on the right side of the thorax and ventral to the brachycephalic artery. A Rumel tourniquet of umbilical tape is placed on the vessel. Incising the caudal mediastinum immediately behind the pericardial sac and ventral to the phrenic nerve approaches the caudal vena cava. The vessel can be visualized deep in the mediastinal space to the right side of the thorax. Right angle forceps are used to place a Rumel tourniquet similar to the cranial cava. Dissection of the caudal cava may be impossible from the fourth intercostal space in dogs with severe cardiac enlargement. In these instances the caudal edge of the incised skin is retracted and a small thoracotomy incision is made at the sixth intercostal space. The cava is easily isolated from this position.

A third Rumel tourniquet is placed on the descending aorta just above the heart base. Tightening this tourniquet for 1 to 2 minutes after inflow occlusion maximizes blood flow to the heart and brain. It is released slowly as cardiac function returns to normal.

The pericardial sac is incised parallel and ventral to the phrenic nerve. Four to six stay sutures are placed in the pericardial sac and secured to the surgical drapes to "cradle" the heart (Figure 42-4). Lidocaine applied topically to the heart and an intravenous lidocaine drip help to minimize surgically induced arrhythmias. Stay sutures of 5-0 polypropylene are placed in the dilated pulmonary artery immediately distal to the pulmonary valve. Venous inflow occlusion is accomplished by tightening the caval tourniquets. After waiting a few seconds for the heart to partially empty, a 1 to 2 cm incision is made between the two stay sutures (Figure 42-5). A small retractor at the ventral end of the incision and the two stay sutures retract the arteriotomy site (Figure 42-6). Suction is used to empty the right ventricle and visualize the pulmonic valve. The dysplastic leaflets are grasped with forceps, and scissors or scalpel used to excise the valve (Figure 42-7). After all three leaflets have been excised or incised, a forceps is used to dilate the valve annulus. A "pop" can be felt as the annulus stretches. One finger is inserted into the outflow tract to assure that the stenosis is relieved. The cranial

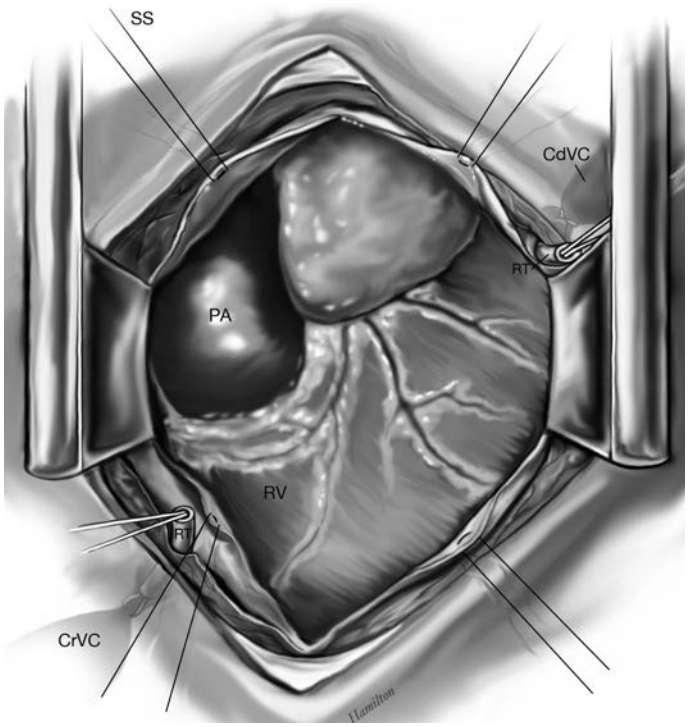

Figure 42-4. Surgical approach to the right ventricular outflow tract and pulmonary artery is shown. The pericardial sac is opened and retracted with stay sutures. Rumel tourniquets *(RT)* are placed around the cranial vena cava *(CRVC)* and caudal vena cava *(CCDVC)*. The pulmonary artery *(PA)* and right ventricle *(RV)* are exposed.

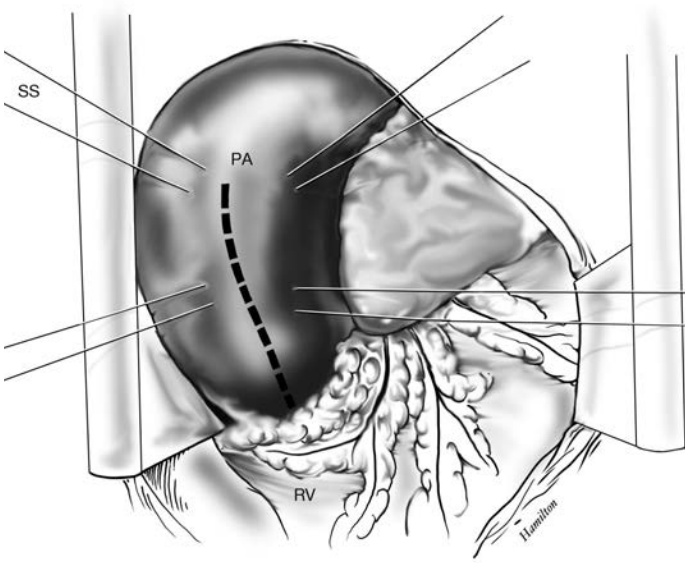

Figure 42-5. Stay sutures *(SS)* are placed in the dilated pulmonary artery. The pulmonary artery *(PA)* is opened to just above the level of the pulmonic valve *(PV)*.

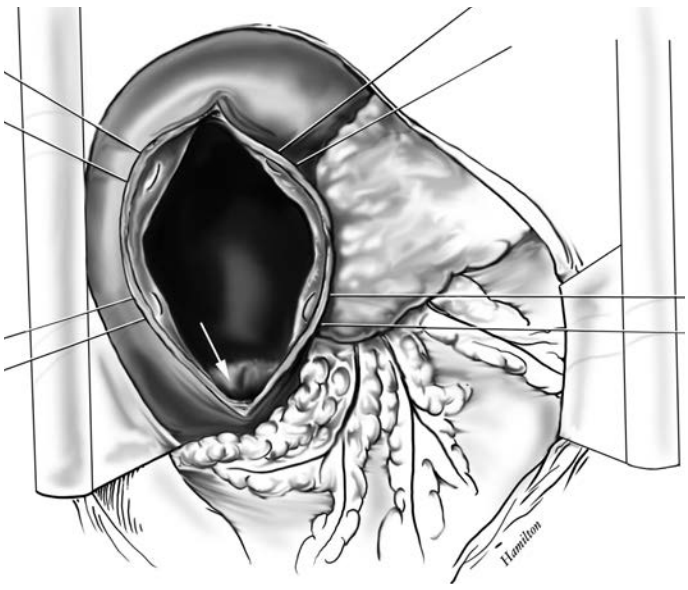

Figure 42-6. The pulmonic stenosis *(PS)* is observed near the ventral end of the arteriotomy.

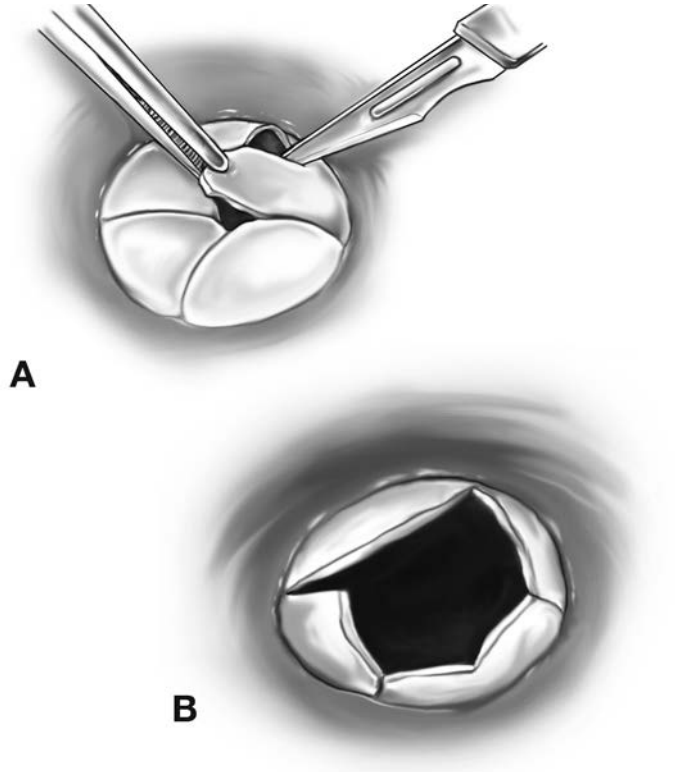

Figure 42-7. A. The dysplastic leaflets are excised using a No. 11 scalpel and/or scissors. **B.** The appearance of the valve after the leaflets have been partially excised and dilated.

Rumel tourniquet is released and the heart and pulmonary artery permitted to fill to remove all intravascular air. The stay sutures are used to elevate the edges of the artery and a Satinsky clamp placed on the arteriotomy site (Figure 42-8). The second Rumel tourniquet is released. Cardiovascular resuscitation is aided by temporarily occluding the descending thoracic aorta with the third Rumel to increase coronary and cerebral blood flow. Cardiac massage and an intravenous infusion of dopamine may be required to reestablish normal cardiac function. Total inflow occlusion of a diseased heart should not exceed two minutes. If this is not sufficient time to complete the procedure, then inflow is terminated and 10 to 15 minutes of normal cardiac function is established. A brief second inflow occlusion can be utilized to complete the procedure. Normal hearts can tolerate four or more minutes of inflow occlusion; however diseased hearts often fibrillate and are difficult to defibrillate.

The arteriotomy is closed with a double row of continuous 5-0 polypropylene sutures, and the stay sutures are removed (Figure 42-9). The pericardial sac is loosely closed with 3-0 absorbable suture. Closing the sac tightly could result in tamponade if the arteriotomy site leaks. The tourniquets are removed, and the thorax lavaged with warm saline to remove all blood. The intercostal nerves are blocked with local anesthetic for analgesia, a thoracic tube placed, and the thorax closed in a routine manner.

Closed Valvulotomy/Dilatation

This procedure is used in patients who likely cannot tolerate even brief in-flow occlusion. The surgical approach is as described above but without inflow occlusion. A purse-string suture is placed

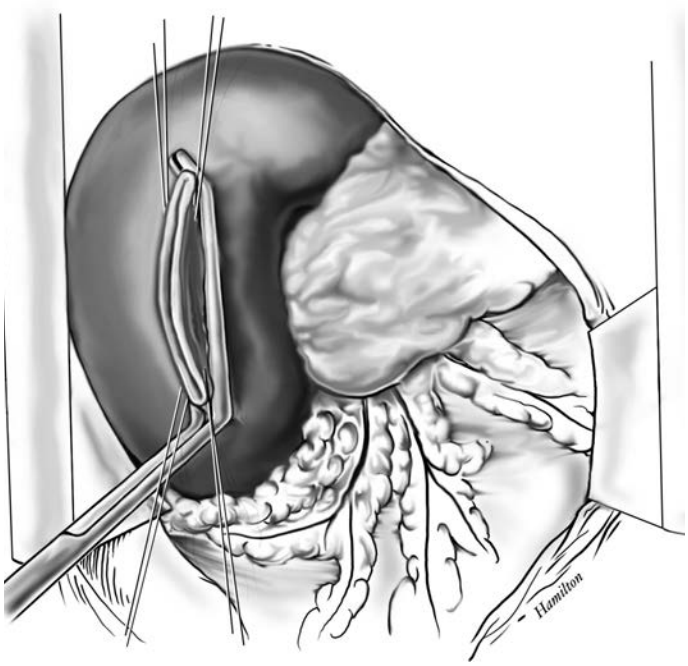

Figure 42-8. Satinsky *(SF)* forceps are used to occlude the arteriotomy site.

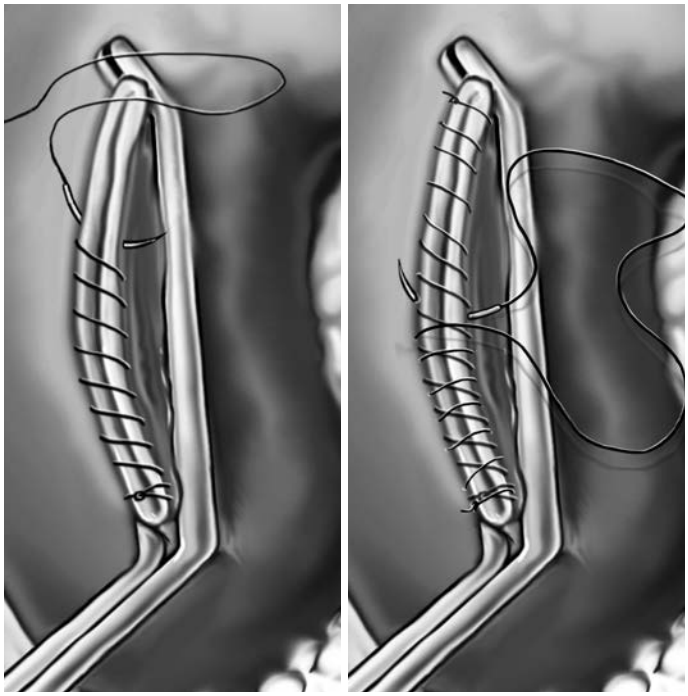

Figure 42-9. The arteriotomy is closed with a double row of continuous monofilament sutures.

in the right ventricular outflow tract just below the pulmonic valve or in the dilated pulmonary artery above the valve. The suture ends are placed through a piece of tubing similar to the Rumel tourniquet. A stab incision is made through the purse string and into the lumen of either the right ventricle or the pulmonary artery. A blunt tipped bistoury or valvulotome is passed through the valve and several blind cuts are made through the stenotic valve by cutting against backpressure applied by the surgeon's finger (Figure 42-10). A forceps is then placed through the purse string and the valve annulus dilated to completely break down

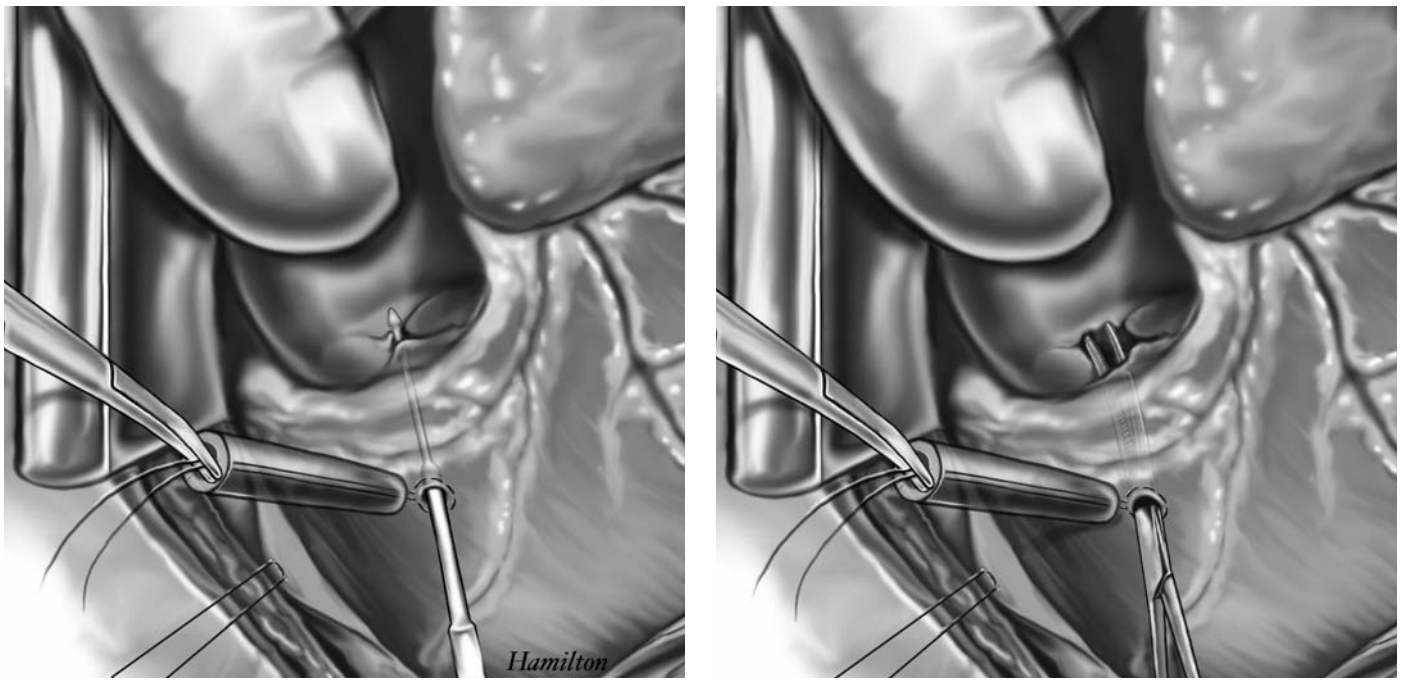

Figure 42-10. A closed valvulotome or bistoury is placed through a purse string in the right ventricle, and the dysplastic valve leaflets are incised.

the stenotic ring. In dogs with severe muscular hypertrophy and a narrow outflow tract, this procedure is more easily accomplished through a purse string in the dilated pulmonary artery. Simple dilatation without first cutting the stenotic valve may only provide temporary relief since the torn and stretched tissue may heal with scar tissue resulting in a new stenosis.

Patch Grafting

The use of patch grafting for repair of pulmonic stenosis in the dog was first reported in 1976.[11] The graft extends over the pulmonary artery to the right ventricle outflow tract and is effective in correcting valvular, supravalvular, and subvalvular stenosis while alleviating infundibular lesions. Patch grafting may be performed by either a closed or open technique. The closed patch graft technique[11,12] relies upon the placement of a cutting wire across the stenotic lesion under the applied patch. Unfortunately the technique does not allow excision of the dysplastic valve and relies upon the surgeon's ability to place a cutting wire blindly across the defect.

An open technique for patch grafting has been described[13,14] The authors prefer a modification of this technique, which is performed through a left lateral thoracotomy at the fourth intercostal space. The lungs are retracted to expose the pericardial sac. Rumel tourniquets are placed around the cranial and caudal vena cava, and the thoracic aorta as described for open valvulotomy/valvulectomy. The pericardium is incised parallel and ventral to the phrenic nerve, with an extension ventral and perpendicular. Pericardial basket sutures are placed. An elliptical shaped polytetrafluoroethylene (PTFE; Gortex, W.L. Gore and Assoc.) patch is cut so that the graft will extend both proximal and distal to the stenotic lesion. The patch is sutured to the outflow tract and pulmonary artery using 4-0 polypropylene suture and a double-armed taper point needle. Suturing is started at the ventral tip of the patch, which is placed on the ventricle with an interrupted suture. The opposite end of the patch is sutured to the pulmonary artery above the stenotic site. The margins of the patch are sutured in a continuous fashion to the ventricle and onto the pulmonary artery. It is critical that the patch is sutured in a "tented" fashion over the stenotic area. This extra graft allows for expansion of the stenotic area. Once the patch has been applied, it is incised longitudinally at an equal distance between the cranial and caudal margins (Figure 42-11A and B). The caval tourniquets are tightened to accomplish venous inflow occlusion. A stab incision with a #11 scalpel blade is made into the pulmonary artery and extended to the dorsal and ventral margins of the patch with Metzenbaum scissors. The valve is inspected and the leaflets excised (Figure 42-12). A forceps may be used to further dilate the valve and annulus. A finger is inserted into the annulus to insure that the stenosis has been relieved. Air is evacuated from the heart by releasing the cranial Rumel tourniquet. The incised patch graft is clamped using Satinsky tangential vascular occlusion clamps. The caudal Rumel tourniquet is then released. The patch graft incision is sutured with 4-0 polypropylene in a continuous pattern (Figure 42-13A and B). Total inflow occlusion time should not exceed two minutes. The Rumel on the aorta is used temporarily to improve heart and brain perfusion. The pericardium is closed loosely with interrupted sutures. A thoracostomy tube is placed and the thoracotomy incision is closed in routine fashion.

Open patch grafting is effective in young animals with severe valvular, but preferably supravalvular, subvalvular, or infundibular stenosis. Care must be taken in identifying an aberrant coronary artery, which crosses the right ventricular outflow tract occasionally in boxers and bulldogs, negating the use of this procedure.

A case series of nine dogs undergoing closed patch grafting has described significant morbidity and mortality associated with the closed patch procedure.[15] There was one intra-operative death,

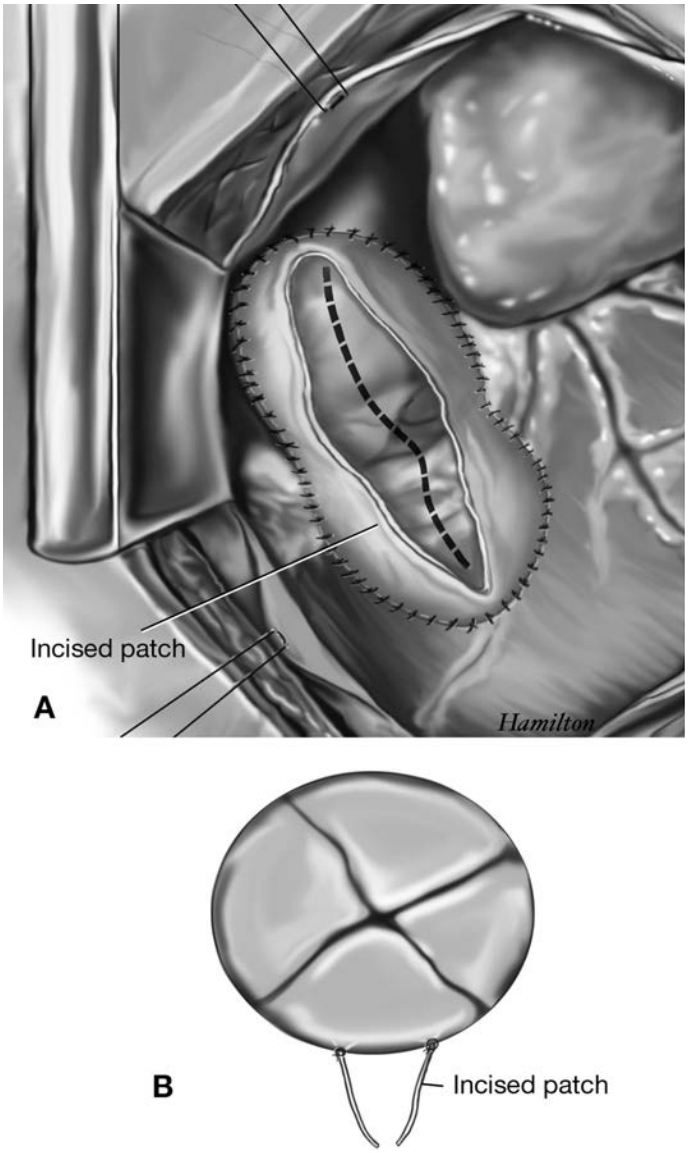

Figure 42-11. A. The patch is cut longitudinally at an equal distance between the cranial and caudal margins. **B.** Cross sectional view of patch applied across stenotic valve.

and blood transfusions were required to treat life-threatening hemorrhage in six of the nine dogs. The clinical signs improved in five of the six dogs that survived in this study. Progression of right ventricular hypertrophy was delayed, but not prevented by the procedure.

Conduits

Vascular grafts or conduits have been used to repair supravalvular pulmonic stenosis in the dog.[16] The use of conduits from the pulmonary artery to the right ventricle may be used to bypass the stenotic pulmonary valve in animals with an aberrant coronary artery. The technique is performed through a left lateral thoracotomy at the fifth intercostal space. The pericardium is opened and sutured as previously described. The stenotic region is observed and an appropriately sized Dacron or PTFE conduit chosen. A Satinsky partially occluding vascular clamp is applied to the pulmonary artery above the site of the lesion. An arteriotomy is made with a #11 scalpel blade and extended with Potts

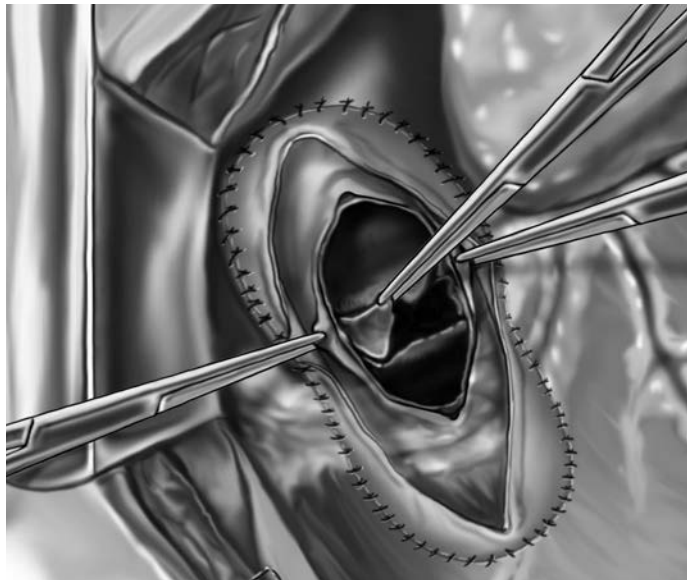

Figure 42-12. The valve is inspected and the leaflets excised.

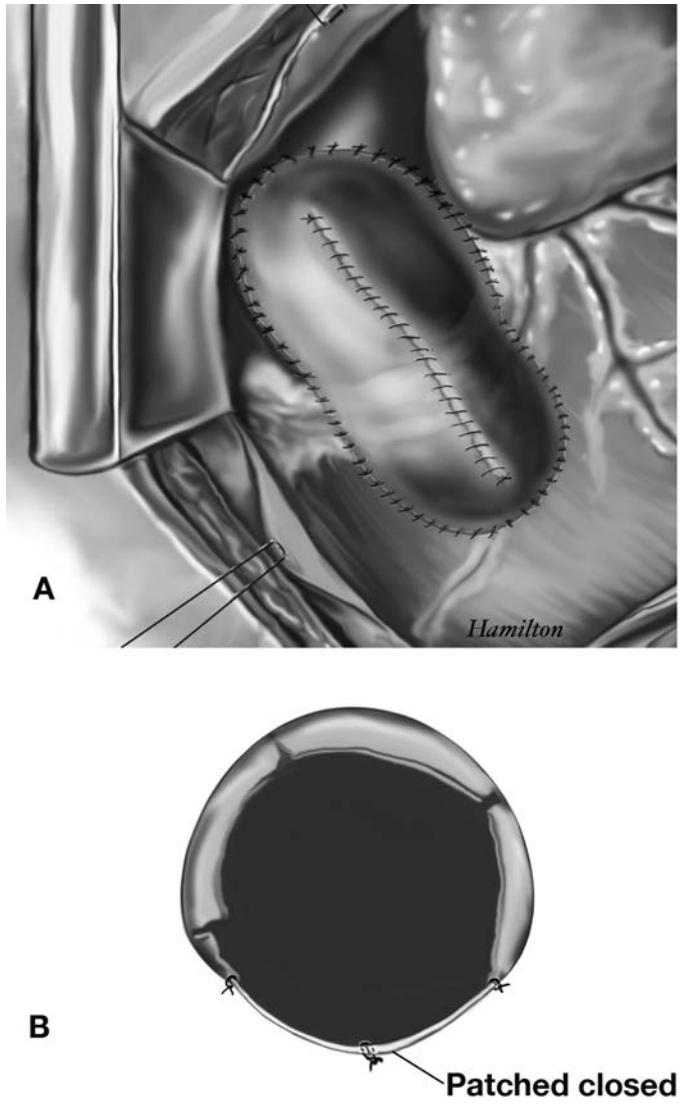

Figure 42-13. A. Completed graft sutured to pulmonary artery outflow tract. **B.** Cross sectional view of patch applied across incised pulmonary outflow tract. Note increase in outflow diameter.

scissors. The conduit is cut at an oblique angle and sutured end-to-side to the pulmonary artery with continuous 5-0 to 6-0 polypropylene suture on a double-armed taper point needle. The conduit is anastomosed to the ventricular wall in end-to-side fashion following coring a hole in the ventricular wall. Closures of the pericardium and thoracotomy incisions are routine.

Conduits, with the exception of those used in supravalvular stenosis (pulmonary artery to pulmonary artery) have been met with limited success in veterinary medicine. The procedure may be best applied under cardiopulmonary bypass.

Cardiopulmonary Bypass

Pulmonic stenosis can be repaired effectively utilizing cardiopulmonary bypass. This technique permits direct visualization and repair of the lesion without the time constraints of inflow occlusion. Valvuloplasties, patches, and conduits can all be performed with cardiopulmonary bypass permitting the surgeon to do precise surgical repairs.[17]

Interventional Catheterization for Congenital Heart Disease

Jonathan Abbott

Introduction

For much of its early history, the technique of cardiac catheterization was utilized exclusively for diagnosis. However, beginning in the 1960's, resourceful pediatric cardiologists developed methods of transcatheter therapeutic intervention. Since that time, the indications for interventional catheterization in both pediatric and adult cardiovascular medicine have expanded remarkably. Obstructive lesions are addressed by balloon dilation, pathologic shunts are occluded by transcatheter techniques, stents have been used to maintain patency of vessels and conduits and more recently, percutaneous methods of valve replacement and repair have been investigated. In veterinary medicine, transcatheter therapy has been confined primarily to balloon dilation of outflow tract obstruction and occlusion of patent ductus arteriosus (PDA). This chapter reviews the current applications of transcatheter intervention in veterinary patients with congenital cardiovascular disease.

Transcatheter Occlusion of Patent Ductus Arteriosus (PDA)

Etiopathogenesis of PDA

The ductus arteriosus connects the ventral aspect of the proximal descending aorta with the dorsal aspect of the pulmonary artery bifurcation. The histology of the normal duct is distinct from that of the aorta and this is relevant to normal closure as well as to the angiographic appearance of the persistently patent duct. The tunica media of the aorta consists primarily of elastic fibers. In contrast, the media of the duct is comprised of smooth muscle fibers in both circumferential and spiral orientations.[1] During fetal life, pulmonary vascular resistance exceeds systemic vascular resistance and the ductus diverts the majority of the right ventricular output to the systemic circulation. Maintenance of fetal ductal patency primarily depends on production of prostaglandin-E.[2]

In normal, term neonates, closure of the ductus begins shortly after birth and initially results from contraction of ductal smooth muscle. The mechanism of ductal closure is complex and likely has a multifactorial basis. However, increases in oxygen tension associated with parturition limit the production of dilative prostaglandins, initiate a vasoconstrictive prostaglandin cascade and decrease the sensitivity of ductal smooth muscle to dilative

stimuli.[2] The time required for functional closure of the duct is species-dependent but generally is within 3 to 5 days of birth. Anatomic ductal closure occurs later and is associated with the development of intimal edema, cellular degeneration and necrosis or apoptosis; the result is the arterial ligament.[1,3]

The cause of post-natal ductal patency in most if not all affected dogs is a deficiency of ductus-specific smooth muscle.[4] In dogs that ultimately develop a patent duct, ductal smooth muscle is replaced by elastic tissue which generally extends from the aortic side of the duct toward the pulmonary artery. In the most severely affected individuals, the media of the entire duct is replaced by elastic tissue. The result is a tubular, large diameter duct that is associated with neonatal pulmonary hypertension and a bidirectional or right-to-left shunt.[5] In less severely affected individuals, the elastic tissue extends a variable distance from the aortic-ductal junction. Because of persistence of functional smooth muscle in the more distal aspect of the ductus, most left-to-right shunting PDA have a conical shape and are narrowest where the ductus joins the pulmonary artery. The duct is widest at the attachment of the aorta and the flask-shaped dilation is known as the ductal ampulla. The cranial aspect of the ampulla is partially roofed by a shelf of tissue, known as the *crista (or plica) reunions,* which extends caudally from the ventral wall of the proximal descending aorta.[1] PDA is heritable in miniature poodles[5] and, based on breed predispositions, PDA likely has a genetic basis in other purebred dogs.

Pathophysiology

The ductus provides a communication between the pulmonary and systemic circulations. The size of the shunt is primarily determined by ductal diameter and the relationship between pulmonary and systemic vascular resistance. When pulmonary vascular resistance is less than that of the systemic circulation, blood shunts from aorta to pulmonary artery. The resultant increase in pulmonary venous return imposes a volume load on the left atrium and ventricle. Most canine PDAs provide resistance to ductal flow so that aortic pressure exceeds pulmonary artery pressure. Even then, the shunt volume can be considerable resulting in left ventricular dilation and hypertrophy, left atrial enlargement, functional mitral valve regurgitation and potentially the development of systolic myocardial dysfunction.

A large, non-restrictive duct necessarily results in systemic pulmonary artery pressures. In this setting, the development of obstructive vascular disease potentially results in suprasystemic pulmonary vascular resistance and shunt reversal. However, shunt reversal is uncommon in dogs and generally occurs in neonates. Patients with right-to-left shunting PDA are not candidates for operative therapy and are treated medically. Shunt direction associated with canine PDA is most commonly left-to-right. The remainder of this discussion relates to the diagnosis and management of left-to-right shunting PDA in the dog.

Clinical Findings

In many, if not most cases, the PDA does not cause clinical signs before the age of 4 to 6 months and the lesion is detected incidentally during routine physical examination. There is a distinct gender predisposition; about two thirds of the affected population is female. Distinct breed predispositions are also evident; Maltese, Pomeranian, miniature poodles, Bichon Frise and Shetland sheepdogs are more likely to have PDA than are mix breed dogs.[6] PDA has been reported in cats but it is uncommon.

A left-to-right PDA results in a continuous murmur; the murmur begins during systole, peaks in intensity at the time of the second heart sound, and persists through at least a portion of diastole. When the heart rate is very slow, or there is pulmonary hypertension related to a large shunt and high pulmonary vein pressures, the murmur may be inaudible during late diastole. More often, the murmur persists through the entire cardiac cycle and has a typical aorticopulmonary or "machinery" quality. The intensity of the murmur generally correlates with the size of the shunt. Very soft and focal murmurs are usually associated with a small shunt while moderate or large shunts typically result in a loud murmur that radiates widely. In patients with large shunts, a distinct systolic murmur due to functional mitral valve regurgitation sometimes can be heard. The third heart sound is audible in some patients; generally this finding reflects a large shunt and high left atrial pressures. When the shunt is moderate or large, the decrease in diastolic arterial pressure widens the pulse pressure and results in a hyperkinetic, or "bounding", arterial pulse.

Diagnostic Evaluation

In the absence of cardiac arrhythmias, the electrocardiogram (EKG) contributes little to diagnosis although most patients do have electrocardiographic evidence of left ventricular hypertrophy.[7] thoracic radiographs of patients with PDA typically have distinctive, if not diagnostic, features. Usually, there is cardiomegaly with left-sided emphasis. Evaluation of the pulmonary vessels may provide evidence of pulmonary hyperperfusion. Prominence of the proximal descending aorta is perhaps the most consistent radiographic feature. In some patients, the main pulmonary artery and left atrial appendage are also prominent resulting in the appearance of three closely associated bulges in the dorosoventral or ventrodorsal projection.

Echocardiography demonstrates variable degrees of left ventricular and left atrial enlargement. Echocardiographic measures of cardiac performance such as fractional shortening, usually are normal or mildly depressed. However, ventricular loading conditions are altered by the shunt and often, by concurrent mitral valve regurgitation which complicates interpretation of functional indices such as fractional shortening. Indeed, evaluation of the end-systolic ventricular dimension provides echocardiographic evidence of myocardial dysfunction in most patients with long-standing, uncorrected PDA. Doppler studies confirm the presence of continuous, disturbed flow within the main pulmonary artery. Although it is sometimes technically difficult to do so, the pulmonary-ductal junction, if not the entire duct, can be echocardiographically identified in the vast majority of patients (Figure 42-14). Transesophageal echocardiography may have a particular utility for more completely defining the dimensions and morphology of the PDA (Figure 42-15).

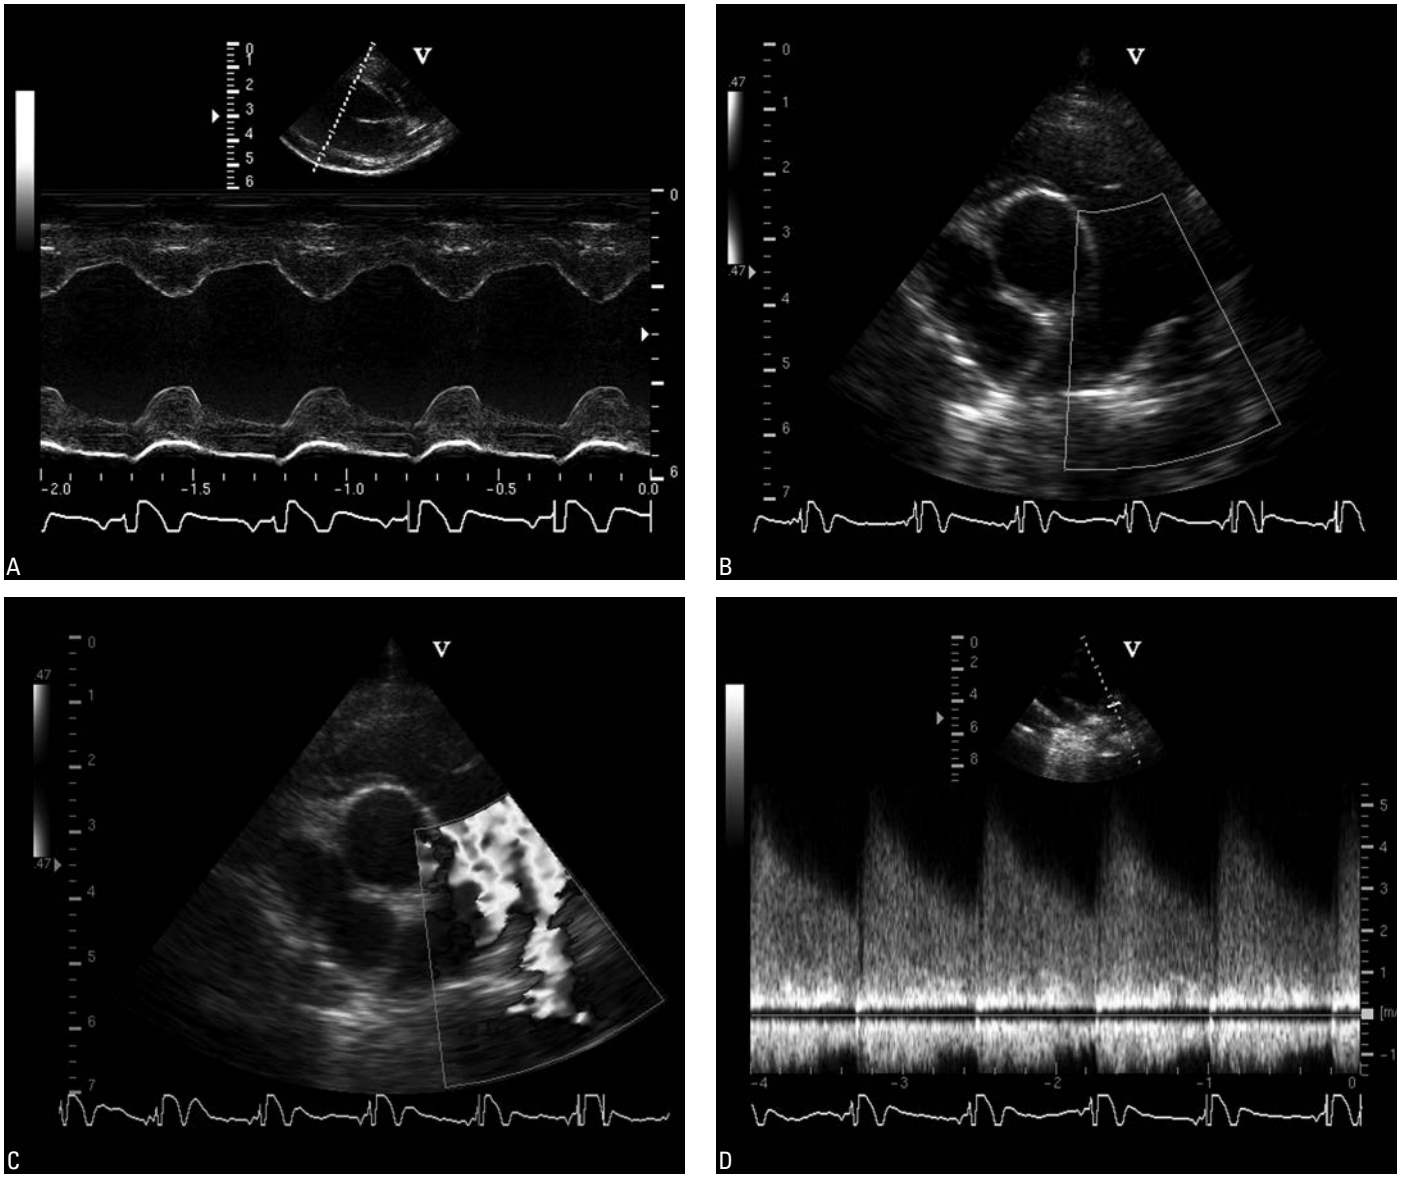

Figure 42-14A-D. Echocardiographic Images from a patient with a moderately large patent ductus arteriousus. An M-mode image **A.** of the left ventrical demonstrates left ventricular dilation and hypertrophy. Cranial, left parasternal images of the main pulmonary artery with **B.** and without **C.** a superimposed color-flow Doppler map show the ductal ampulla and ductal orifice. A continuous-wave Doppler spectrogram **D.** provides evidence of contuous flow into the main pulmonary artery. The velocity close to 5 m/s suggesting that the orifice is resistive.

Other than PDA, there are few disorders that result in a continuous murmur. When it is certain that there is a single continuous murmur and not distinct systolic and diastolic murmurs as can result from ventricular septal defect complicated by aortic insufficiency, the diagnosis is generally assured and the need for further evaluation can be debated. However, echocardiography is recommended in order to confirm the diagnosis before intervention, evaluate myocardial function and identify concurrent malformations which occasionally can complicate the presentation. The need for pre-procedural echocardiography is particularly acute when transcatheter ductal occlusion is contemplated because echocardiographic data can be used to provide a preliminary assessment of the ductal size and morphology.

Management of PDA – General Statements

It is accepted that mortality for canine patients with uncorrected PDA is high and that the risk associated with operative correction is relatively low. Therefore, occlusion of the duct, either by transcatheter methods or surgical ligation is advisable for nearly all patients with PDA. Mortality in uncorrected PDA is primarily due to congestive heart failure; other complications such as ductal endocarditis and progressive vascular disease are uncommon. Because of this, watchful waiting that includes echocardiographic surveillance is probably appropriate for the occasional patient that has a small ductus and minimal or no ventricular enlargement. With respect to treatment decisions, it is relevant that PDA is most common in small breed dogs. Dogs of this signalment are predisposed to the development of geriatric mitral valve degeneration (MR) and conceivably, the development of MR might result in clinical decompensation in older individuals with a previously tolerated ductus. Although there is a small risk associated with correction of PDA, the ratio of risk and benefit is in favor of repair for nearly all patients. The only exception to this general principle is the patient with

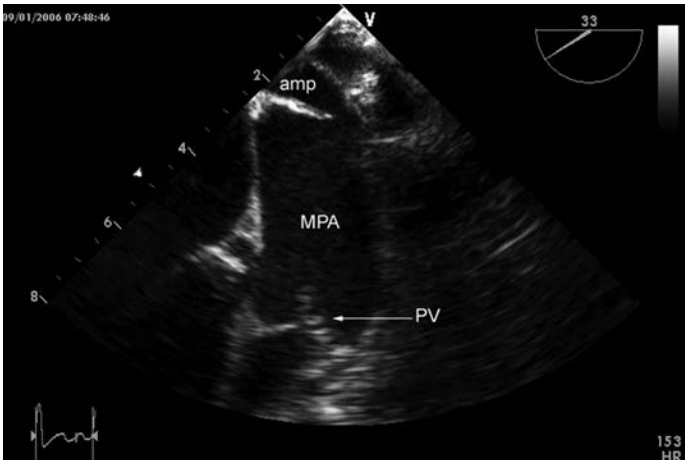

Figure 42-15. This transesophageal *(TE)* echocardiogram was obtained from a Borzoi with a patent ductus arteriousus. The junction of the ductus with the pulmonary artery is distinct. *MPA* = pulmonary artery, *amp* = ductal ampulla, *PV* = pulmonary valve.

a complex cyanotic malformation such as tetralogy of Fallot in which the ductus contributes to pulmonary perfusion.

Transcatheter Occlusion

Transcatheter PDA occlusion using different devices and subtly different techniques has been reported.[8-19] Initially, thrombotic Gianturco coils were used most commonly in veterinary medicine, but use of the recently developed, purpose-designed Amplatz® canine ductal occluder (ACDO) has, to a great extent, superseded that of Gianturco coils in veterinary practice.

Basic Technique – Transcatheter Occlusion

Numerous variations on the basic technique of transcatheter ductal occlusion have been reported. The retrograde trans-arterial approach is described here. After induction of general anesthesia, access to the femoral artery is percutaneously obtained using the modified Seldinger technique or is obtained by arteriorotomy after a small inguinal incision. In the former technique, a needle or short catheter is used to puncture the femoral artery while the patient is dorsally recumbent. When blood pulses from the entry needle, a wire-guide is introduced through the needle into the vessel lumen. The needle is then removed while hemostasis is maintained by digital pressure. A catheter or more often, a vessel sheath-introducer system with hemostasis port, is advanced along the wire into the femoral arterial system. The percutaneous technique is in almost universal use in pediatric and adult catheterization laboratories and has advantages with respect to vessel preservation. However, dogs tolerate post-procedural ligation of the femoral artery without apparent long-term sequlae and furthermore, complications of the percutaneous approach can be catastrophic.[20] If the femoral artery is entered proximal to the inguinal ligament, post-procedural attempts at hemostasis may be ineffective resulting in potentially fatal intra-abdominal hemorrhage. Additionally, severe subcutaneous hemorrhage can result despite appropriate vessel entry site and post-procedural hemostasis.[17] For these reasons, surgical isolation and arteriotomy may be the superior method of arterial access.

Regardless of technique used for vessel access, the use of a hemostasis sheath is advisable to facilitate catheter exchange and the movement of catheters through the femoral artery. The patient is positioned in lateral recumbency and the fluoroscopic image intensifier is centered over the cardiac shadow. Using fluoroscopic guidance, an angiographic catheter such as a pigtail is advanced to the ascending aorta. Central aortic pressures are evaluated and an angiogram is recorded after injection of contrast material in the proximal descending aorta. It is important that the angiogram clearly delineates the entire ductus including the pulmonary-ductal junction (Figure 42-16). The angiographic appearance can be classified according to ductal morphology.[14,21]

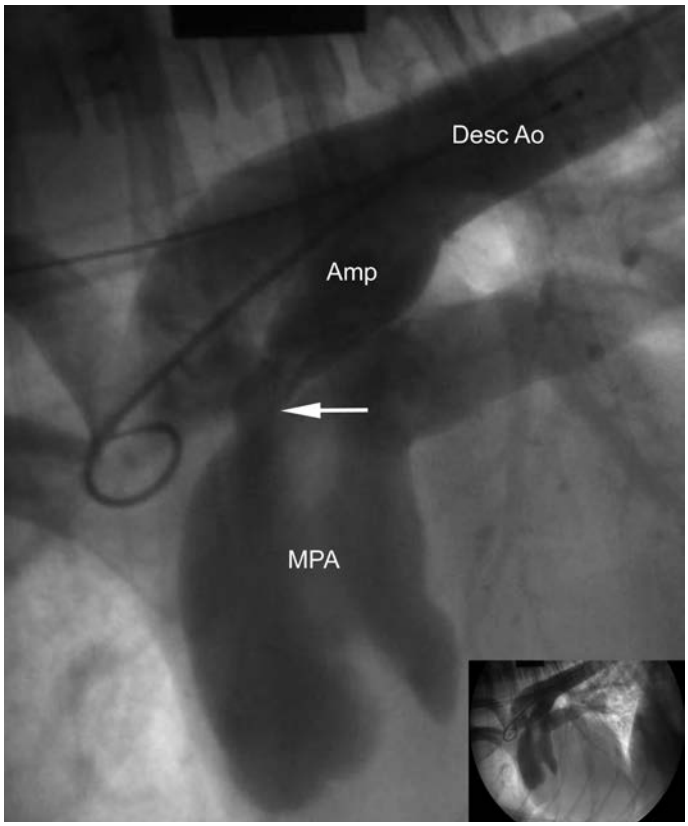

Figure 42-16. Lateral projection of a ductal angiogram obtained from a 6 year old female-spayed Springer Spaniel. Contrast material was injected into the aortic arch through a 5 F pigtail angiographic catheter. The ductal orifice of the pulmonary artery *(arrow)* is moderately large; it measured approximately 5 mm. *Asc Ao* = Ascending aorta, *Desc Ao* = Descending aorta, *MPA* = main pulmonary artery, *Amp* = Ductal ampulla. The inset image includes a larger portion of the thorax to provide anatomical orientation.

Amplatz® Canine Ductal Occluder - Technique

In collaboration with a manufacturer of cardiovascular devices, two veterinary cardiologists, Ngyuenba and Tobias, developed a metallic plug that was specifically designed to occlude the canine ductus.[22] This device, the ACDO, became commercially available in 2007. The ACDO is constructed from 2 to 3 layers of a fine nitinol mesh. The device is both collapsible and self-expanding; in its unstressed state, a waist separates a flat distal disk from a larger proximal, cupped disk. The ACDO is available in a range of sizes that are defined by diameter of the waist. The device is provided by the manufacturer within a tubular cartridge

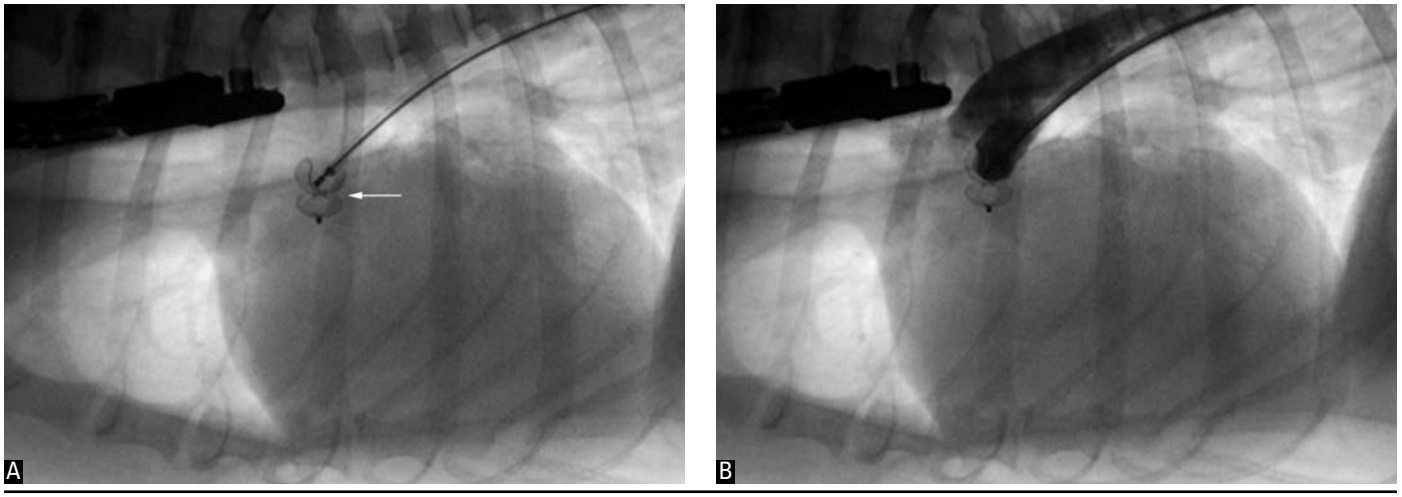

Figure 42-17. An Amplatz Canine Ductal Occluder (ACDO) was deployed across the ductus arteriousus of a 6 year old female Welsh corgi. These fluoroscopic images were obtained **A.** before and **B.** AFTER CONTRAST WAS INJECTED THROUGH THE DELIVERY SHEATH TO PROVIDE A PRELIMINARY ASSESSMENT OF DEVICE POSITION. To ensure device stability, it is important to confirm that the proximal disk assumes it unstressed, cup-shaped configuration prior to device release. In this case, after minor manipulation of the delivery cable, the device assumed its native cup-shape and was then released from the delivery cable.

and attached to a delivery cable. The ACDO is deployed using a retrograde approach after angiographic delineation of the ductus. Femoral arterial access is routine but because some ACDO require relatively large delivery catheters, exteriorization of the artery after inguinal incision is probably the most appropriate technique. The size of the ACDO is selected based on the smallest angiographic diameter of the duct and therefore, careful, quantitative assessment of ductal size is crucial. A device with a waist that is approximately twice the diameter of the minimum ductal dimension is said to be optimal.[19,22] After angiographic evaluation, the duct is crossed with a curved catheter such as an MPA which is then exchanged over a wire-guide for a long sheath or guiding catheter. Alternatively, contrast material for angiography can be injected through a long sheath such as a Mullins, Ansel or CHB type, and if it is possible to cross the duct with a wire-guide advanced through the sheath, this technique obviates the need for a catheter exchange.[23] Predictably, larger devices must be deployed through larger catheters and this must be taken into account not only as the delivery catheter is advanced, but also initially, when a short, vascular access sheath is placed in the femoral artery. When the distal end of an appropriately sized guiding catheter or long vascular sheath is in place within the main pulmonary artery, the device is introduced into the hub of the catheter or sheath using the loading cartridge and then advanced using the delivery wire. The proximal disk is deployed within the pulmonary artery at which time the wire and catheter are withdrawn together until the disk is firmly apposed to the ductal orifice. Then, the catheter is retracted so that the remainder of the device is deployed within the ductus. Suitability of positioning is then evaluated through manipulation of the wire, injection of contrast material through the side-arm of the catheter and potentially, through transesophageal echocardiography (Figure 42-17). If positioning is inappropriate, the device can be withdrawn into the deliver catheter. When the device is properly positioned, and it has resumed it's unstressed configuration, it is detached from the delivery wire (Figure 42-18).

The use of the ACDO is restricted to patients that have a femoral artery of sufficient caliber to accommodate the catheter or sheath required to deploy the device. This limits the use of the ACDO to relatively large patients but a modification of the basic technique of ACDO placement that can be used in patients as small as 2.5 or 3 kg has been described. Briefly, a 4F short vascular sheath is placed in the femoral artery and after angiography, a 4F curved, end-hole catheter is used to enter the pulmonary artery via the duct at which time, the catheter and sheath are removed over an exchange wire, the distal tip of which is left in the pulmonary artery. The outer diameter of a vascular sheath is generally 2F larger than the catheter that it will accommodate; that is, the outer diameter of a 4F sheath is 6 French units. Therefore, after the sheath has been removed, a 6F guiding catheter with hydrophilic coating can generally be advanced over the wire at which point, ACDO with waist diameters as great as 6 mm can be deployed within the duct.[22]

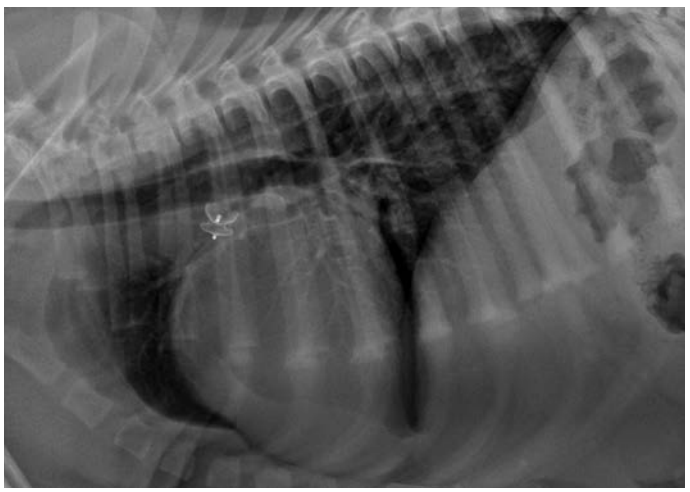

Figure 42-18. This fluroscopic image was obtained after placement of an Amplatz Canine Ductal Occluder **(ACDO)** device within the ductus arteriosus of a 6 month old male Cavalier King Charles spaniel that had concurrent valvular pulmonic stenosis; the latter malformation was addressed by balloon dilation.

Coil Occlusion – Technique

Gianturco coils are manufactured in numerous sizes and configurations but in all cases the device consists of a stainless steel or platinum wire that is tightly wound to produce a helix with a diameter between 0.014-0.043 inches. The wire made up of these primary windings is coiled to produce loops, the specific number of which depends on the length of wire and the diameter of the loop. Dacron tufts are attached to the wire and this makes the coil thrombogenic. The devices are packaged in tubular cartridges. Because the steel has structural memory, the loops reform when the coil is extruded from the cartridge or an intravascular catheter. The size and configuration of each coil is defined by three characteristics: wire diameter, loop diameter and wire length. Wire diameters of 0.035 in, 0.038 in and 0.052 in have all been used for coil occlusion of PDA in veterinary patients. Coils that form loops of numerous sizes ranging from 3 to 20 mm are available. In addition to characteristics that define loop size, number and deformability, some coils such as the Cook Detachable coil and the Cook Flipper are designed for controlled release into the circulation.

After angiographic evaluation, a curved, end-hole catheter such as a Judkins (right), JB-1, MPA or vertebral catheter is advanced to the ductus. Sometimes it is necessary to use a straight but floppy-tipped wire-guide to enter the ductal ampulla. It is useful to advance the catheter across the duct and into the pulmonary artery while monitoring intravascular pressures in order to identify fluoroscopic landmarks that relate to the pulmonary artery-ductal junction. Typically, this junction is close to the ventral border of the tracheal shadow. The dimensions of the coil to be deployed within the ductus are chosen based on measurements obtained from the angiogram or transesophageal echocardiogram. The loop diameter should be about twice the minimal ductal diameter and approximate the diameter of the ampulla. A wire-guide is used to extrude the coil from the cartridge and into the proximal end of the catheter. The coil then can be advanced through the catheter using the wire-guide until the more distal end exits the end of the catheter and begins to form a loop within the circulation. In pediatric practice, it is accepted that one or more loops of the device should be deployed in the pulmonary artery. When using non-detachable coils, most veterinary cardiologists deploy the entire coil within the ampulla of the duct. Provided that the coil forms sufficient number of loops, part of the coil can be deployed in the proximal aorta and then pushed into the ampulla. When coil position appears to be appropriate, the remainder of the coil is extruded from the catheter. When a single coil substantially occludes flow, the mean and diastolic artery pressures rise shortly after deployment but a Branham response generally is not observed. After about ten minutes the ductus is again evaluated angiographically or by transesophageal echocardiography (Figure 42-19). Ideally, the duct is completely occluded during the catheterization procedure although small residual shunts may resolve weeks or months after the procedure. If a substantial shunt persists, additional coils are placed within the first coil. A technique in which a biopsy device is used for controlled release of 0.052 in coils was described and then modified for use in veterinary patients by Miller.[24,25]

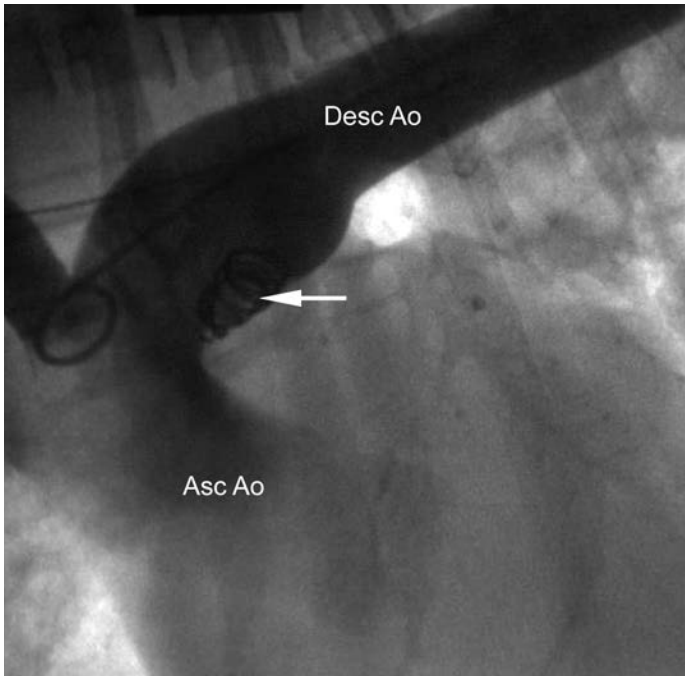

Figure 42-19. Aortogram obtained after two coils were placed in the ductus arteriosus angiographically shown in figure 42-16. A half loop of the smaller coil was deployed in the pulmonary artery. Occlusion of the ductus was nearly complete; in a subsequent frame there was minor opacification of the main pulmonary artery so additional coils were placed.

Outcome/Complications of Transcatheter Occlusion

Of cases in which the procedure is attempted, about 80% are amenable to coil placement and occlusion although this figure likely depends on echocardiographic and angiographic criteria used to select candidates.[11,26] Of patients in which coils are deployed, complete ductal occlusion during the immediate post-procedural period has been reported to occur in 34 to 100% of cases.[11,12,14,26] Specific method, patient selection and perhaps operator experience are variables that likely affect immediate occlusion rates. In general, complete, acute resolution of the shunt can be achieved in 50 to 60% of cases. Delayed ductal closure occurring in the first months after the procedure occurs in about 30% of cases in which a residual shunt is evident in the immediate post-procedural period. Although residual shunting is relatively common it is not necessarily hemodynamically important and often is clinically silent. Indeed, coil occlusion is associated with a hemodynamically satisfactory result in the vast majority of patients subject to the procedure, such that fewer than 5% of cases require a second intervention.[14,26]

The ACDO has filled an important niche in the practice of veterinary interventional cardiology. In contrast to coil occlusion, the rate of short-term occlusion is high and complications are rare. More specifically, Ngyuenba and Tobias reported the initial experience using a prototype of the ACDO.[19] Eighteen dogs with PDA were subject to cardiac catheterization and angiographic characterization of the duct. Ultimately, ACDO were successfully deployed in all patients although in one case, the device, determined afterward to be inappropriately small relative to ductal

diameter, migrated to the left main pulmonary artery. The errant device was not retrieved, adverse effects were not observed and later, during a separate procedure, an ACDO was placed without complications. Complete ductal occlusion was echocardiographically documented in 17 of 18 patients but in one, recurrent ductal patency was evident at one day and at three months after the procedure. Others subsequently confirmed the initial, encouraging results.[23] In a series of 41 canine patients with PDA, procedural success was documented in 40; the small size of one patient precluded placement of the sheath required to deploy a sufficiently large device. Complete ductal occlusion occurred within 24 hours of the procedure in all 40 patients.[19,23] Published results suggest that the ACDO is a device that can be used to successfully occlude PDA over the broad range of ductal size and morphologies. Presumably because the device firmly engages the duct and is attached to the delivery cable until the operator chooses to deploy, device embolization and other complications are rare although a single case of post-procedural device migration was recently reported.[27] Recently, patient outcomes after transcatheter occlusion by one of four different devices and techniques were retrospectively evaluated.[28] Procedural success was documented in 92% of cases but coil occlusion was associated with a greater number of complications than was placement of the ACDO. Patients were not randomized to device type and predictably, operators selected coil occlusion for the cohort for which body-size was smallest as coils can be delivered through relatively small diameter catheters.

Major complications of transcatheter intervention for PDA include intra-operative death, incomplete occlusion, post-procedural hemolysis, and device migration. Mortality associated with transcatheter intervention for PDA generally is quite low, near 2%,[14,26] although higher mortality has been reported in small studies that specifically recruited high risk patients.[29] Post-procedural hemolysis is sometimes associated with persistence of ductal flow after coil occlusion. This complication is apparently uncommon but has been reported in the pediatric literature and in dogs.[26,30]

Other Devices and Techniques

The Amplatzer® ductal occluder (ADO) is a mushroom shaped device that consists of a nitinol framework that is enmeshed with fabric; it was designed for occlusion of the human ductus. The device is extruded from a delivery sheath that is first advanced from the femoral vein, through the ductus and into the aorta. The device is pulled into the duct and released from the delivery wire. Use of this device has been reported in veterinary patients.[16,17]

The Grifka-Gianturco occlusion device consists of a nylon sac that contains Gianturco coils that are deposited in the ductus using a controlled delivery system. The use of this device in a dog has been reported in the veterinary literature.[15]

Some consideration of the relative merits of transcatheter intervention and surgical ligation is unavoidable in any discussion of the treatment of PDA. The advantages of transcatheter intervention are relatively obvious. It is a minimally invasive technique that is generally associated with low mortality. Because it is minimally invasive, morbidity and hospitalization is apt to be less than that associated with thoracotomy and surgical ligation. Certainly, ductal size and morphology are important determinants of procedural success for coil occlusion but the development of the ACDO has expanded the indications for transcatheter therapy to include PDA of diverse size and morphology. Still, patient size does have a bearing on the suitability of candidates for transcatheter intervention. A technique for transcatheter occlusion of PDA using 0.025 in coils in patients weighing less than 3 kg has been described,[13] but in general, femoral arterial access can be problematic in very small patients. To some extent, this difficulty can be overcome if a venous approach is used and indeed, this technique has been used for transcatheter coil occlusion of PDA in cats and dogs.[31,32] However, the use of venous access without concurrent arterial access may pose a risk to the patient in the event of aortic embolization. In contrast, patient-size and ductal morphology likely have a limited effect on the outcome of surgical ligation; experienced operators can successfully ligate PDA in dogs that weigh less than 0.5 kg.[33]

As discussed, there are numerous potentially serious complications of transcatheter intervention for PDA. Most of these complications do not result in patient mortality but they may require referral to a surgeon or additional catheterization procedures. While the clinical importance of hemodynamically inconsequential residual shunts has been not been defined, the prevalence of incomplete occlusion also deserves consideration in a comparison of surgical ligation and transcatheter intervention. When patients are subject to echocardiographic scrutiny after treatment of PDA, the prevalence of incomplete occlusion after surgical ligation varies but is as high as 53% when the Jackson-Henderson technique is used.[34] Furthermore, shunts that persist after coil occlusion are apt to become progressively smaller. In contrast, the mechanism of incomplete occlusion after ligation presumably relates to inadequate dissection of the periductal adventitia, an insufficiently tight ligature or loosening of knots; this being the case, late closure is not to be expected. Incomplete occlusion after placement of an ACDO is considerably less common than after coil occlusion.

Balloon Dilation of Obstructive Lesions

Pulmonic Stenosis

Etiolopathogenesis

Pulmonic (or pulmonary) stenosis (PS) refers to narrowing of the right ventricular outflow tract. PS is a common cardiac malformation in the dog but occurs infrequently in cats.[6] Acquired PS is rare and this discussion will be concerned exclusively with congenital obstruction. The obstruction of the outflow tract most often results from narrowing of the pulmonary valve although subvalvular PS and supravalvular PS are occasionally observed. Subvavular, or infundibular PS, is seldom an isolated lesion and is more often associated with complex malformations such as Tetralogy of Fallot or is the result of right ventricular hypertrophy related to valvular PS.

The cause of PS is unknown although a heritable basis has been established in beagle hounds.[35] Pedigree analyses or planned breeding studies of dogs other than beagles have not been reported. However, the disproportionate occurrence of PS in certain purebred dogs provides indirect evidence that canine PS generally has a genetic basis. The English bulldog, Samoyed, miniature schnauzer and terrier breeds are predisposed to the development of PS.[6] Interestingly, despite a proven genetic basis for pulmonary valve dysplasia in beagles, this breed is not over-represented in epidemiological surveys. PS in English bulldogs requires specific mention. In dogs of this breed, PS has been associated with concurrent coronary artery anomalies.[36] The coronary anomaly that seemingly is most common is sometimes referred to as an "R2A", and is characterized by a single right coronary ostium; the left coronary artery arises from the right main coronary artery and then encircles the infundibulum. It has been suggested that the mechanical effect of the abnormal course of the coronary artery is responsible for maldevelopment of the PV.[37] Certainly, detection of the R2A anomaly has clinical relevance because it is a contraindication for surgical patchgraft procedures and possibly a contraindication for transcatheter balloon dilation.[36,38] Minimally, detection of a circumpulmonary coronary branch requires use of a modified technique in which the diameter of the dilating balloon approximates, rather than exceeds, the diameter of the valve annulus. Recently, coronary anomalies other than the R2A have been reported which emphasizes the importance of angiographic assessment of the coronary anatomy prior to intervention.[39,40]

The pathology of PS is clinically relevant because it is an important determinant of the efficacy of therapeutic intervention. The normal pulmonary valve is a trileaflet structure. Each of the leaflets has a semilunar attachment to the interior of the proximal pulmonary artery. A true fibrous valve annulus does not exist in normal specimens but the ventriculo-arterial ring is a clinically useful landmark which is generally known as the PV annulus.[41] In the pediatric literature, PS characterized by commissural fusion of otherwise normal or mildly thick valve leaflets is known as typical PS. This form of PS is distinguished from more extensive malformation of the leaflets and annulus which is known as valvular dysplasia.[41] In cases of PV dysplasia, the leaflets are abnormally thick and mobility of the cusps is limited by rigidity and abnormal attachment to the neighboring leaflets or pulmonary artery intima. Often, the annulus of the valve is narrow and together these abnormalities serve to narrow the PV orifice. Based on echocardiographic appearance, a similar scheme for classification of canine PS has been proposed; type A PS is primarily the result of commissural fusion while type B results from narrowing of the annulus and restricted mobility of abnormal valve leaflets.[42] Post-mortem examination of beagles with hereditary PS demonstrated a continuum of lesions; some had features of typical PS while others were similar to the valvular dysplasia described in the pediatric literature. At least in beagles with heritable PS, differences in valvular morphology appear to reflect variable expression of a single disease process and therefore it may be that categories of PS are artificial. Despite this, the distinction between dogs with PS and a normal annulus from dogs with PS and annular hypoplasia is clinically useful because the two populations differ in response to transcatheter intervention.[42]

Pathophysiology

Obstruction of the outflow tract increases the impedance to ventricular ejection. In consequence, the ventricle must generate supraphysiologic systolic pressures in order to maintain perfusion pressure distal to the stenosis. As a result, there is a pressure gradient (Δ P) across the obstruction. Peak systolic Δ P that are less than 40 mmHg are generally considered to be mild and those greater than 80 or 100 mmHg, severe.[43,44] Concentric hypertrophy – an increase in myocardial mass without concomitant chamber dilation – at least temporarily offsets the increase in ventricular wall stress that results from outflow obstruction. The mechanism by which compensatory hypertrophy progresses to ventricular failure has not been resolved. Both mechanical and neuroendocrine factors likely contribute. However, the right ventricle is not geometrically suited to the development of high systolic pressures and tricuspid valve regurgitation and myocardial dysfunction are potential sequelae of severe PS.

Clinical Presentation

Canine PS is usually first detected by auscultation when pups are subject to routine veterinary evaluation. At least in young pups, a history of clinical signs related to PS is the exception rather than the rule. PS causes a systolic ejection murmur that usually is heard best over the left heart base. When PS is severe, the murmur generally is loud and typically associated with a precordial thrill. In most cases, the arterial pulse is normal. Thoracic radiographs or EKG do not provide diagnostically specific information. However, most patients with severe PS have radiographic cardiomegaly with right-sided emphasis. Often, the proximal main pulmonary artery is prominent due to development of post-stenotic aneurysm. Pulmonary hypoperfusion is often radiographically evident in patients with severe PS. Electrocardiographic evidence of right ventricular hypertrophy is commonly observed in patients with severe PS although EKG abnormalities are typically absent in patients with mild obstruction. The diagnosis can be confirmed by cardiac catheterization although echocardiography generally has replaced invasive studies for diagnostic purposes. When PS is severe, two-dimensional echocardiographic studies reveal consequences of obstruction including right ventricular hypertrophy and right atrial enlargement. Usually, the valve leaflets are abnormally thick and doming of the leaflets is sometimes observed. This latter finding, which may also be evident angiographically, reflects commissural fusion of valve leaflets and generally predicts a favorable response to balloon dilation. In healthy individuals, the annulus diameter is similar to that of the aorta but in patients with PS, varying degrees of annulus hypoplasia are relatively common. Doppler echocardiography demonstrates abnormal acceleration within the right ventricular outflow tract – a velocity step-up – which is the Doppler correlate of obstruction. Peak velocity across the obstruction is related to Δ P by the modified Bernoulli equation. Agreement between Doppler estimates of Δ P and gradients measured by catheterization is excellent but there are factors that confound the relationship. Most importantly, invasively acquired gradients are generally obtained from veterinary patients who are anesthetized. Pressure gradients depend not only on the severity of stenosis – the degree to which the cross-sectional area of the

orifice is diminished – but also on flow. Because cardiac output is decreased by anesthesia, Δ P obtained by cardiac catheterization may be as much as 50% of Δ P estimated by Doppler echocardiography in the awake or sedated patient.

Identification of Candidates for Intervention/Natural History

Little is known of the natural history of canine PS. The prognosis for children with mild PS is excellent without intervention and the same appears to be true in dogs. Canine patients in which Doppler-derived Δ P exceeds 80 mmHg are at risk of sudden death or death due to congestive heart failure; further, this risk increases incrementally in association with increasing gradient.[44] A history of exercise intolerance or collapse also predicts poor outcome in patients with severe PS.[44] The minimum gradient at which the benefit of therapeutic intervention exceeds the associated risks has not been established. Based partly on the approach adopted by pediatric cardiologists, it has become accepted that intervention is reasonable if Δ P exceeds 80 mmHg even if clinical signs are absent. Several surgical procedures for correction of PS have been described but, based on an apparently favorable risk/benefit ratio, transcatheter balloon dilation is generally recommended as the initial approach to severe PS.

Balloon Dilation

After induction of general anesthesia, access to the femoral vein or external jugular vein is obtained percutaneously or after a small skin incision. Complications of percutaneous venous access are infrequently observed and there are advantages to the percutaneous approach. The decision regarding choice of vessel is primarily one of operator preference.

It is a basic precept of catheterization technique that hemodynamic variables, including Δ P obtained by catheter pullback, are recorded before injection of contrast or attempted intervention. However in dogs, the efficacy of balloon dilation ultimately is judged by the effect on the awake, Doppler-derived Δ P not by the acute effect on measured gradients. Furthermore, in some patients with very severe PS, it can be difficult to cross the obstruction and therefore difficult to justify sacrifice of a therapeutically advantageous catheter placement for the sake of diagnostic completeness. In these difficult cases, a right ventriculogram is recorded at the outset of the procedure (Figure 42-20). Then, an end-hole catheter is fluroscopically guided to the pulmonary artery and is exchanged for a balloon dilation catheter over a long 200 to 260 cm wire guide. This catheter exchange is necessary because therapeutic balloons are carried by catheters that are too stiff to safely manipulate free in the circulation. The balloon is centered across the valve and is inflated with a mixture of saline and contrast material. The proportions of saline and contrast medium are not crucial. It is important that the inflated balloon is fluoroscopically visible but contrast material is quite viscous making rapid inflation and deflation difficult. Something less than 50% contrast material by volume likely is appropriate. The required number of inflations varies. When the dilation is successful, there is first the appearance of an indentation and then abrupt disappearance of this "waist" (Figure 42-21). During inflation, right ventricular stroke volume declines precipitously

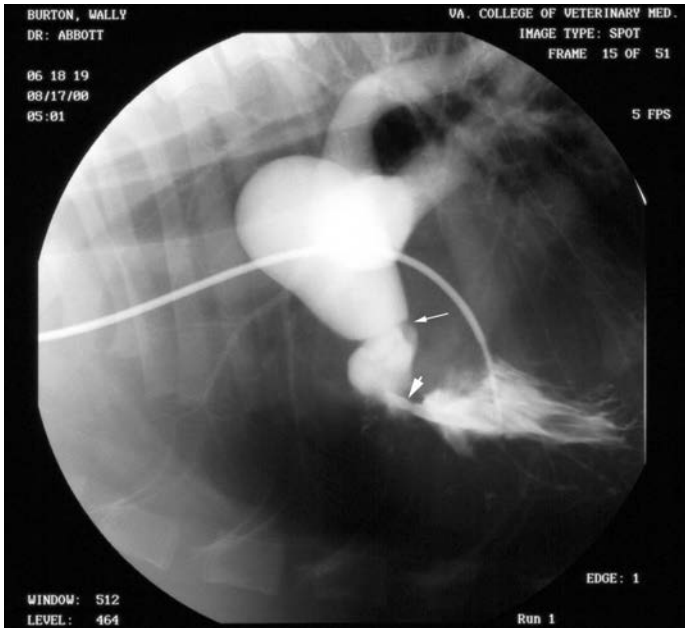

Figure 42-20. Right ventriculogram obtained after injection of contrast material into the right ventricle of a border collie with severe valvular pulmonary stenosis. The valve leaflets are thick *(arrow)* and narrowing of the infundibulum *(arrow head)* provides evidence of concurrent dynamic obstruction of the subvalvular outflow tract. There is pronounced post-stenotic dilation of the main pulmonary artery.

as does, shortly thereafter, systemic pressure and perfusion. In most cases, unassisted hemodynamic recovery occurs promptly after balloon deflation. The balloon catheter is removed over the wire guide. It is important to aspirate from the balloon port to maintain negative pressure and reduce the profile of the balloon while it is withdrawn through the heart and vessels.

Sometimes, perhaps most often in patients with dynamic, infundibular obstruction, the force of ventricular contraction causes the balloon to "pumpkin seed" through the valve orifice resulting in an ineffectual inflation. Patience and gentle tension on the catheter during inflation often will eliminate this difficulty although intravenous administration of acetylcholine immediately prior to inflation can be used to cause a brief period of ventricular asystole.

Balloon catheters are supplied by the manufacturer in numerous configurations. Generally, the balloon is constructed from a plastic polymer such as polyvinyl chloride and surrounds the distal catheter shaft. The catheter has two lumens; one that courses the length of catheter and a second that is used for inflation and deflation of the balloon. The clinically important characteristics of the catheter shaft are length, outer diameter, which is described using the French scale, and inner diameter which is measured in inches.[45] The latter property determines the diameter of guide wire which the catheter will accept. The balloon itself is described in terms of length, outer diameter, profile and material characteristics that determine burst pressure. The length of the balloon is chosen based on ventricular size which is generally related to body size. It can be difficult to maintain the position of a short balloon during inflation but overly long balloons can cause injuries including cardiac perforation and disruption of the tricuspid valve apparatus. A 3

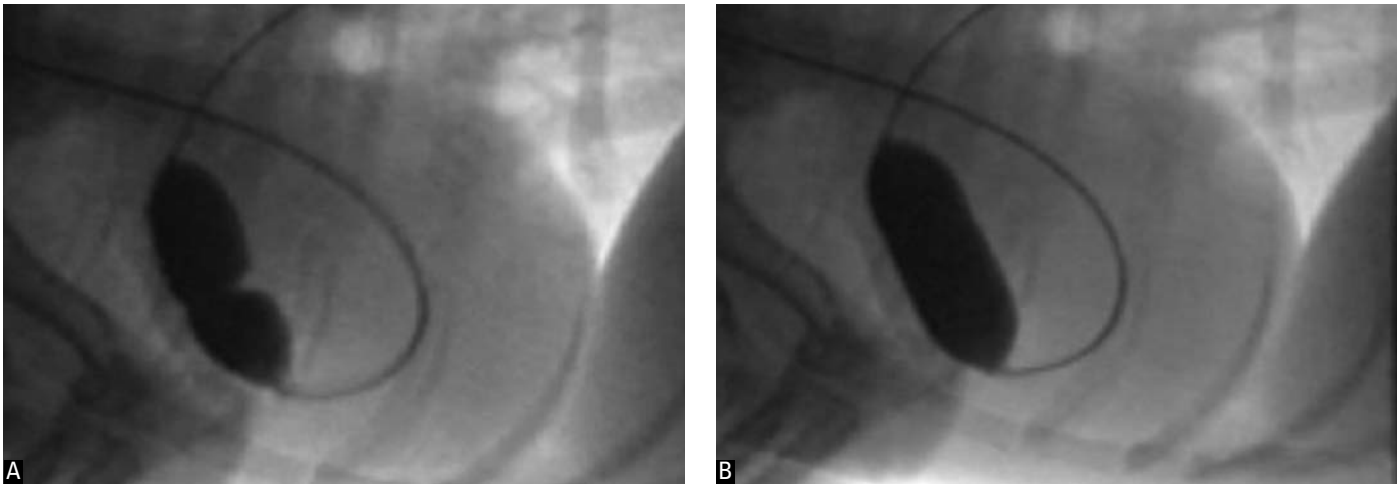

Figure 42-21. Fluoroscopic images obtained during inflation of a balloon in the right ventricular outflow tract of a patient with severe pulmonary stenosis. A "waist" was initially evident **A.** but disappeared at full inflation **B.**

cm balloon is appropriate for most canine patients. Two cm and 4 or 5 cm balloons are sometimes used for very small or very large patients. The outer diameter of the balloon is chosen based on echocardiographic or angiographic assessment of PV annulus diameter. Recommendations regarding balloon diameter have become more aggressive in the years since the introduction of the technique. A balloon diameter that is 120 to 150% of the valve annulus is believed to be optimal. Larger relative balloon sizes have been associated with cardiovascular injury in experimental models and with complications in children.[46,47] Profile is the term used to describe the increment in total catheter diameter which results from the structure of the balloon. Profile and physical characteristics that determine profile are inter-related. Balloons are best constructed of materials that exhibit low compliance and high burst pressures since this most effectively transmits radial force to the valve. However, balloons with those characteristics necessarily have a larger profile than do those with lower burst pressure. Profile is important because unnecessarily large balloons can result in intimal or valvular injury.

Advances in catheter and guide-wire construction including the development of low-profile balloons, flow directed catheters, steerable guide-wires with soft, flexible tips and tip-deflecting wires have expanded the indication for balloon dilation to include patients of virtually any size. However, balloon dilation for PS can be technically difficult in patients that weigh less than 6 or 7 kg. In small patients with tight stenosis, directing a catheter into the right ventricular outflow tract and crossing the obstruction are often the most difficult aspects of the procedure. It may be necessary to make numerous attempts with different catheters and guide-wires. Flow directed catheters often can be used to atraumatically cross a stenotic pulmonary valve. Flow-directed ("wedge") catheters are constructed of soft materials and are equipped with a small balloon near the distal catheter tip. The balloon is filled with room-air causing it to float in the circulation which carries the catheter tip in the direction of blood flow. However, marked tricuspid valve regurgitation makes it difficult to manipulate and advance these catheters. Wire-guides can be used to stiffen the catheter but sometimes this a liability in that flow-directed catheters do not generally accommodate large gauge wires. This difficulty can be circumvented by exchanging the flow-directed catheter for a thin-walled multipurpose catheter which is then, in turn exchanged for the balloon dilation catheter over a stiffer, larger gauge wire. However, this extra manipulation is time consuming and might represent a risk in a hemodynamically unstable patient. A multipurpose catheter can often be coaxed across the obstruction with or without a wire guide. In other cases, the use of specific catheter configurations such as the Judkins (right) coronary catheter or Berenstein catheter can be helpful in crossing the stenosis. Tip-deflecting wires can also be used to direct the tip of a straight catheter into the right ventricular outflow tract. Knowledge of the precise anatomical location of the catheter tip is important because tip-deflecting wires are rather stiff and cardiac perforation is a potential complication.

Results/Efficacy

The safety and efficacy of PBV in the management of PS in humans is well established. In fact, the only indication for surgical correction of isolated PS is failure of technically adequate balloon dilation to effectively decrease the associated ΔP. There are few published data that relate to the efficacy of balloon dilation in veterinary patients. Case reports and case series attest to short-term safety and efficacy of the procedure.[48-51] Recent retrospective cohort studies provide evidence that PBV is associated with a low rate of complications and generally decreases ΔP to a degree that is thought to be prognostically favorable.[42,44,52] In general, it can be stated that PBV decreases ΔP by 50% or more in roughly 75% of dogs with PS. Analysis of patient characteristics and outcome using a Cox multivariable regression model demonstrated that PBV confers a survival advantage in dogs with an initial ΔP that exceeds 80 mmHg.[44] PBV is apparently less effective in the management of canine PS than it is in the treatment of PS in people; possibly this is because of a greater prevalence of obviously dysplastic valves in affected dogs. Indeed, valve morphology is an important determinant of the efficacy of PBV in both humans and dogs. One year after PBV, the mean gradient reduction in dogs with PS normal annulus diameter was 63% while the reduction was only 39% in dogs with a small annulus and thick, immobile valve leaflets.[42] Restenosis after PBV is uncommon. In fact, the

gradient continues to decrease in the months after PBV in some dogs. Partly, this might be due to resolution of dynamic outflow gradients but it has been suggested that a progressive decrease in iatrogenic valvular edema might also be responsible.[53]

Complications

Major complications of PBV including cardiac perforation and death associated with occlusion of ventricular outflow in hemodynamically unstable patients are relatively uncommon. Death due to coronary artery avulsion was previously mentioned in the context of the r2A coronary anomaly that has been observed in brachycephalic dogs.[38] Damage to the tricuspid valve during inflation or during transit through the heart is relatively common. This complication is generally well tolerated provided balloon dilation effectively enlarges the stenotic orifice. Pulmonary valve regurgitation commonly is associated with PS and fairly often, it is worsened by balloon dilation although this seldom has clinical consequences. Arrhythmias are relatively common during manipulation of catheters through the heart but they usually are transient and resolve when the catheter is withdrawn or its position adjusted.

Balloon Dilation of Other Lesions

Subvalvular aortic stenosis (SAS) is one of the most prevalent congenital cardiac malformations in dogs. In its severe form, the lesion most often consists of a fibrous or fibrocartilaginous ring that completely encircles the subvalvular left ventricular outflow tract.[54] In a few cases, there is more diffuse subvalvular narrowing resulting in tunnel stenosis. Severely affected patients are at risk for premature death that is usually the result of sudden, presumably arrhythmic, death.[55] Balloon dilation of SAS in dogs has been reported and the technique is similar to that use in treatment of right ventricular outflow tract obstruction.[56,57] A catheter is advanced to the left ventricular apex from the external carotid or femoral artery and then exchanged over a long wire guide for a suitably sized balloon catheter. The risk of iatrogenic and clinically important aortic valve regurgitation is believed to be high and the balloon is usually chosen to approximate the diameter of the aortic annulus. Short and medium-term gradient reduction has been demonstrated but, relative to a group medically treated with atenolol, balloon dilation did not favourably affect survival.[57] This is not necessarily surprising given the nature of the lesion and the fact that successful surgical treatment failed to demonstrate a survival benefit.[58] Recently, an intervention in which the sequential use of a cutting balloon – one in which microsurgical blades are longitudinally oriented along the exterior of the balloon – and then a high-pressure balloon, has been reported but outcome data have not been published.[59]

With variable success, other less common obstructive lesions have been addressed by transcatheter dilation. Palliation of tetralogy of Fallot using transcatheter balloon dilation has been attempted the dog.[60] Both tricuspid valve stenosis and caudal caval obstruction due to cor triatriatum dexter have been treated by balloon dilation.[61-63] Additionally, balloon dilation of a mid-right ventricular outflow tract obstruction – double-chambered right ventricle – also has been reported.[64]

Surgical Correction of Persistent Right Aortic Arch

Gary W. Ellison

Incidence

Persistent right aortic arch (PRAA) accounts for an estimated 95 percent of all clinically significant vascular ring anomalies in the dog. PRAA is the fourth most common cardiovascular malformation in dogs; only patent ductus arteriosus, pulmonic stenosis, and aortic stenosis have a higher incidence. Other vascular ring anomalies that are less commonly seen include double aortic arch, aberrant right and left subclavian artery, persistent right ligamentum arteriosum and left aortic arch with an anomalous right patent ductus arteriosus.

Purebred dogs are more susceptible than mongrels to PRAA. The condition is likely heritable with German Shepherds, Irish setters and Boston Terriers having a higher incidence than the general canine population. Increased numbers of offspring with PRAA have been observed in certain family lines and were seen in related Greyhounds in a kennel. Two German shepherd littermates with left aortic arch and anomalous right sided PDA are also reported. Single or multiple recessive genes appear to be responsible for the trait and breeding of affected animals is discouraged.

In cats, the exact incidence of PRAA is unknown, but it appears to be less common than in dogs. About one half of the feline cases occur in Siamese and Persian cats, although the absolute numbers are insufficient to make conclusions on breed predisposition.

Animals with PRAA usually are diagnosed shortly after weaning with the vast majority of cases diagnosed before six months of age. Exceptions sometimes occur, however, with dogs as old as 10 years being reported. Virtually all cases of PRAA in the dog and cat involve some degree of esophageal constriction and obstruction resulting in oral or nasal regurgitation.

Surgical Embryology

Persistent right aortic arch occurs when the right fourth arch, instead of the left develops into the functional adult aorta. The right ductus arteriosus degenerates and the left ductus arteriosus remains forming a strap that constricts the esophagus between the left pulmonary artery and the anomalous right aorta. The esophagus is thus constricted by the aorta on the right, the ligamentum arteriosum (LA) on the left dorsolaterally, the pulmonary trunk on the left, and the base of the heart ventrally. Persistent left cranial vena cava occurs concurrently with PRAA about 40 percent of the time however the left cranial vena cava is not clinically significant, as it empties into the right atrium and does not act as an esophageal constricting vascular ring. Its presence may complicate surgical dissection of the LA because it passes over the pulmonary artery and limits visualization of the surgical field. PRAA is associated with concurrent patent ductus arteriosus only about 10 percent of the time. When a patent ductus is present, blood flow through the ductus is minimal and insufficient turbulence is produced to create a murmur.

Clinical Presentaion and Diagnosis

Dogs and cats affected with PRAA are often asymptomatic before weaning but regurgitation of solid food may be observed as early as four to eight weeks of age. A ravenous appetite is typically reported, but the animal usually lags behind litter mates in size and body weight. Regurgitation may occur shortly after eating or may be delayed for several hours. The regurgitated food usually is undigested, covered by mucus, and has a neutral pH. A cough may be present, indicating the presence of aspiration pneumonia.

Auscultation of the heart is usually normal; even in cases of PRAA with patent ductus arteriosus. When present, diagnosis of the patent ductus arteriosus is usually made at the time of surgery. Lung sounds can be normal or rales can be heard if aspiration pneumonia is present. Food retained in the dilated esophagus may produce a gurgling sound upon auscultation. If dilation extends up into the central esophagus, a characteristic postprandial bulge may be seen or palpated at the thoracic inlet. Simultaneous closing of the mouth and external nares while gently squeezing the abdomen may produce bulging of the cervical esophagus.

Abnormal radiographic signs seen on survey radiographs include moderate or marked focal left curvature of the trachea near the cranial border of the heart on a VD or DV view. Ventral tracheal displacement, mediastinal widening, and occasionally a right sided descending aortic shadow may be seen on the lateral view. Ventral tracheal displacement and narrowing is caused by the dilated esophagus. If only the cranial thoracic esophagus is dilated, the trachea returns to a normal position at the tracheal bifurcation over the heart base and the trachea and theheart will be displaced ventrally.

An esophagram should be performed to confirm the diagnosis. Cranial thoracic esophageal dilation is associated with an abrupt esophageal narrowing over the heart base at the fourth or fifth rib. On the ventral dorsal view, the esophagus may be displaced to the left just proximal to the esophageal constriction with an indentation into the right side of the esophagus. The presence of a poststenotic esophageal dilatation is thought to indicate a more guarded prognosis for return to normal esophageal function. Fluoroscopic swallowing studies may be used to evaluate the quality of esophageal peristalsis in the dilated esophagus both pre and postoperatively. Esophageal endoscopy can be useful in evaluating the magnitude of esophageal dilation and also ruling out other causes of constriction of the intrathoracic esophagus. Occasionally, angiography may be needed to diagnose more complex vascular ring anomalies other than PRAA.

Presurgical Considerations

Definitive treatment for PRAA involves surgical ligation and division of the ligamentum arteriosum as soon after weaning as possible. Feeding of slurries alone without relieving the esophageal constriction is not effective since the pre-stenotic esophageal dilation often enlarges with time. Animals with PRAA are often presented in a debilitated, cachectic, and dehydrated state that requires special presurgical considerations. Fluid or electrolyte imbalances should be corrected before surgery. Aspiration pneumonia, if present, compromises the patient's ability to effectively ventilate the lungs. Placement of gastric feeding tubes to establish esophageal bypass in combination with broad-spectrum antibiotic therapy may be indicated preoperatively in patients with severe aspiration pneumonia.

We use propofol for rapid intravenous induction and tracheal intubation. Immediately after induction, the patient should be assisted in its ventilatory effort. Anesthesia is maintained with inhalant anesthesia. The dilated esophagus should be evacuated with suction prior to surgery since a grossly enlarged cranial esophagus may inhibit the ability to inflate the cranial and middle lung lobes during thoracotomy.

Surgical Technique

Surgical ligation of the LA is best accomplished through a left fourth thoracotomy. The cranial lung lobe is packed caudally with moistened surgical sponges. The esophagus, aorta, main pulmonary artery, and left vagus nerve are identified. The mediastinal pleura is transected longitudinally and the vagus nerve is reflected dorsally with 2-0 silk. The LA is usually longer than normal and is often difficult to visualize within the fibrous ring. It is most easily located cranial to the recurrent laryngeal nerve. If a persistent left cranial vena cava is present, it may have a hemizygous branch that obscures the LA. This structure can be double ligated, transected and reflected ventrally. If an aberrant left or right subclavian artery is present, it can be ignored if the vessel is not compressing the esophagus. If esophageal constriction is present, the subclavian vessel may be elevated and divided between ligatures. Adequate collateral circulation will be provided by the vertebral arteries.

The LA is carefully elevated off the esophagus from its left lateral aspect. Blunt dissection of the LA is performed in a caudal to cranial direction with right-angle Mixter or Lahey forceps (Figure 42-22A). Care must be taken during dissection near the pulmonary artery, as this vessel is easily torn. When the ligament is successfully freed and isolated, two ligatures of 0 surgical silk are placed as close to the aorta and pulmonary artery respectively as possible (Figure 42-22B). The LA is then transected between the ligatures. Traction then is placed on the ligatures, and the esophagus is dissected free of any residual fibrous bands between the aorta and pulmonary artery (Figure 42-22C). A 22 French Foley catheter is then introduced through the mouth into the esophagus and passed to the esophageal constriction. Inflation of the cuff at the constriction helps visualize any residual fibrous constricting bands and facilitates their dissection and removal. Extreme care is necessary during this dissection because the esophagus is thin and easily perforated. Passage of the inflated cuff back and forth at the stricture site will help further dilate the constriction. (Figure 42-22D).

With moderate esophageal dilation, passage of food improves once the constriction is relieved. Plication or resection of a dilated esophagus only reduces redundant tissue and does not restore normal esophageal peristalsis. If severe chronic dilation is present, plication of a redundant esophagus with Lembert-type gathering sutures of 4-0 nylon or polypropylene can be attempted but is of questionable benefit. If plication is attempted, care must be taken to not penetrate the mucosa of the esophagus, as leakage around the sutures may occur and postoperative pleuritis or pyothorax may result. Hand-sewn resection of the dilated cranial esophagus is not recommended because of its thin wall and inherent tendency for leakage. For intractable regurgitation, resection of a dilated esophagus with TA55 autostapling equipment has been attempted but with only fair results. Plication or resection of a dilated esophagus only reduces redundant tissue and does not restore normal esophageal peristalsis.

After ligation and division of the LA is completed and the esophagus freed of constricting fibrous bands, a thoracostomy tube is placed and routine thoracic closure is performed. Postoperative antibiotics are continued if aspiration pneumonia is present. I use combinations of bupivacaine rib blocks, intramuscular opioids or continuous rate infusion of opioids or ketamine and injectable NSAIDS to manage postsurgical pain (See Chapter 9). Blood glucose levels are closely monitored during recovery from anesthesia particularly in small breeds of dogs.

Postoperative Feeding

Elevated feedings of small quantities of semisolid food are provided three or more times daily starting the day following surgery. Feeding of liquid diets should be avoided. The semisolid solid food usually does not pocket in the cervical esophagus and will not reflux into the trachea as easily as liquid diets if regurgitated. The animal is held upright by the owner or is fed from a stool or platform that requires the forelimbs to be elevated off the ground. Holding the patient upright while rocking it slowly back and forth may also facilitate passage of the food. Gradually, over several days, the food is increased in consistency until feeding of solid food is attempted. If regurgitation subsides, elevated feedings are continued for at least eight weeks before horizontal feedings are attempted. Some animals will resume regurgitation with horizontal feedings, requiring that vertical feedings be adopted as a lifelong procedure.

Prognosis

Morbidity and mortality associated with persistent right aortic arch that is seen in the perioperative period is usually due to aspiration pneumonia. Animals surviving the postoperative period and leaving the hospital regurgitate less frequently following surgery and demonstrate good body weight gain with time. Those that survive at least six months do particularly well. In one study of 25 dogs, 70 percent of animals followed for two to four weeks had no regurgitation; but in those animals followed for 6 months 92 percent did not regurgitate after eating. Less

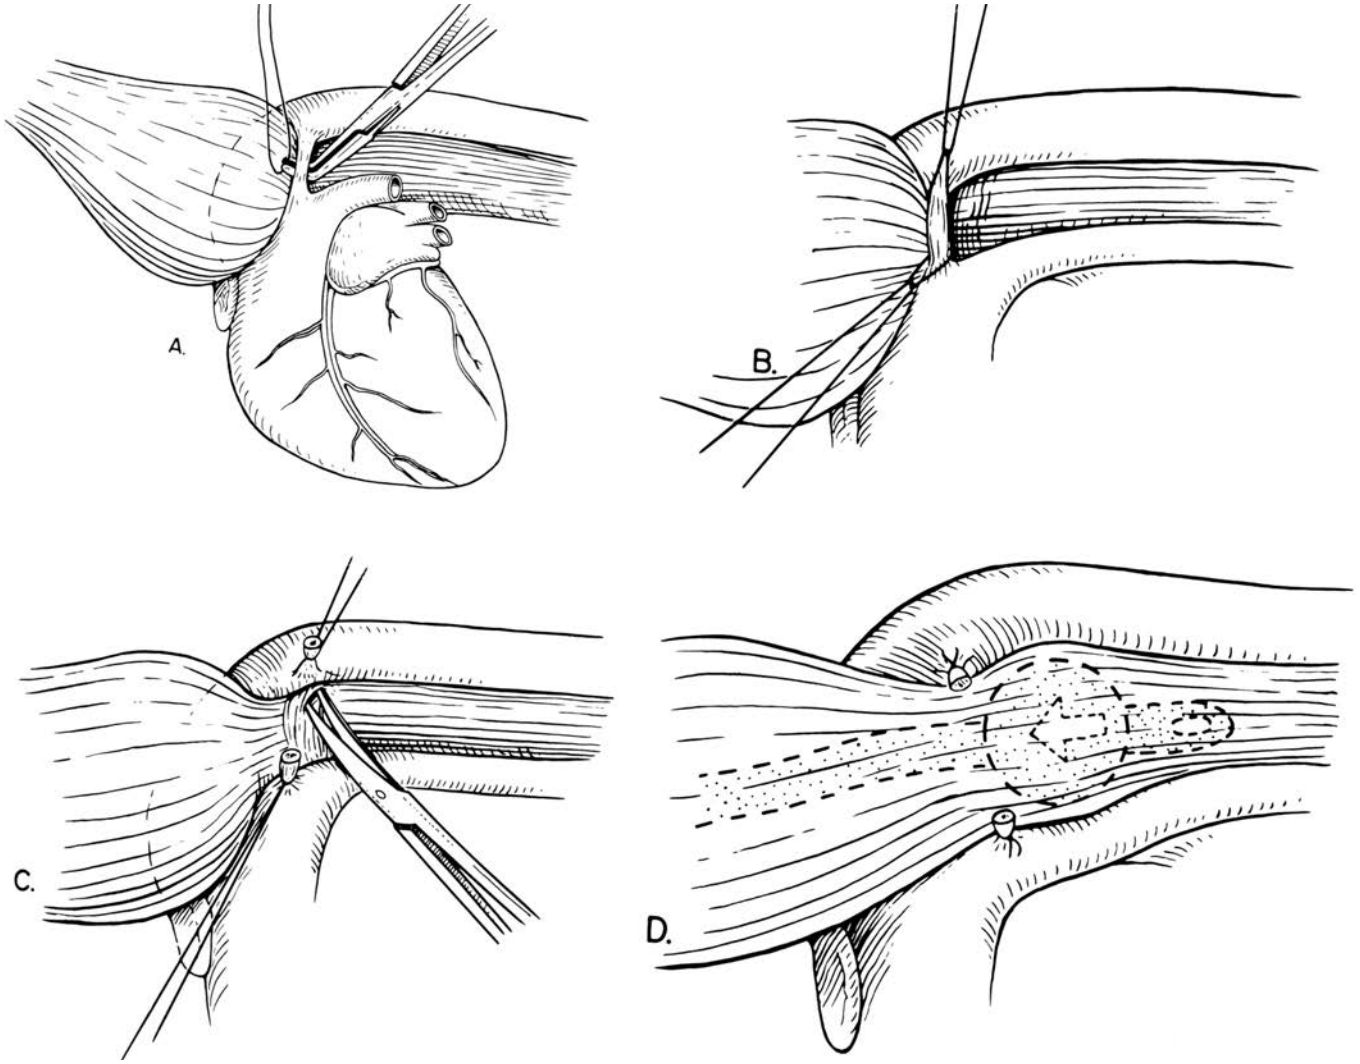

Figure 42-22. Surgical ligation and division of ligamentum arteriosum. **A.** Right-angle forceps are used to bluntly dissect around the ligamentum arteriosum and grasp 0 silk. **B.** Silk ligatures are knotted around the ligamentum arteriosum. **C.** After division of the ligamentum arteriosum remaining fibrous bands are carefully removed with Metzenbaum scissors. **D.** Use of Foley catheter to ensure that constriction has been relieved. See text for details.

than 10 percent of the cases failed to respond to surgery and were euthanized. Conversely, it is thought but not proven that dogs or cats with post-cardiac esophageal dilation tend to continue regurgitation after surgery and respond less favorably to surgery.

A contrast esophagram performed 24 to 72 hours after surgery will serve as a baseline and demonstrate adequate release of the constriction. Contrast studies performed three to four months postoperatively are recommended to evaluate the esophagus for decreasing dilation. Esophageal dilation usually decreases with time, but is not reversible. Likewise, esophageal peristalsis also usually improves with time, but never returns to normal. The exact cause of postcardial esophageal dilation associated with PRAA is unknown, but interference with the vagus nerves at the esophageal constriction may play a role in decreasing esophageal peristalsis.

At the present time, early surgical ligation and division of the ligamentum arteriosum offers patients with PRAA a reasonable long-term prognosis. Reversal of clinical signs is less likely as the age of the animal increases. In addition to surgical management, prolonged upright feeding may be required. Although some degree of esophageal dilation remains after surgery the frequency and severity of regurgitation is usually reduced over time.

Thorascopic Correction of Praa

Since the last edition of this text veterinary surgeons with an interest in minimally invasive surgery have thorascopically ligated and divided the LA in dogs with persistent right aortic arch. The reported advantages of this technique are 1) improved visualization of the LA during surgery 2) less postoperative patient discomfort, and 3) minimal intraoperative hypothermia. Disadvantages include equipment costs, technical expertise required, and the need for selective and specialized anesthesia techniques. This appears to be a promising method for surgical management of PRAA and larger clinical studies should be forthcoming.

Surgical Treatment of Pericardial Diseases and Cardiac Neoplasms

John Berg

Diseases affecting the canine pericardium can result in either pericardial effusion or pericardial constriction, both of which can be managed surgically. Antemortem diagnosis of feline pericardial disease is rare.

Anatomy and Physiology of the Pericardium

The pericardium is a fibrous sac composed of an outer fibrous layer and an inner serous layer. The serous layer is divided into the visceral pericardium (epicardium), which adheres firmly to the surface of the heart, and the parietal pericardium, which lines the interior surface of the fibrous pericardium. The pericardial cavity lies between the serous layers and normally contains a small quantity of clear fluid.

The fibrous pericardium forms a tough, thick sac that blends with the adventitia of the great vessels at the base of the heart. It is attached to the diaphragm in the xiphoid region by the sternopericardiac ligament ventrally and by pleural reflections caudally. The phrenic nerves course across the dorsal third of the pericardium on the left and right sides.

The functions of the pericardium are not completely understood, and its physiologic significance has been debated in literature. The following functions have been attributed to the pericardium: prevention of overdilation of the heart, protection of the heart from infection and from formation of adhesions to surrounding tissues, maintenance of the heart in a relatively fixed position within the chest, regulation of the interrelation between the stroke volumes of the two ventricles, and prevention of right ventricular regurgitation when ventricular diastolic pressure is increased.

Suggestions that the pericardium serves no vital functions have arisen from observations that humans and animals can live normally after pericardiectomy. Studies in animals suggest that the heart probably undergoes some minor dilation after pericardiectomy, although significant impairment of cardiac function has not been demonstrated.

Pericardial Effusion

Pathophysiology

Pericardial effusion is an abnormal accumulation of fluid within the pericardial sac. Severe pericardial effusion may result in cardiac tamponade, a potentially life-threatening compression of the heart in which intrapericardial pressure rises sufficiently to affect cardiac function. Cardiac tamponade occurs when enough pericardial fluid accumulates to exhaust the limits of pericardial elasticity. Once the pericardium can no longer stretch to accommodate additional fluid, the addition of small amounts of fluid begins to produce rapid increases in intrapericardial pressure.

Cardiac tamponade primarily affects cardiac function during diastole and has little effect on systolic function. Because intra-pericardial pressure is transmitted directly through the ventricular wall, diastolic filling pressures rise until the diastolic pressures within each ventricle are equal to one another and to intra-pericardial pressure. The right atrium and ventricle are more thin walled than the left, and are more susceptible to compression, so that signs of cardiac tamponade mimic signs of right heart failure. As predicted by the Frank-Starling law, decreased diastolic filling results in decreased myocardial stretching, force of contraction, and cardiac output.

The cardiovascular system attempts to compensate for falling cardiac output through peripheral arterial and venous vasoconstriction and increased heart rate.

However, these compensatory mechanisms may themselves stress the heart. The catecholamines responsible for vasoconstriction increase myocardial oxygen consumption, and tachycardia decreases coronary blood flow by decreasing the proportion of the cardiac cycle spent in diastole, when coronary flow occurs. Coronary flow is further compromised by low cardiac output and pressure on the coronary vessels produced by the pericardial fluid. These factors may produce myocardial ischemia and can eventually lead to cardiac decompensation.

Causes

The most common causes of pericardial effusion in the dog are neoplasia and idiopathic hemorrhagic pericardial effusion. Most

neoplastic effusions are hemorrhagic and result from acute or chronic hemorrhage from the tumor surface. Intra-pericardial cysts, pericardial effusions caused by bacterial or fungal infections, and other less common causes of pericardial effusion have also been reported.

The most common neoplastic cause of pericardial effusion is right atrial hemangiosarcoma. This tumor generally arises from the right auricular appendage, although the right atrial wall may be involved. German Shepard dogs and other large breeds are predisposed. The tumor is highly metastatic and almost always spreads to other organs such as the liver or lungs before it is discovered in the heart.

Chemodectomas arise from the aortic bodies located around the aorta at the heart base. The aortic bodies are composed of chemoreceptor tissue sensitive to blood pH, carbon dioxide content, and oxygen tension, and they are involved in the regulation of ventilation. Chemodectomas vary in their location around the aorta and in their degree of local invasiveness. The metastatic rate of this tumor is unknown. Although chemodectomas may occur in any breed, brachycephalic breeds may be predisposed, suggesting that chronic hypoxia may be an underlying cause. Anecdotally, the apparently high incidence of chemodectoma among dogs in Colorado further implicates chronic hypoxia in the pathogenesis of the tumor.

Other neoplastic causes of pericardial effusion are much less common. Malignant diseases that may metastasize to the heart or pericardium include hemangiosarcoma, lymphosarcoma, melanoma, and mammary adenocarcinoma. Mesothelioma can occasionally cause pericardial effusion, either alone or in combination with pleural or peritoneal effusion.

Idiopathic hemorrhagic pericardial effusion, a poorly understood syndrome, is also a common cause of pericardial effusion in the dog. It occurs predominately in large and giant breeds, has a distinct male predilection, and affects dogs of all ages. Patients have signs of acute or chronic cardiac tamponade, which may respond to either conservative treatment or surgical management. Although the cause of this syndrome is unknown, a similar syndrome in humans is suspected to be either viral or immune-mediated. Histologically, blood vessels of the canine parietal (and possibly visceral) pericardium appear to be the targets of the disease process and are the source of pericardial hemorrhage.

Intra-pericardial cysts are large, benign mass lesions that occasionally cause effusion and cardiac tamponade in young dogs. The cysts arise from the apex of the pericardial sac and resemble acquired cystic hematomas grossly and histologically. Although the cause of intra-pericardial cysts is unknown, it is possible that they develop from herniated omental or falciform fat in dogs born with small peritoneopericardial diaphragmatic hernias. Intra-pericardial cysts usually are diagnosed in dogs between 6 months and 3 years of age, although they occasionally are identified later in life.

Infectious pericardial effusion is reported to be caused most commonly by migrating grass awns. Many different species of bacteria have been cultured from the pericardial fluid of effected dogs. Pericardial effusion caused by infection with *Coccidioides immitus* has been reported in geographic areas, such as the southwestern United States, where the fungal agent is endemic. Young, large breed dogs are usually affected, and dogs may or may not have chronic histories of coccidioidomycosis. The pericardial disease is usually both effusive and constrictive.

Other potential causes of pericardial effusion include congenital peritoneopericardial hernias, left atrial rupture secondary to mitral insufficiency, blunt or penetrating trauma, congestive heart failure, and uremia. Pericardial effusion resulting from the latter two conditions is usually inconsequential and tends to be a postmortem finding only.

History and Clinical Signs

Dogs with cardiac tamponade are usually presented with acute or chronic histories of nonspecific signs suggestive of right-sided heart failure. These include lethargy, dyspnea, cough, abdominal distension, anorexia, weight loss, and exercise intolerance. Acute collapse with no prior signs is seen occasionally. In general, the history is not helpful in differentiating neoplastic from idiopathic hemorrhagic pericardial effusion; signs may be acute or chronic in either condition.

Several physical findings may suggest cardiac tamponade as the cause of right-sided heart failure. These include muffled heart sounds, pronounced jugular pulses and jugular distension, and weak arterial pulses. Hepatomegaly, ascites and peripheral edema may also be present. Pulsus paradoxus is an exaggerated pattern of change in arterial pressure with respiration, characterized by a weak pulse during inspiration and a stronger pulse during expiration. The sign is often present but overlooked in dogs with pericardial effusion, and may be best appreciated in dogs breathing slowly while lying in lateral recumbency.

Diagnostic Evaluation

The diagnostic evaluation of dogs with signs compatible with cardiac tamponade should be aimed at demonstrating pericardial effusion and determining its underlying cause. Pericardial effusion can be demonstrated in most cases using a combination of electrocardiography, thoracic radiography, and M-mode or 2-dimensional echocardiography. Diminished QRS voltages and electrical alternans are seen in a significant proportion of electrocardiograms. Diminished QRS amplitudes are likely caused by decreased conduction of electrical impulses through fluid media, although decreased ventricular filling may be involved. Pleural effusion as well as pericardial effusion can produce decreased QRS voltages. Electrical alternans is a beat-to-beat variation in QRS amplitude produced by a swinging motion of the heart within the pericardial sac.

Thoracic radiography demonstrates pericardial effusion if the volume of effusion is substantial. Generalized heart enlargement is seen, and the heart may have a characteristic globoid appearance, which is best demonstrated on dorsoventral views. Pleural effusion, ascites, hepatomegaly and distension of the caudal vena cava may also be present.

M-mode echocardiography is the most sensitive test available for detecting pericardial effusion and differentiating pericardial fluid from cardiomegaly and peritoneopericardial hernias. Effusions are demonstrated in approximately 90% of cases, and volumes as small as 75 ml can be detected.

Because pericardial effusions caused by neoplasia have a distinctly poorer prognosis than idiopathic hemorrhagic and other effusions, the detection of cardiac masses, particularly right atrial hemangiosarcomas, is an important part of the diagnostic evaluation. Cytologic examination of fluid obtained by pericardiocentesis (discussed later) generally does not differentiate neoplastic from idiopathic hemorrhagic effusions. In both cases, the fluid is hemorrhagic and non-clotting, and it contains predominately red blood cells, macrophages, and reactive mesothelial cells. Demonstration of neoplastic cells is extremely rare, and care must be exercised in cytologic interpretation because reactive mesothelial cells can have neoplastic characteristics. Exudative effusions are usually caused by bacterial or fungal infection; the causative organism may be visible on cytologic examination or identified by bacterial or fungal culture.

Two-dimensional echocardiography is the most sensitive test available for detecting cardiac masses and for determining preoperatively whether a mass is likely to be surgically resectable. In the hands of experienced cardiologists, echocardiography is highly sensitive and highly specific for both right atrial masses and heart base masses. Examination from both sides of the thorax allows accurate localization of cardiac masses. Because right atrial hemangiosarcomas are often small (1 to 2 cm in diameter), they occasionally escape detection. Involvement of the right atrial wall, which increases the difficulty of surgical excision, often can be detected echocardiographically. Chemodectomas often can be visualized in association with the ascending aorta. Small, discrete chemodectomas confined to the aortic area may prove resectable, whereas larger, more invasive masses are less likely to be resectable. Chemodectomas may be situated on either the right or left side of the aorta, and ultrasonography can assist in the selection of a surgical approach. Mesotheliomas have a diffuse growth pattern and usually are not detected with ultrasonography. Intrapericardial cysts are large lesions that are detected easily by echocardiography.

Routine laboratory tests may occasionally be useful in determining the cause of pericardial effusion. A complete blood count may show neutrophilia with a left shift in dogs with infectious effusions. Increased numbers of nucleated red blood cells or schistocytes are suggestive of right atrial or splenic hemangiosarcoma. Serum fungal titers are usually elevated in dogs with pericardial effusion caused by *Coccidioides immitus* infection. Marked elevations in serum levels of certain cardiac troponins, which are markers of myocardial ischemia and necrosis, may suggest that right atrial hemangiosarcoma rather than idiopathic effusion is present. Cardiac troponin assays are not routinely available to veterinarians at the current time.

Unfortunately, on rare occasions, it may be difficult to make a definitive diagnosis, and particularly to differentiate right atrial hemangiosarcoma from idiopathic hemorrhagic pericardial effusion, without exploratory thoracotomy.

Treatment

Pericardiocentesis

Indications: Pericardiocentesis is preformed for both diagnostic and therapeutic purposes. The removal of small volumes of pericardial fluid in patients with cardiac tamponade can result in rapid and dramatic decreases in intra-pericardial pressure and is often a lifesaving measure. Approximately 50% of dogs with idiopathic hemorrhagic pericardial effusion can be successfully treated by periodic pericardiocentesis, performed when necessary to relieve cardiac tamponade. Multiple pericardiocenteses, days to weeks apart, may be necessary to produce a resolution, and recurrence of pericardial effusion is reported to occur as late as 4 years after pericardiocentesis. Owners of dogs treated by pericardiocentesis alone should be made aware of the potential for sudden recurrence of cardiac tampondade. The advantages of pericardiectomy over pericardiocentesis are discussed below.

Technique: Pericardiocentesis is performed at the right third, fourth, or fifth intercostal space near the costochondral junction. Excellent descriptions of this procedure are available elsewhere.

Pericardiectomy

Indications: Pericardiectomy is used most often to treat idiopathic pericardial effusions and effusions caused by neoplasia, intrapericardial cysts, infection, and penetrating foreign bodies. Effusions caused by congestive heart failure or uremia usually are treated medically. The specific goals of pericardiectomy depend on the primary disease being treated. Pericardiectomy may be performed either by open thoracotomy or with thoracoscopy.

In pericardial effusion caused by neoplasia, the pericardium is often excised to allow surgical exploration of the heart. Pericardiectomy alone, without excision of the neoplastic mass, traditionally has been thought to be of little or no value. However, a study of dogs undergoing thorascopic partial pericardiectomy without mass excision showed that all dogs with neoplastic effusions experienced palliation of signs of cardiac tamponade. Median survival of treated dogs was only 1 month; however, some dogs survived beyond 1 year. In addition, 2 separate studies have shown that dogs with chemodectoma can have prolonged survival after open pericardiectomy alone: median survival times were greater than 2 years in both studies, and were significantly longer than survival times of dogs that did not undergo pericardiectomy. Although it seems reasonable to assume that pericardiectomy combined with excision of neoplastic masses should produce superior results to pericardiectomy alone, this has not yet been proven in controlled trials. Excision of right atrial hemangiosarcomas, chemodectomas, and intrapericardial cysts is discussed below.

Idiopathic hemorrhagic pericardial effusion can be treated successfully by creation of a pericardial window or by partial pericardiectomy below the level of phrenic nerves which allow any persistent effusion to be removed by the large absorptive area of the pleural space. Although the condition often is manageable by periodic pericardiocentesis, early pericardiectomy has some advantages. Treatment by pericardiocentesis

alone risks a sudden recurrence of life-threatening cardiac tamponade. Pericardiectomy does not entail long term risks for the patient, and, unlike pericardiocentesis, eliminates most of the tissue responsible for the effusion. Some evidence suggests that idiopathic pericardial effusion may progress to pericardial constriction, although this appears to be uncommon; surgery is technically simpler, and is associated with a better prognosis, for pericardial effusion than for pericardial constriction. Finally, early surgical exploration may allow identification of small tumors that were not revealed by echocardiography, and may offer the best chance for their removal.

The indications for open versus thorascopic pericardiectomy are not firmly established. Advantages of thoracotomy include its wide availability, the ability to more thoroughly explore the thorax, and its potential to permit resection of neoplastic mass lesions. The major advantages of thorascopic pericardiectomy are reduced postoperative pain and morbidity, and a more rapid recovery time. In thorascopic pericaridectomy, a small pericardial window is usually created, whereas with thoracotomy, partial pericardiectomy below the level of the phrenic nerves may be performed. Traditionally, creation of a pericardial window has been thought to be associated with a risk that residual pericardium would adhere to the surface of the heart, resulting in recurrent pericardial effusion. Early experience with thorascopic pericardiectomy and with percutaneous balloon pericardiotomy suggests that the risk of this complication is quite low. Minimally invasive approaches are most often indicated when there is a high index of suspicion that the effusion is idiopathic, eg. in dogs with no echocardiographic evidence of a cardiac mass who have developed recurrent effusion months after pericardiocentesis. Small masses involving the tip of the right auricular appendage may be removed with minimally invasive techniques. Thoracotomy should be chosen for resection of auricular masses not deemed amenable to minimally invasive surgery, and for heart base masses. In circumstances other than these, the choice between thorascopic and open pericardiectomy is a matter of the surgeon's and owner's preferences. The technique for thorascopic pericardiectomy is discussed elsewhere.

Surgical approach: When the cause of pericardial effusion is unknown, either a right fifth intercostal thoracotomy or a median sternotomy may be performed. Excision of right atrial tumors may be accomplished with similar ease through either approach. For the majority of dogs with idiopathic effusions, a right sided approach, followed by creation of a pericardial window and inspection of the right atrial appendage to rule out hemangiosarcoma, is a reasonable approach. When partial pericardiectomy below the level of the phrenic nerves is deemed necessary, either a median sternotomy or an intercostal approach may be used. Subtotal pericardiectomy is somewhat easier to perform through a median sternotomy, because an intercostal approach does not permit good visualization of the opposite side of the thorax. In addition, if an intercostal approach is used, the heart must be elevated as the far side of the pericardial sac is excised, a maneuver that temporarily impairs venous return. Chemodectomas are approached through either a right or left fourth intercostal thoracotomy, depending on the location of the tumor as determined by ultrasonography. Intrapericardial cysts are best approached through a median sternotomy, which facilitates subtotal pericardiectomy and allows inspection of the diaphragm for a peritoneopericardial hernia.

Technique: Once the thoracotomy is completed, the phrenic and vagus nerves are identified. The phrenic nerve may be isolated and gently retracted with a Penrose drain, although retraction of the nerve usually is unnecessary. The vagus nerve is located more dorsally and is unlikely to be damaged during pericardiectomy. To create a pericardial window, a controlled stab incision is made in the pericardium ventral to the phrenic nerve with a scalpel blade, and pericardial fluid is removed by suction. The incision is then extended with Metzenbaum scissors or electrocautery to create a window several centimeters in diameter ventral to the phrenic nerve. The right atrial appendage is inspected to rule out the presence of a right atrial mass by carefully retracting the cranial and dorsal edges of the window. If partial pericardiectomy below the level of the phrenic nerves is to be performed, the initial incision is continued cranially and caudally until it is completed circumferentially (Figures 42-23 and 4-24). If an intercostal approach has been used, completion of the pericardiectomy on the left side requires elevation of the heart. An assistant should cradle the patient's heart in one hand and gently rotate the apex of the heart laterally and dorsally to permit incision of the pericardium below the level of the left phrenic nerve. Because elevation of the heart impairs venous return, this maneuver should be performed as quickly as possible. Diseased pericardia are often thickened and extremely vascular, and care must be taken to limit hemorrhage with electrocautery. Once the sternopericardiac ligament is divided, either with electrocautery or between ligatures, the pericardial sac can be removed and submitted for histopathology. A thoracostomy tube is placed before closure, and postoperative management generally is uncomplicated. The thoracostomy tube may be removed after 12 hours if it is unproductive.

For dogs with bacterial pericardial effusion, long-term antibiotics, selected on the basis of culture and sensitively testing, should be administered postoperatively. The prognosis for these dogs is generally excellent.

Figure 42-23. A highly vascular pericardial sac as viewed through a right intercostal thoracotomy in a dog with idiopathic hemorrhagic pericardial effusion.

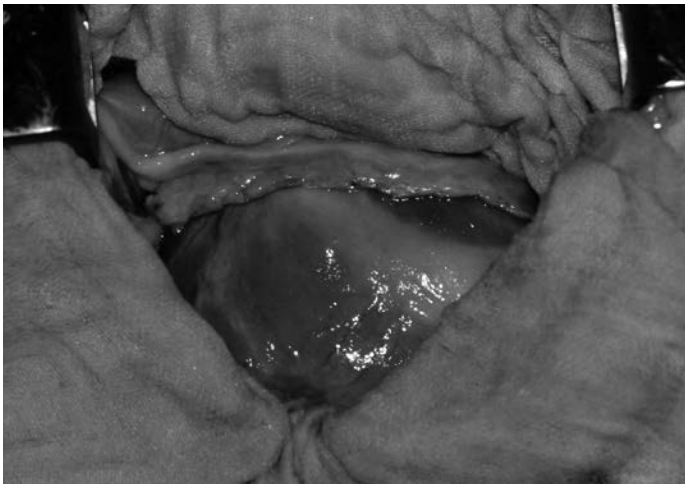

Figure 42-24. Appearance of the pericardial sac shown in figure 42-23 following partial pericardiectomy below the level of the phrenic nerves.

Excision of Intrapericardial Cysts

Intrapericardial cysts are usually located at the apex of the pericardial sac and can be excised readily by routine subtotal pericardiectomy (Figure 42-25). If the patient has an associated peritoneopericardial hernia, the edges of the hernia are incised, and the defect is closed with a row of simple continuous sutures.

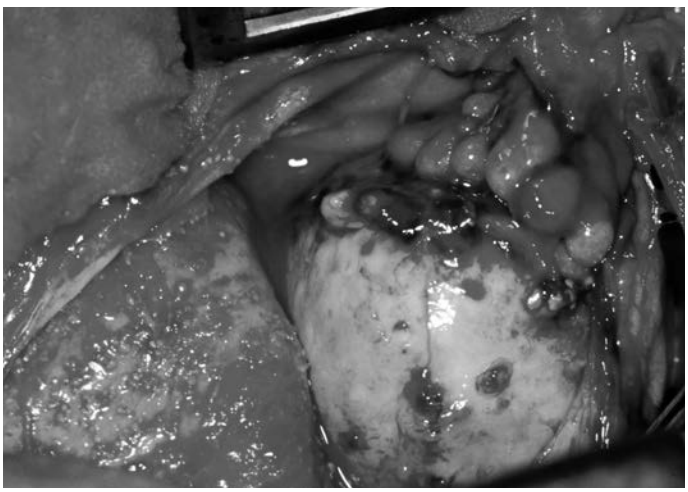

Figure 42-25. An intrapericardial cyst (right) adjacent to the apex of the heart (left).

Excision of Right Atrial Hemangiosarcoma

Indications: Excision of right atrial hemangiosarcomas should be considered palliative, because the tumor almost invariably metastasizes prior to detection. The goal of surgery is to prevent a recurrence of cardiac tamponade. Many hemangiosarcomas are confined to the right auricular appendage, and are therefore amenable to surgical excision as described below. Inflow occlusion or cardiopulmonary bypass are required to excise tumors with significant right atrial wall involvement.

Technique: After median sternotomy or right fifth intercostal thoracotomy, an incision is made in the pericardial sac approximately 1 cm below and parallel to the phrenic nerve. The pericardial incision is extended cranially and caudally as far as necessary with Metzenbaum scissors or electrocautery to fully expose the auricular appendage. Exposure may be improved by using stay sutures or Babcock forceps to retract the incised edges of the pericardial sac.

Figure 42-26. A right atrial hemangiosarcoma as viewed through a right intercostal thoracotomy.

Either conventional suturing or surgical stapling equipment may be used to remove right atrial masses. If conventional suturing is elected, a tangential vascular clamp is placed across the base of the auricular appendage. The appendage is transected immediately distal to the clamp, leaving a cuff of auricular tissue. The margin of the excised tumor should be inspected to ensure that excision was complete; if possible, at least 1 cm of normal auricular tissue should be removed with the tumor. The auricle is then oversewn with two rows of simple continuous sutures, with rows oriented perpendicularly to each other (Figures 42-26 and 42-27). 3-0 or 4-0 polypropylene suture on a tapered needle may be used.

Surgical stapling is faster and less technically demanding than hand suturing. A 55 mm thoracoabdominal stapler is used, with 3.5 mm staples (Kendall-Tyco Corp, Norwalk, CT). The stapler

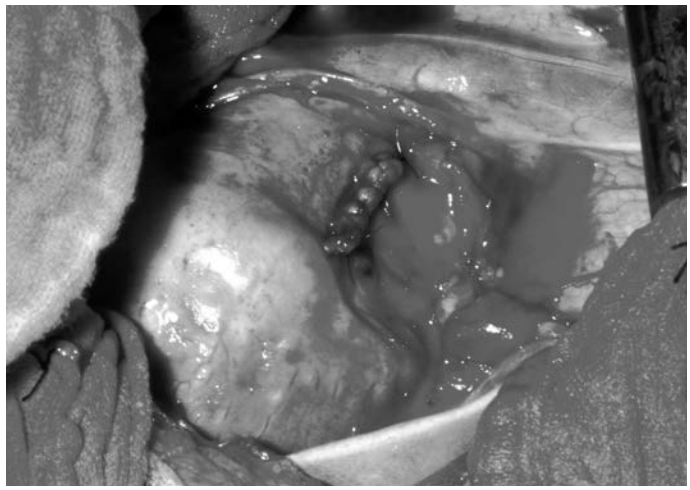

Figure 42-27. Appearance of the auricular appendage shown in figure 42-25 following excision of the mass and oversewing of the auricular incision.

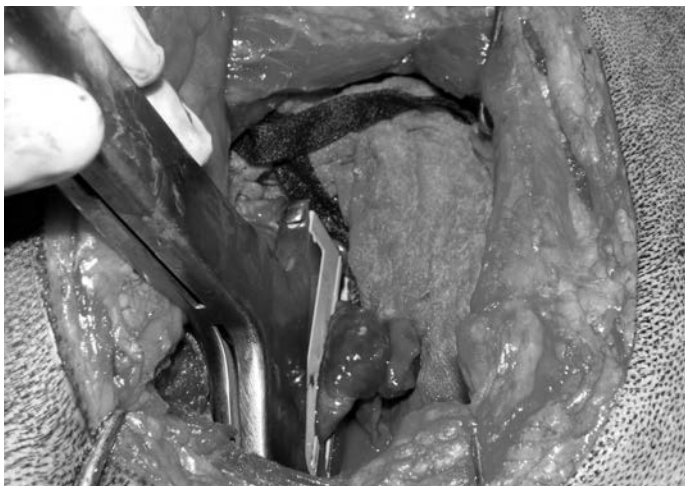

Figure 42-28. Use of a surgical stapler to excise a hemangiosarcoma of the right auricular appendage.

should be positioned to provide a 1 cm resection margin (Figure 42-28). If there is room, a tangential vascular or other noncrushing clamp should be placed across the base of the auricle before releasing the stapler; the clamp should be slowly released as the staple line is inspected for bleeding. If necessary, the staple line may be oversewn with a layer of simple continuous suture. After tumor excision, a partial pericardiectomy should be performed.

Prognosis: Because right atrial hemangiosarcoma is a highly metastatic tumor, surgical excision is purely palliative. Mean survival time after surgery is reported to be approximately 4 months. Euthanasia is performed in most affected dogs because of distant metastases, usually to the liver or lungs, within a few months of surgery. Unfortunately, no compelling evidence yet exists to suggest that survival times in dogs with either splenic or right atrial hemangiosarcoma can be significantly prolonged with adjuvant chemotherapy, and prospective controlled clinical trials are needed.

Excision of Chemodectomas

Because of the difficult location of chemodectomas, their highly vascular nature, and the excellent survival times reported following pericardiectomy alone, pericardiectomy without tumor excision should be considered a viable alternative to tumor excision for this disease.

Technique: Control of hemorrhage is the major difficulty encountered during attempts at tumor excision. Because of their location, chemodectomas must be marginally excised at the gross limits of the tumor; wide margins are impossible to provide. Excision is best accomplished by slow, meticulous, sharp dissection with the help of electrocoagulation. Care must be taken to avoid perforating the aorta or pulmonary artery; cotton-tipped swabs are useful for slowly dissecting the tumor away from these structures. Before closure, the tumor bed should be closely inspected, and residual points of hemorrhage should be controlled with precise electrocoagulation.

Prognosis: Chemodectomas seem to be slow-growing tumors, and limited experience suggests that dogs undergoing excision of small chemodectomas can have prolonged survival postoperatively. Whether surgical excision improves survival beyond that associated with pericardiectomy alone is unknown. Studies investigating the efficacy of chemotherapy or radiation therapy have not yet been reported.

Pericardical Constriction

Pathophysiology and Causes

As in cardiac tamponade resulting from pericardial effusion, pericardial constriction restricts diastolic volume. Diastolic filling is limited by the fibrotic pericardium, which acts as a noncompliant shell around the heart.

Pericardial constriction in dogs usually is idiopathic. Like idiopathic hemorrhagic pericardial effusion, the condition occurs predominately in medium-size and large breeds, although no evidence of male sex predilection exists. Some evidence based on isolated case reports indicates that idiopathic hemorrhagic pericardial effusion can progress to pericardial constriction, although this seems uncommon. Whether idiopathic pericardial constriction and idiopathic hemorrhagic effusion are different manifestations of the same syndrome, or are separate disease entities, is unknown.

Dogs with pericardial disease caused by *Coccidioides immitus* infection most commonly have a combination of effusive and constrictive pericarditis. This condition should be considered in any dog with pericardial disease in geographic regions where the fungus is endemic.

History, Clinical Signs, and Diagnosis

Dogs with constrictive pericardial disease are usually presented with signs of chronic right-sided heart failure. Abdominal distension, dyspnea, weakness or syncope, exercise intolerance, and weight loss are common signs. Typical physical examination findings are ascites, jugular distension, and weak arterial pulses. Poorly auscultable heart sounds are also common. A "pericardial knock," produced as blood is rapidly compressed against the rigid ventricular wall, may be heard on auscultation. Approximately half of dogs with pericardial effusion-constriction caused by *C immitus* infection have chronic histories of coccidioidomycosis, producing signs such as lameness, dermatopathy, and uveitis.

Definitive diagnosis of pericardial constriction may require surgical exploration, although a presumptive diagnosis can often be made preoperatively based on a combination of physical, electrocardiographic, imaging, and hemodynamic findings. One or more abnormalities may be present on electrocardiographic examination. Decreased QRS amplitudes and increased P-wave duration are the most common findings. Radiographs may reveal free pleural fluid and mild to moderate cardiomegaly. Echocardiographic findings that support the diagnosis include decreased end-diastolic diameter, decreased fractional shortening, flattening of left ventricular free-wall motion during late diastole, and rapid premature diastolic closure of the mitral valve. Dogs with pericardial effusion-constriction caused by *Coccidioides immitus* infection usually have elevated serum

titers for antibodies against the organism. In general, a diagnosis of pericardial constriction should be considered in dogs with signs of right-sided heart failure that cannot be explained by pericardial effusion, congenital or acquired heart disease, or pulmonary hypertension. Surgical exploration should be performed if the condition is suspected.

Subtotal Pericardiectomy for Pericardial Constriction

Technique: Because significant epicardial fibrosis usually is not present in dogs with idiopathic pericardial constriction, most dogs can be treated successfully by subtotal pericardiectomy, as previously described. Median sternotomy is the preferred approach because it allows visualization and division of any epicardial adhesions that may be present. In dogs with significant epicardial fibrosis, epicardial decortication may be necessary. This is a difficult procedure that may require partial removal of myocardial tissue. Caution is necessary to avoid inadvertent damage to coronary vessels. Epicardial decortication is associated with significant perioperative morbidity and mortality.

In dogs with effusion-constriction caused by *C immitus* infection, extensive mature adhesions to the epicardial surface of the heart are likely to be present, and pericardiectomy may be significantly complicated by hemorrhage. Adhesions may be disrupted manually and by careful instrument dissection. Strips of pericardium overlying the coronary vessels may be left in place if there are firm adhesions to the vessels. If fibrosed, the epicardium may be removed from areas distant from the coronary vessels, using scissors or a periosteal elevator to carefully lift the epicardium from the myocardium. The perioperative mortality rate in a series of dogs with *C immitus* pericarditis undergoing partial pericardiectomy was 23.5%, and among dogs that were discharged from the hospital, the 2 year survival rate was 82%.

Chapter 43

Lymphatics and Lymph Nodes

Management of Chylothorax

MaryAnn Radlinsky

Etiology

Chyle is a fluid made up of lymph and chylomicrons absorbed by the intestinal lacteals; as a result of digestion, the fluid is high in triglycerides. Chylothorax refers to the accumulation of chyle in the pleural space. Normally, chyle is returned to the systemic circulation by the thoracic duct, which is the continuation of the cisterna chyli. The cisterna chyli receives lymph from the abdominal organs and the pelvic limbs and lies in the dorsal retroperitoneal space adjacent to the aorta and left kidney. The thoracic duct variably consists of many branches lying dorsal to the thoracic aorta and ventral to the azygous vein on the right side of the thorax in the dog. The duct crosses to the left side in the mediastinum at the level of the fifth or sixth thoracic vertebra. The lymphaticovenous junction is associated with the left external jugular vein, its junction with the cranial vena cava, or the jugulosubclavian angle.[1] Chylothorax occurs when the flow of chyle is increased (*e.g.* increased hepatic production of lymph) or when entrance of chyle into the venous system is impeded (*e.g.* increased venous pressures or obstruction of the lymphaticovenous junction). Any process that increases the cranial vena caval hydrostatic pressure or causes complete or relative obstruction of the lymphaticovenous junction predisposes an animal to chylothorax.[2]

Increased systemic hydrostatic pressure may be secondary to cardiac disease or abnormalities of the cranial vena cava. Many disease processes associated with either right heart failure or conditions associated with compression or obstruction of the vena cava, lymphaticovenous junction, or thoracic duct have been reported to cause chylothorax (Table 43-1). Cardiac diseases associated with increased venous pressure cause an increase in lymph production secondary to hepatic congestion and thereby increase the flow of lymph in the thoracic duct.[3,4] Concurrent, increased venous pressure diminishes flow through the lymphaticovenous junction (relative obstruction). Both processes cause the accumulation of chyle within the pleural space. Direct or indirect trauma to the thoracic duct has been associated with the development of small amounts of chylous effusion within the pleural space.[5] The thoracic duct heals rapidly with linear or transverse trauma or iatrogenic trauma, and the pleural effusion should be short-lived (1 to 2 weeks) with no specific therapy required for resolution.[6]

Although many disease conditions have been associated with chylous effusion, the most common cause of chylothorax is idiopathic. Abnormal lymphatic flow or pressure within the thoracic duct is thought to lead to thoracic lymphangiectasia. Lymph leaks from the dilated, tortuous branches of the thoracic duct, which are most evident in the cranial thorax.[7] The pulmonary lymphatics may also play a role in cases of idiopathic chylothorax that fail to respond to therapy.[8] All potential underlying disease processes (Table 43-1) must be ruled out prior to diagnosing the disease as idiopathic, as failure to diagnose an underlying condition will deny the patient definitive therapy.

Table 43-1. Conditions Associated with Chylothorax in Dogs and Cats

Cardiomyopathy
Mediastinal neoplasia (Lymphosarcoma, thymoma)
Trauma
Cranial vena cava thrombosis
Fungal infection, granuloma
Dirofilariasis
Congenital anomaly (tetralogy of Fallot, cor triatriatum dexter, tricuspid dysplasia, thoracic duct anomaly)
Pericardial effusion, constrictive pericarditis
Heart base tumor
Diaphragmatic hernia
Hyperthyroidism
Lymphangioleiomyomatosis

Diagnosis

History and Physical Examination

Any breed of dog or cat of any age may develop chylothorax. The Afghan hound, Shiba Inu, Siamese, and Himalayan breeds may have an increased prevalence of the disease. Afghan hounds tended to develop the disease in middle age; young Shiba Inus, and older cats were more often affected. Both males and females developed the condition equally.[4]

The presence of pleural effusion usually results in ventilatory compromise. The volume and rapidity of fluid accumulation determine the signs present. Chylothorax may result in no significant signs until the patient becomes dyspneic. Coughing may be the first and only sign associated with chylothorax, and occasionally chylothorax is an incidental finding. The etiology of cough with chylothorax may be related to the primary problem (e.g. heart failure, neoplasia) or may be due to inflammation caused by the presence of chyle within the pleural space. The history of chronic chylothorax often includes depression, exercise intolerance, inappetance, and weight loss. If an underlying disease exists, the history may be representative of that condition.

Tachypnea or dyspnea with rapid, shallow ventilation, or a restrictive ventilatory pattern, and decreased pulmonary and cardiac sounds on auscultation are usually present in cases of pleural effusion. Cats may demonstrate a "breath holding" type of breathing pattern in which forceful inspiration is followed by delayed exhalation.[9] Lung sounds may be present with increased bronchovesicular sounds dorsally. Chylothorax is rarely unilateral. Other findings include thin body condition, pallor, arrhythmias, cardiac murmurs, or other signs associated with a primary disease. Animals with cranial mediastinal mass

lesions or thrombosis may exhibit cranial vena cava syndrome (i.e. edema of the head, neck, and forelimbs with jugular venous distention).

Diagnostic Imaging

Radiographic evaluation of the dyspneic patient is not advised in a significantly compromised patient. Oxygen supplementation, minimal handling, and dorsoventral and horizontal beam imaging rather than lateral and ventrodorsal views may decrease the stress of imaging. The index of suspicion for fluid in the pleural space must be considered prior to imaging, as therapeutic thoracocentesis can decrease the risk associated with imaging in these patients. Radiographic signs of pleural fluid include effacement of the cardiac and diaphragmatic silhouettes, retraction of the lung borders from the thoracic wall, "scalloping" of the lung edges, pleural fissure lines, rounding of the lungs, widening of the mediastinum, and obscuring of the other intrathoracic structures.[10] The presence of a large amount of fluid decreases the ability to diagnose cardiac, pulmonary, or mediastinal masses and hilar lymphadenopathy. Radiographs should be remade after removal of the thoracic effusion to increase the diagnostic efficacy of thoracic radiographs.

Failure of pulmonary expansion after therapeutic thoracocentesis should alert the clinician to the possibility of fibrosing pleuritis or pulmonary parenchymal disease such as persistent atelectasis, pulmonary neoplasia, or lung lobe torsion. Animals with fibrosing pleuritis often remain dyspneic, despite removal of pleural effusion and confirmation of minimal fluid on thoracic radiographs. Fibrosis of the visceral pleura is thought to be related to the chronic presence of chylous effusion and an alteration in mesothelial cell function, leading to an imbalance in fibrin production and degradation.

Air in the lungs will reflect sound and decrease the generation of ultrasonographic images of intrathoracic structures. Therefore, ultrasound examination of the thorax should be performed prior to removal of all pleural fluid, as the fluid will provide an acoustic window for imaging the mediastinum. Ultrasonography is also used to evaluate cardiac structure and function and to diagnose whether pericardial effusion is present.

Computed tomography (CT) and magnetic resonance imaging (MRI) have been used with success for thoracic evaluation in dogs. Normal anatomic structure has been reported, and CT has been used to evaluate questionable pulmonary and non-pulmonary conditions identified radiographically. Questionable radiographic and ultrasonographic findings should be evaluated with CT to localize and determine the extent of the abnormality. CT has also been used to guide fine needle aspirates (FNA) and percutaneous biopsies of pulmonary and nonpulmonary mass lesions. The complication rate associated with FNA or transcutaneuos biopsy with CT guidance was 43% in one study, and the diagnostic accuracy was 65% for FNA and 83% for biopsy. The main disadvantage of CT and MRI is the need for and risk of general anesthesia in compromised patients. CT and MRI are becoming more available to practitioners, but the cost benefit ratio must be considered prior to their use.

Laboratory Findings

Thoracocentesis with fluid analysis is imperative in every case of pleural effusion. Fluid should be placed in an ethylenediaminetetraacetic acid (EDTA) tube for cell counts and cytological examination. Fluid should also be saved in a serum tube (*i.e.* "clot tube") for biochemical analysis and aerobic and anaerobic culture. Chylous effusion is grossly opaque white or white with a red or pink tinge (Table 43-2).[11,12] The fluid is high in lipid, which may interfere with refractometric quantification of protein. The total nucleated cell count is usually less than 10,000/µL, consisting mainly of small lymphocytes.[4] Lower numbers of macrophages may be present and filled with lipid. With chronicity, lymphocytes may be depleted due to decreased production in the face of continued cell loss to the effusion, nondegenerate neutrophils then become the primary cell type in the effusion. Neutrophils may also be the primary cell type in patients that have undergone multiple thoracocentesis, which may induce pleural inflammation. If the repeated aspirates of pleural fluid result in secondary bacterial colonization and sepsis, degenerate neutrophils appear in the fluid.

Table 43-2. Characterization of Chylous Pleural Fluid in Dogs and Cats

	Dogs	Cats
Specific gravity	1.022-1.037	1.019-1.038
Total Protein (g/dl)	2.5-6.2	3.5-7.8
Average nucleated cells/µL	6,127	11,919

The definitive diagnosis of chylous effusion relies on biochemical testing of the pleural fluid and serum. With chylothorax, triglyceride content of the pleural fluid is higher than that of the serum and cholesterol levels in the pleural fluid is less than that in the serum. Other tests, (*e.g.* ether clearance and Sudan staining for fat) may also be used to diagnose chylous effusion. Concurrent aerobic and anaerobic culture of the fluid are recommended. Psuedochylous effusion, opaque, white fluid devoid of chyle, has been associated with tuberculosis and rheumatoid pleurisy in man but has not been identified in dogs or cats.

Complete blood count, biochemical profile analysis, and urinalysis should be done and may aid in the identification of a primary cause of chylothorax. They may also be useful in monitoring for lymphopenia, hyponatremia, and hyperkalemia, which have been associated with repeated thoracocentesis in the medical management of the condition.[13] Significant protein and fluid loss due to chronic chylous effusion may also be reflected in the patient's biochemical profile and urinalysis. Feline leukemia virus (FeLV), Feline immunodeficiency virus (FIV), and heartworm tests are also recommended to rule out primary disease processes.

Differential Diagnoses

Other causes of cough should be included in the initial differential list if cough is present; however, pleural effusion should be identified early in the evaluation of the patient with chylothorax. Other types of pleural effusion (*e.g.* hemorrhage, transudate, exudate) are ruled out upon fluid analysis. Chylous effusion

may be classified as either a modified transudate or exudate, depending on the reference used to characterize pleural fluid types (See Table 43-2). Primary disease processes that cause chylothorax (See Table 43-1) should be ruled out by diagnostic evaluation including thoracic radiography and ultrasound examination, echocardiography, CBC, biochemical analysis, urinalysis, FeLV, FIV, and heartworm testing, and abdominal radiography and ultrasound. If primary disease conditions are eliminated, the diagnosis of idiopathic chylothorax, which is the most common form of chylothorax, is made.

Medical Management

Any primary condition associated with secondary chylothorax should be treated or the effusion may persist. Treatment of the underlying condition may not, however, guarantee diminution of chyle. Resolution may also take time (*e.g.* months), depending on the primary condition. While treating the primary condition, the accumulation of chyle within the pleural space may be managed with intermittent thoracocentesis as dictated by clinical signs (*e.g.* dyspnea associated with a restrictive breathing pattern). Fluid balance and electrolytes should be monitored for significant alterations secondary to repeated thoracocentesis (described in laboratory findings) and is of more concern in patients requiring frequent fluid removal.[13] Fat soluble vitamins should be added to the diet of patients undergoing prolonged medical management of chylothorax due to the continued loss into the pleural space.[3] Recurrent thoracocentesis may also result in secondary bacterial infection of the fluid, despite the high lecithin content, which is thought to have a bacteriostatic effect.[9] Immunodeficiency has also been hypothesized with the removal of protein and cells by repeated thoracocentesis.

Concurrent dietary changes may alter the fat content of the effusion and improve fluid absorption from the pleural space, thereby decreasing the frequency of thoracocentesis. Low fat diets are therefore recommended in the treatment of idiopathic chylothorax. The fat content of commercially available low fat diets is approximately 6%.[4] Medium chain triglyceride supplementation may not result in improved nutritional status; they may not be directly absorbed into the intestinal venous system as previously hypothesized. Dietary management and fluid removal rarely result in resolution of cases of spontaneous, idiopathic chylothorax.

The addition of different medications has been attempted in an effort to increase the rate of resolution of idiopathic chylothorax. Benzopyrones are compounds extracted from the Brazilian Fava D'anto tree.[14] They have been used to treat lymphedema in people and have been used to treat idiopathic chylothorax in dogs and cats. Their action may decrease vascular leakage, increase protein lysis and absorption, stimulate macrophage function, and increase tissue macrophage numbers. Rutin, a benzopyrone agent (Rutin, Nature's Plus, Melville, NY), resulted in improvement in two of four cats treated, and has been reportedly associated with resolution of the disease in two other case reports.[14-16] The empiric dose of rutin ranges from 50 to 100 mg/kg PO q 8 h.[14] A large clinical trial of its use in dogs and cats with idiopathic chylothorax has not yet been reported, but it is commonly used as part of the medical treatment of chylothorax.

Octreotide (Sandostatin®, Novartis Pharma B.V., Arnhem, the Netherlands) is an experimental agent for the treatment of idiopathic chylothorax. The somatostatin analog has been used to treat chylothorax in people and was associated with a more rapid decline in the amount of pleural chyle following experimental transection of the thoracic duct in dogs.[17] The response to octreotide may be due to inhibition of pancreatic, biliary, and gastric secretions, decreased gastric blood flow, decreased intestinal transit time, and constriction of lymphatic vessels.[17,18] A small therapeutic trial of 10 mg/kg SC q 8 h therapy for 10 to 28 days resulted in resolution of signs in two of three cats. Neither of two dogs treated with octreotide showed a response to therapy.[18] Side effects occurred in two patients and consisted of diarrhea and loose stools.[18] The response of dogs and cats to octreotide has not been investigated investigated in a clinical trial.

Corticosteroid treatment to combat fibrosing pleuritis and furosemide administration to decrease chylous effusion have not been evaluated. Furosemide has not been shown to alter the accumulation of chyle in the pleural space. Its use could result in further fluid loss and dehydration, so it is not recommended for treating chylothorax. Likewise, corticosteroids have not been shown to have any beneficial effect in the treatment of chylothorax, and their use should be reserved for underlying conditions requiring corticosteroid therapy.

It is, however, important to monitor any patient undergoing prolonged medical management for the occurrence of fibrosing pleuritis. Chronic exposure of mesothelial cells to chyle may result in altered fibrin production and degradation.[9] An imbalance of fibrin may result, leading to the deposition of fibrin on the visceral pleura. Fibrosis of the visceral pleura can result in severe lung lobe atelectasis. Radiographic evidence of failure of complete pulmonary expansion following thoracocentesis or dyspnea in the face of minimal pleural effusion should alert the clinician to this problem, which may decrease the prognosis associated with further therapy. Due to the risk of nutritional and fluid imbalance and fibrosing pleuritis, prolonged medical management (beyond 4 to 8 weeks) is not recommended.[3]

Surgical Management

Many surgical techniques have been developed in an attempt to improve the resolution rate of idiopathic chylothorax in dogs and cats, which indicates that the definitive therapy has not been established. Surgical treatment is usually sought in animals with chronic chylothorax despite proper medical management and in cases in which medical therapy becomes impractical. Surgical techniques include mesenteric lymphangiography in conjunction with thoracic duct ligation and pericardectomy, passive or active pleuroperitoneal or pleurovenous shunting, omentalization, and ablation of the cisterna chyli.[19-22] Resolution rates associated with thoracic duct ligation alone range from 53% to 20 to 53% in dogs and cats, respectively.[11,12,23] Concurrent or subsequent pericardectomy may dramatically improve the success rate of thoracic duct ligation to 90%.[2] Both thoracic duct ligation and pericardectomy may be performed with video-assisted thoracoscopic surgery (i.e. thoracoscopy).

Chylothorax resolution rates with omentalization and ablation of the cisterna chyli have not been reported in large numbers of dogs, but these procedures may offer future alternatives for therapy. Redistribution of the effusion into the abdominal cavity or directly into the venous system may be required in cases of persistent chylous or non-chylous effusion after surgery has been attempted and has failed.

Surgical Techniques

Mesenteric Lymphangiography

Mesenteric lymphangiography is recommended prior to ligation of the thoracic duct to provide the surgeon with the number and location of thoracic duct branches. Lymphangiography is repeated after thoracic duct ligation to ensure that all branches have been ligated. If patent branches remain, ligation and lymphangiography should be repeated. An abdominal approach is required, and lymphatic catheterization may be difficult, especially in cats and small dogs. The main disadvantage of lymphangiography is prolongation of surgery time. The other disadvantage is that small thoracic duct branches may remain patent but not fill with contrast material during lymphangiography. The small remaining branches could be a cause for the high failure rate associated with thoracic duct ligation.

Cream (1 to 2 mL/kg) may be fed once an hour for 3 to 4 hours prior to surgery to opacify the lymphatics, making them easier to identify. A right paracostal approach to the abdomen is made in dogs; a ventral midline approach may be made in cats in conjunction with a transdiaphragmatic approach to the thoracic duct.[7] The ileocecocolic region is exteriorized, and the lymphatics evaluated (Figure 43-1). If necessary, a small volume (0.25 to 0.5 mL) of dilute methylene blue dye may be injected into a lymph node to aid in the visualization of efferent lymphatics. Repeated injection of the dye is not recommended, as Heinz body anemia or renal failure may occur.

A 22 to 20-gauge over-the-needle catheter is placed in a lymphatic, secured to the mesentery with suture, and connected to extension tubing preloaded with heparinized saline. The catheter and extension tubing is then sutured to the adjacent segment of intestine to decrease the risk of catheter dislodgement. A three-way stopcock is placed on the end of the extension tubing for contrast injection. Water soluble contrast (1 mL/kg) is diluted 1:1 or 1:0.5 with sterile saline to decrease the viscosity of the solution and ease injection.[2,7,9] Lateral and ventrodorsal radiographs are recommended after injection. Ventrodorsal radiographs should allow visualization of a larger number of thoracic duct branches than lateral views. Alternatively, computed tomography may be done, which allows visualization of the thoracic duct and its branches without superimposition of adjacent structures or further manipulation of the patient.[24] Unfortunately, CT is not available within the surgical suite, making re-evaluation after thoracic duct ligation more difficult. The risk of catheter dislodgement is increased if the patient must be moved to an imaging suite for lymphangiography.

The indwelling lymphatic catheter may also be used for embolization of the thoracic duct with cyanoacrylate.[25] The advantage of embolization is the lack of a thoracic approach and the use of a simple approach to the abdomen. The disadvantages of embolization include thrombosis of the cranial vena cava and embolization of pulmonary artery branches.[25] Positive pressure ventilation may stop migration of cyanoacrylate during its polymerization phase and decrease the risk of embolization of structures other than the thoracic duct.[25] The efficacy of embolization can be evaluated with lymphangiography and repeated if necessary. Thoracic duct embolization, however, has not been studied in a large number of clinical cases.

Standard lymphangiography requires laparotomy and prolongs operative time. A simpler method of injection of the mesenteric lymph nodes with 0.22 mL/kg of aqueous contrast did result in a readable lymphangiogram in four of five dogs if images were made within one to two minutes.[26] The difference between a pressurized lymphatic injection by a catheter and mesenteric lymph node injection is not known.

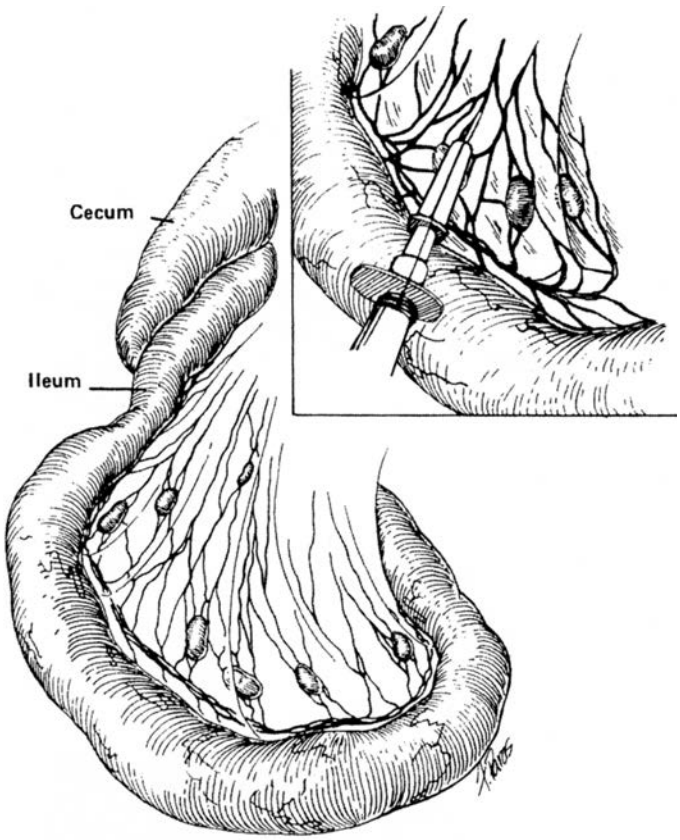

Figure 43-1. Anatomy of the lymphatics adjacent to the cecum and placement of a lymphatic catheter (inset).

Thoracic Duct Ligation

Ligation of the thoracic duct causes new lymphaticovenous anastomoses to form, resolving the effusion and its associated clinical signs.[2-4,7,11-12,23] The thoracic duct should be ligated in the caudal thorax where the fewest number of branches are located. An intercostal thoracotomy is performed on the right side in dogs and on the left side in cats, located at the eighth, ninth, or tenth intercostal space (Figure 43-2). The duct and its branches are located dorsal to the descending aorta and ventral to the azygous vein and sympathetic trunk. The surgeon ligates all branches of

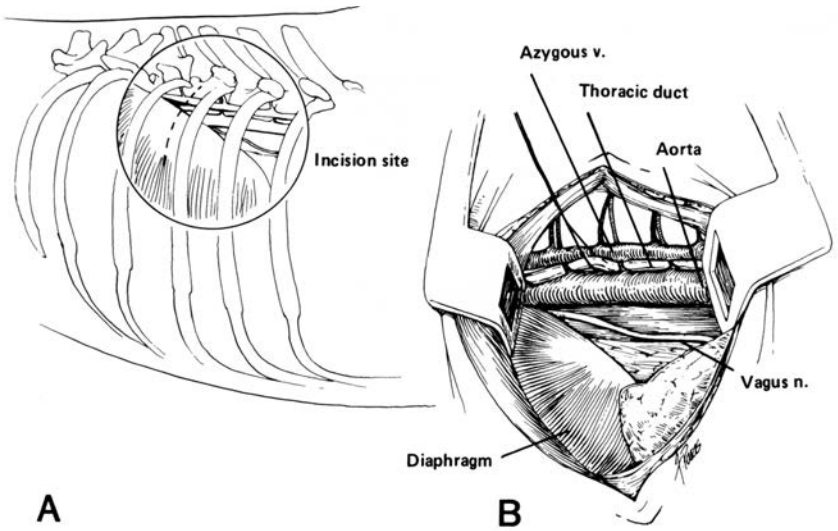

Figure 43-2. Ligation of the thoracic duct. **A.** Right, tenth, lateral intercostal thoracotomy **B.** Anatomy of the structures at the site of ligation.

the thoracic duct with silk (2-0 or 3-0) or hemostatic clips. As with mesenteric lymphangiography, the thoracic duct may be colored by injecting methylene blue dye into the lymphatic catheter or directly into a mesenteric lymph node. Mesenteric lymph node injection reliably colored the canine thoracic duct within ten minutes and lasted up to one hour in one experimental study.[27]

An alternative approach to thoracic duct ligation is to ligate all structures dorsal to the aorta and ventral to the sympathetic trunk, including the azygous vein.[28] Thoracoscopic ligation of the thoracic duct has also been developed in dogs.[29] Portals are placed in the middle of the chest at the ninth intercostal space and at the junction of the dorsal and middle thirds of the chest at the eighth and tenth intercostal spaces.[29] Hemostatic clips are applied to the thoracic duct ventral to the cranial lumbar or caudal thoracic vertebrae, prior to the emergence of the azygous vein into the thorax.[29] With any method of ligation, the area dorsal to the aorta should be completely evaluated for branches of the thoracic duct, some of which may lie further lateral than previously described.

Pericardectomy

Conditions that result in increased hydrostatic pressure may contribute to the accumulation of chyle in the thorax by two mechanisms. Increased hydrostatic pressure may increase the production of lymph in the viscera and caudal body, which will increase the flow of chyle in the thoracic duct.[2] Concurrently, the increased hydrostatic pressure in the cranial vena cava will impede drainage of lymph from the thoracic duct into the venous system. Pericardectomy may decrease venous hydrostatic pressure, decreasing both causes of fluid accumulation.[2] Pericardectomy was described in 20 patients (10 dogs and 10 cats) with idiopathic chylothorax.[2] It was a primary treatment (n=2) or was done in conjunction with thoracic duct ligation in cases with persistent chylous or nonchylous effusion following thoracic duct ligation.[2]

Pericardectomy with thoracic duct ligation resulted in a 90% rate of resolution of effusion in the clinical cases reported.[2] All dogs and eight of ten cats were successfully treated with the combination of the two procedures, which is rapidly becoming the mainstay of therapy for idiopathic chylothorax.[2] Pericardectomy was done by retracting the pericardium into the intercostal thoracotomy used for thoracic duct ligation or by an additional intercostal thoracotomy.[2] Pericardectomy is described in Chapter 42.

Ablation of the Cysterna Chyli

Ablation of the cisterna chyli was developed in an attempt to force lymphaticovenous anastomosis formation within the peritoneal cavity, rather than in the thoracic cavity.[22,30] Ablation of the cisterna chyli was theorized to relieve the increase in lymphatic hydrostatic pressure caudal to the site of thoracic duct ligation, which is a proposed mechanism for collateral lymphatic formation and persistence of pleural effusion following thoracic duct ligation. Thoracic duct ligation alone allows new lymphaticovenous anastomoses to form with the azygous vein, but in dogs that underwent ablation of the cisterna chyli with thoracic duct ligation, the anastomoses formed with the caudal vena cava or phrenicoabdominal vein, mesenteric root, or azygous vein.[30]

Thoracic duct ligation is performed as described above. The cisterna chyli is approached through the abdominal ventral midline.[22,30] The peritoneum adjacent to the left kidney is incised, and perirenal fat dissected until the cisterna is identified ventral to the aorta. Sharp excision of all cisternal membranes is recommended. Seven of eight clinical cases responded to the combination of thoracic duct ligation and ablation of the cisterna chyli.[22] Pancreatitis complicated one case but no other significant complications were noted.[22]

Omentalization of the Thorax

The omentum is an organ that has been used in the treatment of chronic wounds, abscesses, cystic structures. Omentum provides a rich network of blood and lymphatic vessels for healing and presumably a large surface area for the absorption of fluid and obstruction of vascular leakage. The function of the omentum in the treatment of chylothorax is unknown; its lymphatic drainage is via the thoracic duct. Omental advancement through the

diaphragm has been associated with a positive outcome in one dog and one cat with idiopathic chylothorax.[20,21]

Pleuroperitoneal or Pleurovenous Shunting

Persistent chylous or nonchylous effusion following surgical treatment for idiopathic chylothorax may respond to pleuroperitoneal or pleurovenous shunt placement. (Figure 43-3) A commercially available shunt utilizes a one-way, manually compressed pump to move fluid from the pleural space into the peritoneal cavity or the venous system.[19] Although seemingly more physiologically sound, pleurovenous shunting can cause major venous, right atrial, or right ventricular thrombus formation. Peritoneal fluid accumulation is well tolerated by veterinary patients, so pleuroperitoneal shunt placement is more commonly performed.[4] Pre-existing peritoneal conditions that could prevent fluid absorption are a contraindication for pleuroperitoneal shunt placement.

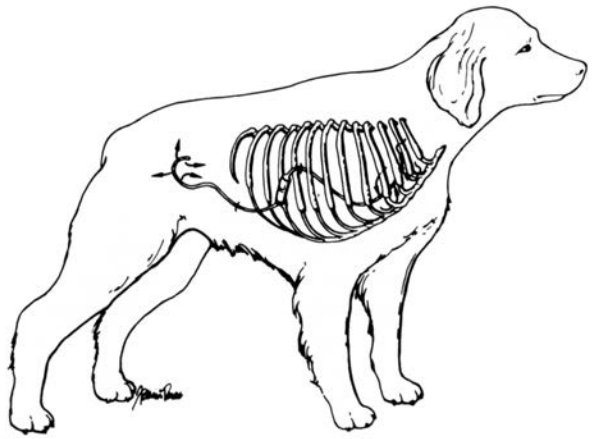

Figure 43-3. Placement of a pleuroperitoneal shunt. (From Smeak DD, et al. Management of intractable pleural effusions in the dog with pleuroperitoneal shunt. Vet Surg 1987;16:212.)

The shunt catheter consists of an afferent portion, pump chamber, and efferent limb. The entire system is placed in heparinized saline and filled until no air bubbles are present. A small thoracotomy incision is made over the sixth, seventh, or eighth intercostal space.[4] The afferent limb is placed in the chest, and a tunnel is made in the subcutis through which the efferent limb is passed, allowing the pump chamber to lie over and be secured to the ribs.[4] Securing the chamber to the adjacent ribs allows postoperative compression of the chamber for pleural evacuation. The efferent limb is introduced into the peritoneal cavity through a small skin incision and pursestring suture in the abdominal musculature.[4] Alternatively, the efferent limb is tunneled over the shoulder and into the caudal cervical region, and the efferent limb is introduced into the jugular vein. The efferent limb should be inserted no further than the cranial vena cava. Alternate venous insertion sites include the caudal vena cava or azygous vein.

Unfortunately, many complications have been associated with shunting of pleural fluid including obstruction of the catheter by clot or kink formation, dislodgement of the pump chamber from the thorax, severe abdominal distention, pyothorax, peritonitis, and pleural compartmentalization.[19] The pump chamber moves 1mL of fluid with each compression and may cause patient discomfort and poor client compliance due to the amount of care required to maintain pleural evacuation. These complications may result in shunt removal, replacement, or patient euthanasia.[19]

Postoperative Care

Patients should be monitored closely for complications associated with thoracotomy and or laparotomy. The need for fluid evacuation postoperatively is dependent on clinical signs and laboratory evaluation of ventilation. Resolution of pleural fluid accumulation following surgery should be monitored, as recurrent chyle accumulation or accumulation of a modified transudate may complicate recovery. Lung lobe torsion has also been associated with chylothorax or other pleural effusions.[31] Chronic chylous effusion may also result in fibrosing pleuritis and dyspnea despite evacuation of fluid.

Transdiaphragmatic Approach to Thoracic Duct Ligation in Cats

Robert A. Martin

This technique is one of several surgical procedures used in an attempt to disrupt the flow of abdominal lymph drainage through the thoracic duct system in cats; it is specifically aimed at resolving chylothorax when no identified underlying cause can be found. Occlusion of the thoracic duct system results in the formation of alternate abdominal lymphaticovenous communications to return chyle to the circulation.[1] After a ventral midline celiotomy, a left transdiaphragmatic thoracotomy exposes the thoracic duct system for occlusion with hemostatic clips.[1] The procedure allows vital staining and immediate ligation of the thoracic duct system through a single body wall incision. The technical description of the procedure follows.

Surgical Technique

The cat is placed in dorsal recumbency, and the abdomen is prepared for aseptic surgery. A ventral midline incision is made from the xiphoid cartilage caudal to the umbilicus. The jejunum, ileum, and ascending co-Ion are identified and are exteriorized to locate the mesenteric lymph nodes. A more caudal lymph node is selected, usually the right colic, for injection of 1% Evans blue solution (Sigma Chemical Co., St. Louis, MO). Direct puncture with a 25-gauge needle on a 1-mL syringe is used to deliver 0.1 to 0.2 mL of dye into the selected node. A dry surgical sponge is used to contain any leakage of dye on removal of the needle, thus minimizing abdominal contamination. Lymphatic

drainage of the injected dye is immediate. By retracting the descending duodenum ventrally and to the left, the stained intestinal lymphatic trunk is easily visualized as it courses through the duodenal mesentery dorsally toward the cisterna chyli. The transparent wall of the intestinal trunk is covered by visceral peritoneum, which can be delicately dissected away to improve the ease of cannulation of the intestinal trunk with a 22-gauge, over-the-needle catheter (Jelco intravenous catheter x 1 inch, Johnson & Johnson, Inc., Arlington, TX). After stylet removal, spillage of dye from the catheter should be contained by capping the catheter either with an injection cap (PRN Adapter, Becton Dickinson Vascular Access, Sandy, UT) or by attaching the 1-mL syringe containing the Evans blue solution. The catheter is fixed to the mesoduodenum with circumferential ligatures of small-diameter suture material (4-0 or 5-0), and the viscera are returned to the abdomen. Gentle manipulation of viscera minimizes disruption of the catheter.

The left side of the diaphragm is identified by retracting the stomach and left liver lobes caudomedi-ally. A left transdiaphragmatic thoracotomy is performed by incising the diaphragm from a point 2 cm dorsolateral to the xiphoid cartilage dorsally toward the left diaphragmatic crus until adequate exposure of the caudal thoracic aorta is achieved. By curving the diaphragmatic incision to parallel the costal arch, the medial portion of the incised diaphragm can more readily be used as a retractor to contain and displace the abdominal viscera caudomedially. Several stay sutures in the medial margin of the diaphragmatic incision are used for retraction.

The left caudal lung lobe is displaced cranially with a moistened sponge to expose the caudal thoracic aorta. The thoracic duct system should be identified in the areolar tissues surrounding the aorta by its staining from the previously injected Evans blue solution. An additional injection through the catheter in the intestinal trunk may be necessary to improve visualization of the thoracic duct branches. The thoracic aorta is dissected from the thoracic duct system just cranial to the aortic hiatus of the diaphragm. The least number of branches of the thoracic duct system is present for ligation at this location.[2] The aortic dissection is performed by beginning directly along its ventral ad-ventitia to minimize disruption of any of the thoracic duct branches, which are incorporated in areolar tissue dorsally and laterally. A moistened umbilical tape is passed around the aorta, which is then retracted ventrally to expose the stained thoracic duct

system completely within the mediastinal tissues. Contraction of aorta occurs during dissection and retraction. Without immobilization of the thoracic aorta by complete circumferential dissection and isolation, complete exposure to the thoracic duct system cannot be achieved consistently.

Multiple hemostatic clips (Hemoclip [medium], Edward Week, Inc., Research Triangle Park, NC) are used to mass ligate any visible thoracic duct branches, without an attempt to isolate individual ducts before ligation. Usually, a single duct arising from the cranial pole of the cisterna chyli abdominally passes through the diaphragm and gives rise to one or two main thoracic branches, which can be identified at this site along with occasional minor collateral branches.[2] A major thoracic duct branch courses on the left dorsolateral aspect of the thoracic aorta. Looping collateral branches or a major or minor thoracic duct may be identified along the right dorsolateral aspect of the thoracic aorta, and multiple cross-communications between longitudinal ducts usually exist more cranially. The number of cross-communications increases cranial to the preferred site of ligation (Figure 43-4), which is just cranial to the aortic hiatus of the diaphragm (ventral to T13). The paired sympathetic trunks that lie lateral to the thoracic duct system should not be included in the ligation.

After thoracic duct system ligation, a second injection of dye into the intestinal trunk catheter is performed to highlight any collateral branches at the site of ligation that may have been unidentified but require ligation. The moistened sponge on the left caudal lung lobe is removed, and the lobe is reinflated. The thorax is lavaged with warm balanced electrolyte solution, and all fluid is removed from the thorax with suction. The diaphragm is closed in a simple continuous suture pattern dorsally to ventrally with 3-0 monofilament absorbable suture material. Thoracentesis may be performed through diaphragmatic puncture or through a previously placed thoracostomy tube until negative intrathoracic pressure is established. The abdominal lymphatic catheter is removed, and two-layer or three-layer abdominal closure is performed.

Postoperative Care

Postoperatively, a thoracostomy tube is maintained for 24 hours or until thoracic effusion becomes minimal. The success of the procedure is determined by resolution of the chylothorax without recurrence. Perioperative antibiotics are indicated and should be continued until after the thoracostomy tube is removed. Frequent short-term follow-up evaluations are indicated to monitor the cat for recurrent thoracic effusion.

Lymph Node Biopsy

MaryAnn Radlinsky

Indications

Lymph node biopsy is indicated to evaluate persistent lymphadenopathy, determine if a neoplastic process is present, and to aid in the diagnosis of vague clinical signs associated with systemic disease. Lymphadenopathy may or may not be present; normal sized lymph nodes may still be involved in a disease process. The presence of metastasis for staging of disease or for definitive diagnosis of the type of neoplasia, as in lymphosarcoma, are common reasons for lymph node biopsy. Lymph nodes may also be sampled for the diagnosis of infectious disease or immune mediated conditions.[1-3] Non-diagnostic lymph node fine-needle aspirates (FNA) are also an indication for node biopsy. Peripheral lymph node biopsy is a simple and quick procedure with few complications. The information gained outweighs the risk of the procedure, which can be performed by needle, incision, or excision. Lymph node biopsy during open procedures such as laparotomy or thoracotomy rarely increases the risk associated with the approach or primary disease process. The information obtained may be extremely important for cancer staging and providing an accurate prognosis for the owner. For example, the survival time in dogs with bronchogenic carcinoma of the lung is markedly decreased for patients with lymph node metastasis at the time of surgery.[4] Excisional lymph node biopsy may be indicated to decrease tumor burden prior to adjuvant chemotherapy, (*e.g.* malignant melanoma), to decrease tumor activity (*e.g.* insulinoma, mast cell tumor), or if the nodes are causing clinical signs because of their size (*e.g.* colorectal compression caused by medial iliac lyphadenopaty).

Contraindications and Complications

Contraindications to lymph node biopsy are rare. A complete evaluation of the patient should be performed prior to sedation or general anesthesia for lymph node sampling. Hemorrhage is one potential complication of lymph node biopsy with needle, incisional, or excisional techniques. Animals with coagulopathies should have the disorder corrected by administration of plasma, a blood transfusion, or vitamin K therapy prior to surgery.

Lymph nodes may have a generous blood supply, and vessels should be carefully ligated as necessary during the procedure. Specific lymph nodes such as the medial iliac, hypogastric, and hepatic lymph nodes are anatomically associated with large blood vessels. The external and internal iliac vessels and the portal vein are adjacent to the lymph nodes and trauma to those vessels can lead to significant hemorrhage. Complete excision of the mesenteric lymph node(s) may be difficult due to the risk of compromise to the blood supply of the bowel. Edema is rarely a complication of lymph node biopsy.[5]

Biopsy Techniques

Selecting a Biopsy Site

Physical examination or the anatomic location of disease usually dictates which lymph nodes are selected for biopsy. The superficial lymph nodes are easiest to sample from patients with generalized lymphadenopathy or unexplained systemic illness (Figure 43-5). The popliteal and mandibular lymph nodes are easily palpated and sampled in patients with normal sized lymph nodes. The mandibular lymph nodes may display reactive hyperplasia due to constant exposure to exogenous antigens of the oral cavity and although they are readily palpated and approached for biopsy, they may not be representative of the condition present.[6] The same is true for lymph nodes draining the gastrointestinal tract. Normal inguinal and superficial cervical, or prescapular, lymph nodes may also be sampled if necessary, but are not as easily approached. A single approach for the lymph nodes draining the head, parotid, mandibular, retropharyngeal areas, has been described for the staging of maxillofacial neoplasms.

The lymph nodes draining an abnormal site or lesion should be sampled in any case requiring lymph node biopsy. Therefore, the regional lymphatic anatomy should be considered prior to biopsy. A detailed description of lymphatic anatomy should be consulted if the anatomy is not readily apparent. Alternative methods of determining lymph node drainage of a particular site include magnetic resonance imaging and computed tomography following injection of contrast material into the affected region.[7] Advanced imaging methods with coloration of the lymph nodes and scintigraphic identification of sentinel lymph nodes have not been widely used in veterinary patients.

The drainage areas for specific superficial lymph nodes should be considered prior to lymph node biopsy. The *parotid lymph nodes* drain the nasal planum, skin, and subcutis of the frontal and temporal regions and many of the muscles of the ear and head. Drainage from the parotid lymph nodes is to the retropharyngeal lymph nodes. The *mandibular nodes* drain the nose, lips, superficial muscles of the head, and parts of the tongue, oral cavity, and pharynx. Efferent lymphatics from the mandibular lymph nodes proceed to the retropharyngeal lymph nodes. The *superficial cervical lymph nodes* drain the skin and subcutis of the caudal head, thoracic cavity, neck, shoulder, and portions of the thoracic limb. Drainage from the superficial cervical lymph nodes is to the right lymphatic duct, thoracic duct, or directly into the jugular vein. The *axillary lymph nodes* drain an area similar to but extending more caudal to the drainage area of the superficial cervical lymph nodes. The axillary lymph nodes also drain portions of the thoracic limb and cranial mammary glands. Efferent lymphatics from the axillary lymph node drain to the right lymphatic duct, thoracic duct, tracheal duct, or external jugular vein. The *inguinal lymph nodes* drain the skin and subcutis of the ventrolateral trunk, pelvic and tail areas, medial and lateral thigh, perineum, and caudal mammary glands. The drainage from the inguinal lymph nodes proceeds to the external iliac lymph node. The *popliteal lymph nodes* drain the majority of the pelvic limb structures, mostly distal to the location of the lymph node. Efferent lymphatics go to the inguinal and external iliac lymph nodes.[8,9]

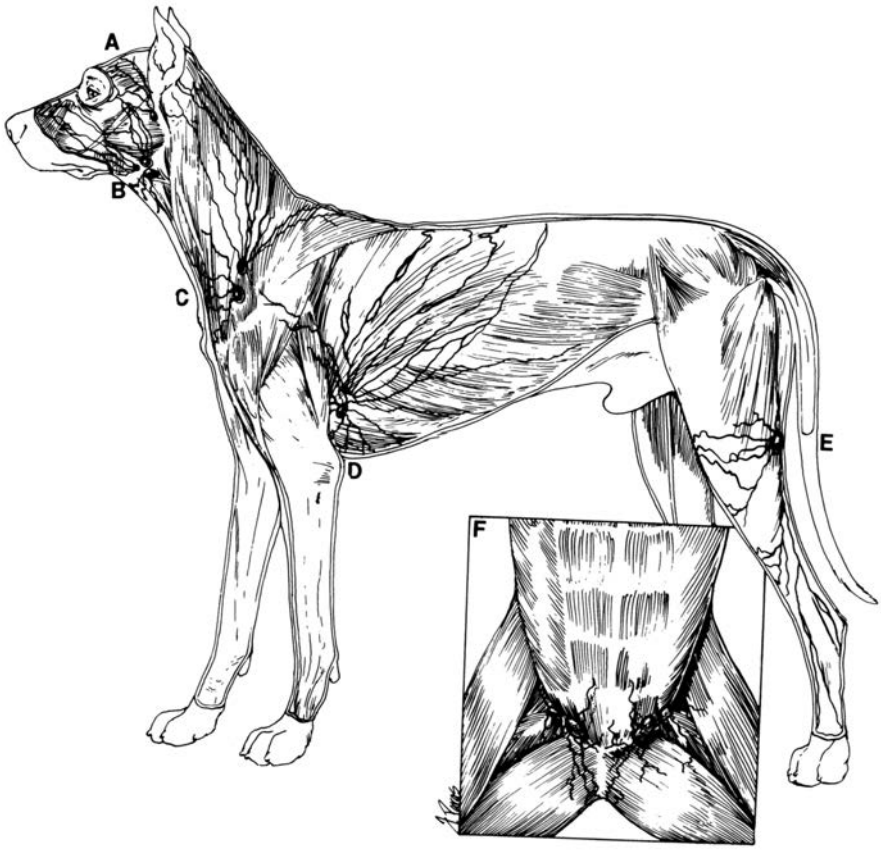

Figure 43-5. Superficial lymph nodes in the dog. *A.* Parotid lymph node *B.* Mandibular lymph node *C.* Superficial cervical lymph node *D.* Axillary lymph node *E.* Popliteal lymph node *F.* Inguinal lymph nodes.

Fine-Needle Aspiration (FNA)

Any of the superficial lymph nodes that can be palpated and stabilized can be aspirated. Sedation or anesthesia is usually not required, nor is skin preparation necessary. The only equipment needed is glass slides, a 10 or 12 cc syringe, and 22 to 25 gauge needle. Two methods of aspiration exist. One technique uses suction generated by the needle and syringe, the other does not. The lymph node is grasped, and the needle placed within the parenchyma. If suction is used, 8 to 10 cc of suction is generated. The needle is carefully redirected within the lymph node and suction reapplied. Discontinue the procedure if blood appears in the hub of the needle. Release suction prior to withdrawal of the needle from the lymph node. The needle should be removed from the syringe, and 5 cc of air is aspirated into the syringe, the needle is replaced on the syringe, and the material in the needle is immediately sprayed onto a clean glass slide.

If suction is not used, stabilize the lymph node by palpation and insert the needle into the parenchyma. The needle is redirected multiple times; discontinue the procedure if blood appears in the hub of the needle. Fivecc of air is aspirated into a 12 cc syringe, the needle is applied to the end of the syringe, and the material is sprayed onto a clean glass slide. With either procedure, the contents of the needle must be sprayed onto a clean glass slide immediately, and a vertical or horizontal squash preparation made. Only gentle pressure is used to make the smears, as lymph node tissue is extremely fragile; cellular and nuclear damage will interfere with interpretation of the cytology. Wright's stain is applied to evaluate the smears.[10]

Tru-Cut Biopsy

Enlarged lymph nodes can be biopsied with a 14 to 16 gauge Tru-Cut needle, which supplies a cylindrical core of tissue. This method may be used for sampling superficial lymph nodes in cases in which a diagnosis is not apparent on fine needle aspiration cytology and can often be performed under sedation. The lymph node is stabilized by hand, and a stab incision made in the skin over one end of the lymph node. The needle is introduced into the lymph node so that the sampling chamber will ideally remain in nodal tissue only during the biopsy process. Automated or manual biopsy needles are available.

Incisional Biopsy

An incisional biopsy requires a surgical approach to the lymph node and removal of a wedge of tissue for biopsy. Incisional biopsies are usually done on lymph nodes that are difficult to completely excise without consequences, as with mesenteric lymph nodes, and are achieved with stabilization of the lymph node. Superficial lymph nodes are approached by a skin and subcutaneous incision and muscular dissection as needed to expose the lymph node. A wedge of lymph node is excised using a number 15 scalpel blade. The wedge is oriented transverse to the long axis of the lymph node and is removed with minimal handling to avoid damaging the architecture of the specimen. The defect is closed with small (3-0 to 4-0) absorbable suture in a horizontal mattress pattern for hemostasis (Figure 43-6). The approach is closed routinely. Impression smears of the biopsy sample can be made prior to placing the sample in formalin.

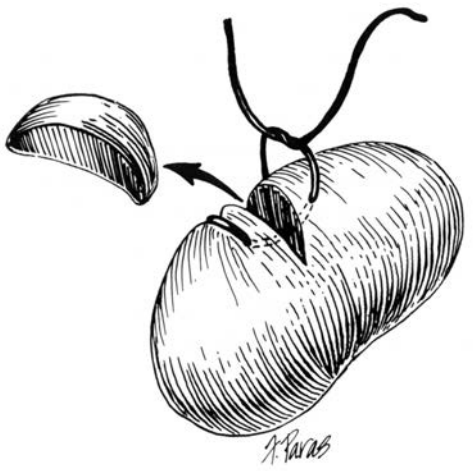

Figure 43-6. Incisional biopsy of a lymph node. The sample is oriented transverse to the longitudinal axis of the lymph node, and closure is achieved with a horizontal mattress suture.

Ideally, the surface is blotted dry with absorbent paper, and the cut surface is lightly pressed against a clean glass slide; care should be taken to not damage the biopsy specimen during any part of the process. Fungal or bacterial cultures may also be obtained prior to fixation.

Excisional Biopsy

Superficial lymph nodes may be excised with heavy sedation and local anesthetic depending on the patient's temperament and physical status. General anesthesia for superficial lymph node extirpation is recommended in most patients and is required for deep, abdominal, or thoracic lymph node excision. For superficial lymph nodes, the node is palpated and stabilized with external pressure toward the skin surface. An incision is made longitudinally over the lymph node, and blunt dissection is used to mobilize the node. Afferent vessels may or may not require ligation; more frequently hilar vessels are ligated.[8] Deep, abdominal, or thoracic lymph nodes are evaluated during surgical exploration. Care is taken when dissecting the lymph nodes from surrounding structures, particularly nerves and vessels. Hemostasis is achieved with ligation and electrocautery in most cases, however, collateral damage to the lymph node can occur if cautery is applied close to the nodal surface.

The lymph node should be handled carefully to avoid structural damage. Samples may be collected for fungal and bacterial culture, and the lymph node may be sectioned for impression smears. The sample should be placed in an adequate volume of 10% formalin for processing.

Chapter 44

Spleen

Surgery of the Spleen

Dale E. Bjorling

Introduction

The spleen is suspended in a portion of the greater omentum (the gastrosplenic ligament) that extends from the diaphragm, fundus, and greater curvature of the stomach to the spleen.[1] The splenic artery arises from the celiac artery and supplies branches to the left lobe of the pancreas as it courses to the splenic hilus (Figure 44-1). The splenic artery divides into a dorsal and a ventral branch several centimeters from the spleen. The dorsal branch continues to the dorsal portion of the spleen, where it gives off the short gastric arteries. The left gastroepiploic artery arises from the ventral branch of the splenic artery before it contacts the spleen. Venous drainage from the spleen is through the portal vein.

The spleen contains smooth muscle and is innervated by both sympathetic (from the celiac plexus) and parasympathetic (from the vagus) nerve fibers. The spleen also has a considerable population of adrenergic receptors that control contraction and relaxation.[2]

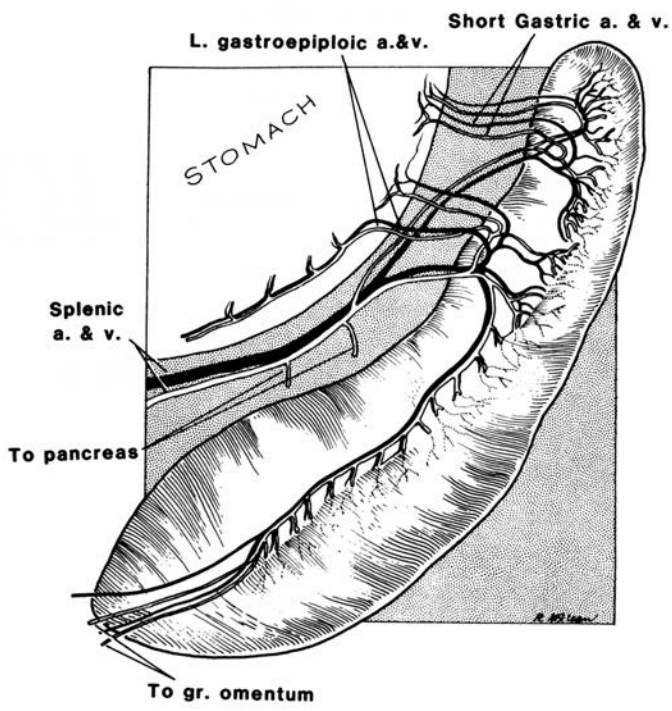

Figure 44-1. Vasculature of the spleen. The splenic artery and its branches give off vessels that supply the pancreas and the greater curvature of the stomach.

Multiple spleens are uncommon in dogs, but trauma may result in the widespread dissemination of splenic tissue throughout the abdomen. Such fragments of splenic tissue become revascularized, and the resultant condition (splenosis) may be confused with neoplasia. Intentional splenic reimplantation during surgery has been recommended as a means of salvaging splenic function,[3] but the mere presence of tissue of splenic origin does not ensure that normal splenic function will be maintained.[4,5]

The spleen may have white fibrin deposits or siderotic plaque on its surface. Siderotic plaque consists of iron and calcium deposits and is brown or rust colored. This appearance should not be considered abnormal. Similarly, splenic nodules (areas of benign hyperplasia) may be confused with neoplasia. Distinguishing splenic nodular hyperplasia from neoplasia may be difficult without a biopsy. The size of the spleen is variable, and the spleen may appear abnormally large during barbiturate anesthesia or when it is relaxed during minimal adrenergic stimulation. Anemia, blood loss and stress all cause the spleen to contract.

The spleen has several functions: blood storage, blood filtration and phagocytosis of particles, parasites, bacteria, and damaged or aged red blood cells; contributions to the body's immune defenses; hematopoiesis; and iron metabolism. The spleen may retain as much as 10% of the total red blood cell mass[6,7] that can be discharged into the general circulation in response to adrenergic stimulation during stress or blood loss. The structure of the spleen places red blood cells in close contact with macrophages; therefore, red cells that are damaged, contain parasites, or have immunoglobulins attached to the surface are removed from circulation in the spleen. The spleen also appears to remove blood-borne bacteria efficiently.[8] It produces immunoglobulins (particularly I gM) and opsonins, as well.[9] Although not reported in animals, overwhelming sepsis after splenectomy has occurred in human patients.[10] Hematopoiesis is not a significant function of the spleen in adult animals, unless it is necessitated by decreased function of the bone marrow. Iron is extracted from hemoglobin as red blood cells are broken down and is stored in the spleen for future transport to the bone marrow for production of more hemoglobin.

Indications

Indications for removal of the spleen include neoplasia, torsion of the splenic pedicle (isolated or in conjunction with gastric dilatation volvulus), and severe traumatic injuries. Splenectomy has been recommended as adjunctive treatment for immune mediated thrombocytopenia and hemolytic anemia unresponsive to medical therapy.[11] The spleen is often removed in dogs used as blood donors to prevent undetected infection with Haemobartonella canis or Babesia canis. Because the spleen has several functions, partial splenectomy should be considered (when feasible) to retain functional splenic tissue.

Hemangiosarcoma is the most common primary tumor of the spleen. Other tumors of the spleen include hemangioma, leiomyosarcoma, fibrosarcoma, lymphosarcoma, plasma cell sarcoma, mast cell sarcoma, and reticular cell sarcoma. Euthanasia of an

animal should not be recommended to an owner solely because of the presence of a splenic tumor. Splenectomy prevents intra abdominal bleeding subsequent to rupture of the tumor, and mean survival times of at least 4 to 6 months in the dog[12,13] and longer in the cat[14] may be expected after splenectomy for hemangiosarcoma. Removal of the spleen for treatment of splenic leiomyosarcoma in dogs resulted in a median survival of 10 months.[15] The spleen may also be enlarged because of infiltration with mast cells in association with feline systemic mastocytosis. Splenectomy appears to improve the duration of survival in affected cats.[16]

Determining when irreversible splenic injury has occurred after torsion of the splenic pedicle is difficult. The onset of clinical signs may be insidious or peracute, necessitating emergency surgery.[17] Occlusion of the splenic vein causes vascular stasis, and the vessels ultimately become thrombosed. If the spleen is engorged and blue black, or if thrombi are observed within the vasculature, the spleen should probably be removed. Untwisting the splenic pedicle to restore circulation may release toxic byproducts of anaerobic metabolism.

Preoperative Considerations

Intravenous fluid administration should begin before, and should continue during and after, splenectomy. The rate of administration and total volume given depend on the animal's condition. If the hematocrit is low (less than 18 to 20%), a transfusion of whole blood or packed red blood cells before surgery should be considered. Although a certain percentage of the red cell mass is removed with the spleen, this volume of cells does not contribute to the peripheral hematocrit at the time of the surgical procedure. Removal of the spleen, however, has a negative effect on the body's ability to compensate for subsequent blood loss. The presence of a splenic tumor is an indication that the patient should be evaluated thoroughly to detect primary tumors or other sites of metastasis that would diminish the animal's ability to tolerate anesthesia and surgery or would decrease its life span after surgery.

Surgical Techniques

Splenorrhaphy

Superficial lacerations of the capsule of the spleen may be closed with sutures. If hemorrhage from the splenic wound is brisk, the injured tissue can be devascularized by ligation of the arteries supplying the wounded area near their junction with the spleen (Figure 44-2A and B.). This tissue does not remain ischemic, and collateral circulation develops within 3 weeks.[18] Large isolated arteries within the splenic parenchyma that have been injured can be individually ligated. The splenic capsule is closed with 3-0 or 4-0 absorbable suture swaged onto an atraumatic needle in an interrupted or continuous pattern (Figure 44-2C). It may be necessary to close the defect in the spleen with an interrupted or continuous horizontal mattress suture pattern placed in the splenic parenchyma to control hemorrhage. Pressure may be applied to the surface of the spleen to control continued hemorrhage, or the omentum may be wrapped around the spleen. If complete hemostasis cannot be achieved, a partial or total splenectomy should be performed.

Partial Splenectomy

A portion of the spleen can be removed for biopsy purposes or to treat localized splenic trauma or abscessation. A partial splenectomy can be performed with sutures or a mechanical stapling device. The vascular supply of the area to be removed is isolated, ligated, and divided. The tissue to be removed soon assumes an ischemic appearance. The parenchyma is compressed between the fingers along the proposed line of excision. Two pairs of forceps are applied to the spleen approximately 1 to 2 cm apart (Figure 44-3A). Atraumatic forceps (large, straight vascular forceps or Doyen intestinal forceps) should be applied to the splenic remnant to be retained; crushing forceps may be applied to the portion to be excised. The spleen is completely incised between the two forceps approximately 3 to 5 mm from the atraumatic forceps. The capsule is closed with 3 0 or 4 0 absorbable suture in a simple continuous pattern, and the forceps are removed (Figure 44-3B). A second suture line is placed

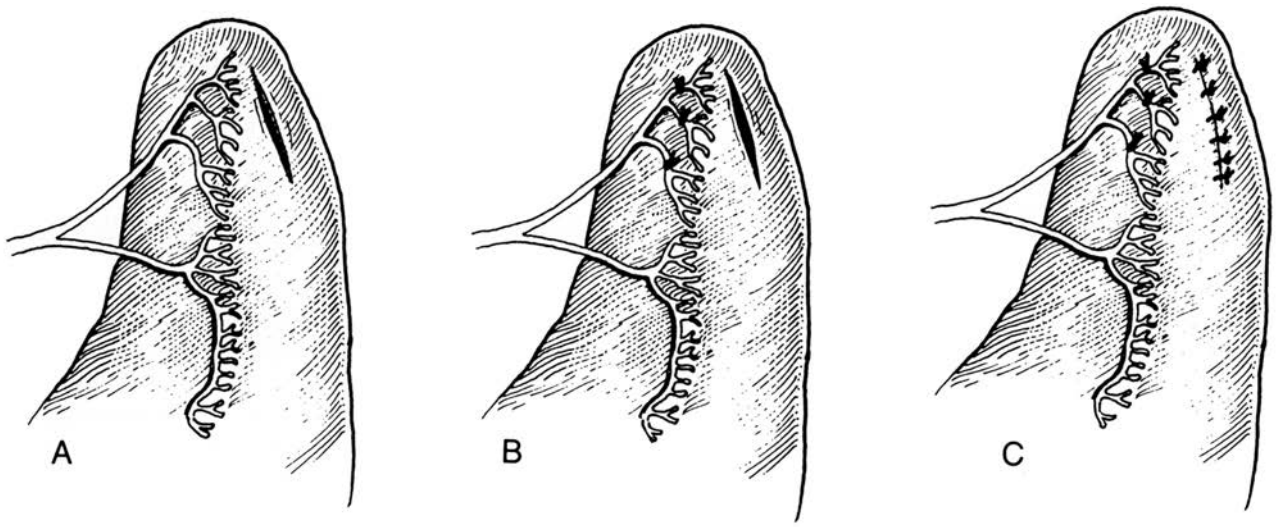

Figure 44-2. A. Laceration of the spleen. **B.** The vessels supplying the injured area of the spleen are ligated to control hemorrhage. **C.** The laceration in the capsule of the spleen is closed with absorbable sutures in a simple interrupted or continuous pattern.

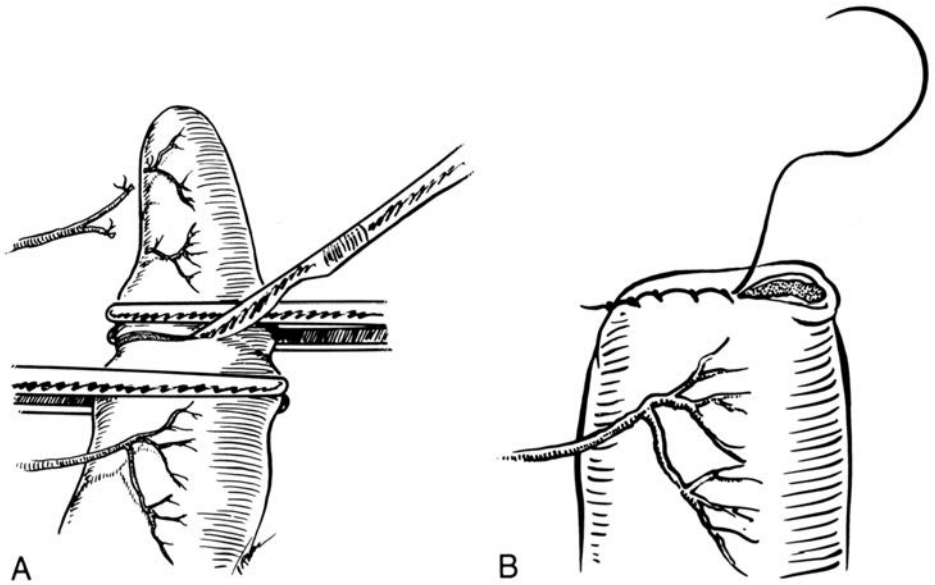

Figure 44-3. Partial splenectomy. **A.** After the vessels supplying the portion to be removed are ligated and divided, crushing forceps are applied to the tissues to be removed and atraumatic forceps are applied to the splenic remnant. The spleen is then divided between these forceps a few millimeters from the atraumatic forceps. **B.** The spleen is closed with absorbable suture in a simple continuous pattern. A second suture line is placed proximal to the first to control hemorrhage.

proximal to the first suture material in a continuous horizontal mattress pattern to ensure hemostasis. Partial splenectomy can be performed easily with stapling devices. Staples of a length sufficient to incorporate all tissue must be used. In most animals, staples at least 3.5 mm in length are adequate; if splenic tissue cannot be compressed to a width less than 2 mm, staples 4.8 mm in length should be used.[19] If hemorrhage is observed after application of staples and excision of a portion of the spleen, individual vessels can be ligated.

Splenectomy

Splenectomy is usually performed though a midline celiotomy. The incision should be of sufficient length to allow the spleen to be easily delivered from the abdomen. If an essentially normal spleen is being removed (e.g., to prevent hidden parasitemia or to treat an autoimmune disorder), 1 to 2 mL of 1:100,000 epinephrine can be applied to the surface to cause the spleen to contract. Use of larger volumes or higher concentrations of epinephrine may predispose the animal to cardiac arrhythmias, especially if anesthesia is maintained with halothane.

Vessels should be ligated as close to the hilus of the spleen as possible to minimize the potential for damage to the left gastroepiploic and short gastric vessels that supply the greater curvature of the stomach or the vessels passing to the left lobe of the pancreas. Ligation of vessels during splenectomy can be achieved with suture, metal clips, a mechanical stapling device or vessel sealing device. Although absorbable suture may be used for ligation of vessels, I prefer 2-0 or 3-0 silk. The vasculature of the spleen is usually isolated, ligated, and then divided. Alternatively, two rows of hemostatic forceps may be applied to the vasculature. The vasculature is divided, and vessels are ligated after the spleen has been removed. This technique often results in placement of ligatures some distance from the spleen, thereby increasing the potential for inadvertent ligation of vessels supplying the stomach and pancreas. As mentioned previously, when splenectomy is performed to treat splenic torsion, the splenic pedicle should not be untwisted. The vessels are usually adequately accessible to allow individual ligation near the spleen. If this is not possible, forceps can be applied, and the vessels can be ligated individually after the spleen has been removed.

The abdomen should be explored thoroughly after removal of the spleen. When the spleen has been removed to treat neoplastic disease, particular attention should be paid to the liver and lymph nodes, and biopsies should be obtained if these structures appear abnormal. The pancreas and stomach should be examined to be sure that these structures and their vasculature have not been damaged during surgery.

The splenic bed should be examined for hemorrhage before closure of the abdomen. Lavaging the abdomen with sterile saline or another balanced salt solution helps to remove blood clots and improves the surgeon's view of the splenic pedicle.

Postoperative Complications

Hemorrhage as a result of displacement of a ligature is the most common complication of splenectomy. Intraabdominal hemorrhage causes a progressive decline in the packed cell volume and plasma protein concentration when these values are measured repeatedly. Abdominal paracentesis and diagnostic peritoneal lavage also are useful for detecting hemorrhage after splenectomy. If tests support a diagnosis of intra abdominal hemorrhage after splenectomy, the abdominal incision should be reopened, and the splenic bed should be examined directly. A transfusion of whole blood may be required to compensate for blood loss. If a donor is not available, blood may be retrieved

from the patient's abdomen, mixed with an appropriate volume of anticoagulant, and given back to the patient (autotransfusion). This blood should be filtered as it is administered to remove microemboli and other debris. Blood should be removed from the abdomen using suction or sponges, and clots should be removed from the splenic bed to allow direct observation of the splenic vessels.

In the absence of continued hemorrhage, anemia after splenectomy is of limited duration if the bone marrow is functioning satisfactorily. Splenectomy does impair the capacity of the animal to maintain the circulating red blood cell volume during hemorrhage. Removal of the spleen 2 to 3 weeks before experimentation impaired the ability of anesthetized dogs to respond to hypoxemia.[20] Although this phenomenon may be transient, it does suggest that animals that have undergone splenectomy may be less able to maintain cardiovascular homeostasis during surgery, anesthesia, or other stressful situations.

Damage to the vasculature of the stomach or pancreas can cause ischemic necrosis of these organs. Pancreatitis may result from traumatic handling of the pancreas during surgery. These complications occur infrequently.

Ventricular arrhythmias have been reported to occur in as many as 44% of dogs after splenectomy, and it has been observed that these may not be detected in the absence of continuous electrocardiographic monitoring.[21] Not all dogs that develop ventricular arrhythmias after splenectomy require treatment, and treatment of arrhythmias often prolongs hospitalization. Treatment should be reserved for ventricular arrhythmias that result in significant pulse deficits or ventricular rates that exceed established standards.[22]

As mentioned previously, overwhelming septicemia (occasionally observed in humans after splenectomy) has not been reported after splenectomy in dogs and cats. However, splenectomy may render animals more susceptible to infection by blood borne organisms (Haemobartonella, Babesia). Other, as yet undetected immunologic abnormalities may also result from splenectomy in dogs and cats.

Editors Note: Reported survival times in dogs following splenectomy for malignent neoplasia vary considerably. Consultation with an oncologist regarding chemotherapy following surgery is recommended.

Surgical Techniques in Small Exotic Animals

Surgery of Pet Ferrets

Neal L. Beeber

Introduction

In recent years, the domestic ferret has had a dramatic increase in popularity. In 1990, the number of pet ferrets in the United States was estimated to be more than 7 million.[1] As these animals have increased in Popularity, they have become more common in veterinary practices. This discussion deals with some of the more common surgical procedures in ferrets.

Preparation and Fasting

Healthy ferrets make excellent surgical candidates, are hardy, and with attention to certain parameters they do not present any unusual anesthetic risks. The intestinal tract is short, resulting in a gastrointestinal transit time of 3 to 4 hours.[2] For this reason, patients are only fasted for 4 to 5 hours before surgery, except in the case of insulinoma resection, for which the fast is 3 hours.

Sedation and Anesthesia

Isoflurane is the anesthetic of choice; however, halothane can also be used, except in critically ill patients. A nonrebreathing system is used with a flow rate of 0.6 to 1.0 L per minute. No premedication is required. In many cases, ferrets can be masked until they are sufficiently anesthetized to allow endotracheal intubation. This can usually be accomplished with a flow rate of 2 L and a 4 to 5% isoflurane concentration. The animal relaxes in 2 to 5 minutes. Because struggling or excitement is minimal, chamber induction is not usually necessary. Maintenance level of isoflurane is 1.75 to 2.5%. It is often necessary to use a small amount of lidocaine (0.1 mL) to paralyze the larynx to accomplish intubation, as in the feline species. All ferrets are intubated except for the most minor procedures. Use of 1.5 to 4.5 French endotracheal tubes is sufficient for most ferrets. If the tubes are allowed to become cold in a refrigerator, they will become stiff and more easily introduced into the trachea. Because ferrets vary in body size, several tube sizes should be available. Some breeding establishments have been importing European ferrets, which are generally larger than the American breeds and commonly weigh up to 5 to 6 lb. These ferrets need slightly larger endotracheal tubes. Whenever possible, a cuffed tube is recommended.

Ketamine and diazepam ketamine combinations can be used as a preanesthetic, for intubation, or for short procedures intramuscularly at a dose of 10 to 20 mg/kg for ketamine and 1 to 2 mg/kg for diazepam. In my opinion, acepromazine should not be used in ferrets because of this agent's vasodilatative properties and the possibility of heat loss. Ferrets should be placed on a warm water recirculating system to prevent heat loss, and any intravenous fluids to be administered should be warmed to 85 to 90° F. The patient's rectal temperature should be monitored during the surgical procedure. A simple and inexpensive way to accomplish this is to use a digital outdoor thermometer available commercially for under $15 (indoor outdoor thermometer, Radio Shack catalog No. 63 854). The probe can be inserted directly into the rectum or attached to a red rubber catheter as a stylet.

Except for a routine spay, neuter, or other minor procedure, a 24 gauge intravenous catheter (Baxter Quickcath 24 gauge 1.6 cm) should be placed for all surgical procedures. The cephalic vein is the most common site for placement, but lateral saphenous, jugular, and intraosseous catheters can also be used. When a jugular catheter is necessary, a 24 gauge cephalic catheter can be placed in the jugular vein. The types of fluids administered depend on the type of surgical procedure performed and are discussed under the appropriate section. Ferrets are monitored with a pulse oximeter, which works well in this species. Recovery time depends on the animal's condition and length of anesthesia; however, when isoflurane is used alone, recovery is remarkably fast and smooth.

General Surgical Considerations

Ferret skin is tougher than dog or cat skin, so slightly more pressure may need to be exerted. One often sees a thick subcutaneous fat layer, which should be dissected bluntly. The linea alba is readily apparent. A stab incision should be made into the abdominal cavity and extended. Care should be taken to avoid the spleen because it is often large in this species. Most common types of sutures can be used depending on the operation performed. I prefer to close the abdomen with 4-0 polydioxanone (PDS), polypropylene (Prolene), or nylon. Most nonabsorbable suture material with a cutting needle can be used for skin sutures. Ferrets rarely chew external sutures.

Ovariohysterectomy

Most ferrets sold as pets in the United States are neutered before 6 or 7 weeks of age, so ovariohysterectomy is not a common procedure, as in dogs and cats. Ferrets should be spayed by 6 months of age, however, if they are not to be used for breeding. Ferrets are induced ovulators. If they are allowed to remain in estrus, potentially fatal bone marrow suppression may result from estrogen toxicity. Medical treatments to terminate estrus are available;[3] however, spaying is recommended.

The surgical procedure is similar to that for cats. The ferret is placed in dorsal recumbency, and the abdomen is shaved and prepared. A 3 to 4 cm midline incision is made 1cm posterior to

the umbilicus. Blunt dissection is used to dissect through the fat layer and subcutaneous tissue to expose the linea alba. An incision is made through the linea and is extended. Usually, a layer of fat is encountered. The uterus of ferrets is bicornate, as in cats. The uterus can be elevated by using a spay hook, or sometimes it can be seen lying just under the incision by bluntly moving the fat. The uterus of the ferret is not nearly as friable as that of the rabbit. Ferrets have a high degree of body fat, and the ovarian tissue and vessels may be obscured. The surgeon must be certain to ligate the ovarian vessels completely using 2-0 or 3-0 gut. The uterus is easily exteriorized and the suspensory ligament is readily torn. The uterus is ligated with gut and is removed. The abdomen can be closed with any of several sUi types in a simple interrupted pattern using 4 U nlonl filament absorbable or nonabsorbable material. The same suture or gut can be used for the subcutaneous or subcuticular layer. The skin can be closed with 3-0 or 4-0 nylon. Chewing of sutures has not been a problem. If the surgical procedure is performed in the morning, the ferret is released the same day. Postoperative antibiotics are not necessary. Skin sutures are removed in 7 to 10 days.

Orchiectomy

Like ovariohysterectomy, orchiectomy (castration) is usually done in young ferrets before they are sold to pet stores. For this reason, the average practitioner is not called on to perform this operation routinely. If an intact male ferret is presented, the owners should be encouraged to have the ferret castrated. In some cases, intact male ferrets are more aggressive, especially if intact females are nearby. The main objection to intact males is the heavy musky odor they produce. Many times, castration alone is enough to control odor, making descenting unnecessary. Testicular tumors have been reported, but a true incidence is difficult to estimate because most domestic ferrets arc neutered.[4,5]

Castration in the ferret is similar to castration in the dog. The ferret is placed in dorsal recumbency, and the prescrotal area is shaved. One prescrotal incision is made through which both testicles may be exteriorized. An open or closed method can be used. The spermatic cord and vessels are ligated with 4-0 gut, are iricised, and allowed to retract into the incision. The subcutaneous tissue is closed with gut, and the skin is closed with 4-0 nonabsorbable suture, which is removed in 7 to 10 days. Chewing the sutures has not been a problem. Alternatively, two incisions can be made in the scrotum, and the vessels can be clamped and ligated with 4-0 chromic gut. With this method, the scrotal incisions are not closed, similar to the procedure in cats. The ferrets are released the same day.

Adrenalectomy

Adrenal tumors are among the most common neoplasms of ferrets. In our practice, adrenalectomy is the single most common surgical procedure performed in these animals, followed by insulinoma resection. In a retrospective study performed at our hospital and the Animal Medical Center from 1987 to 1991, the following types and frequency of biopsy results were recorded: adrenocortical adenoma, 64%; nodular adreno cortical hyperplasia, 26%; and adrenocortical carcinoma, 10%. In the patients with adreno cortical carcinoma, no gross or microscopic evidence of metastasis was seen. In addition, 70% of the cases occurred in females.[6] Since this study, I have had the opportunity to operate on many more cases and have found that the biopsy percentage has shifted to adrenocortical adenoma. Hyperplasia now accounts for 95% of the cases, and the ratio of males to females has equalized. In addition, the earlier study found that 64% of ferrets had disease of the left adrenal gland, 20% had disease of the right gland, and 16% had bilateral disease. In the years after the study, my colleagues and I have seen left sided disease in 75% of patients, right sided disease in 15%, and bilateral disease in 10%.

Clinical signs, in order of decreasing frequency, are vulvar swelling, alopecia, pruritus, polydipsia, and polyuria. The diagnosis is based on clinical signs and abdominal ultrasonography. The accuracy of the ultrasound diagnosis depends on the experience of the ultrasonagrapher. Recently, a study indicated that the concentrations of certain plasma steroid hormones can be used as a marker for the disease.[7] Even though the clinical signs may indicate the presence of an adrenal tumor, the clinician should obtain a presurgical ultrasound study whenever possible. This examination helps to rule out other causes of the clinical signs and indicates which adrenal gland is diseased. This distinction becomes important because removal of the right gland is technically more difficult, owing to its location under the caudate liver lobe and its proximity to the vena cava. The differential diagnosis of adrenal gland disease includes ovarian remnants, an intact female reproductive tract, pheochromocytoma, seasonal hair loss of ferrets, nutritional deficiencies,[8,9] mycosis fungoides,[10] and infestation by external parasites. I have also seen a ferret with cutaneous *Malassezia pachydermatis* infection that caused generalized hair loss. Adrenal disease in ferrets is not the same as Cushing's disease because the clinical signs and pathologic changes are not caused by an increase in plasma cortisol concentration.

Preparation

After the diagnosis is made, a complete blood screen and chemistry panel should be evaluated for each patient. Any abnormalities should be investigated and treated preoperatively. One of the most common abnormalities is hypoglycemia because many ferrets concurrently have insulin secreting tumors of the pancreas. Because these islet cell tumors are generally malignant, the prognosis should be discussed with the owners before proceeding. In addition, an in hospital blood glucose determination should be made immediately before anesthesia is induced, to make certain the blood sugar is still normal after the presurgical fasting period. Another important presurgical consideration is the possibility of underlying cardiac disease. Both hypertrophic and dilated forms of cardiomyopathy are seen in ferrets.[11] At this time, clients are advised that a presurgical echocardiogram should be performed if possible. If this is not feasible, chest radiographs and careful cardiac auscultation should be performed. Every patient undergoing adrenalectomy receives an intravenous catheter. Various fluid types may be used; however, if one has any question about the presence of

an insulinoma, 5% dextrose is the fluid of choice. Each patient receives a presurgical injection of antibiotics.

Left Adrenalectomy

The ferret is placed in dorsal recumbency, and the abdomen is shaved from the area of the xiphoid cartilage to the inguinal area. An incision is made starting 1 to 2 cm from the xiphoid and extending 4 to 5 cm caudally. After dissecting through the fat and subcuta¬neous tissue, a stab incision is made in the linea alba and is extended with scissors. A self retaining Gelpi retractor should be used for good exposure. As in other species, a complete abdominal exploratory operation should be performed. It is especially important to check the pancreas for the possibility of insulinoma nodules (see later). In addition, all male ferrets should be examined for the presence of paraurethral cysts (discussed later). The surgeon generally must retract the spleen and intestines toward the right side of the ferret's body. A laparotomy pad soaked in warm saline can be used to hold structures away from the surgical site. Alternately, the spleen and small intestines can be exteriorized through the incision and placed to the right. This maneuver pulls the mesentery away from the area of the adrenal gland and affords excellent exposure. Any exteriorized tissues should be covered with a warm moist lap pad to prevent tissue drying. The left adrenal gland is located just medial and proximal to the left kidney. This gland is located within a fat pad, and if diseased, it is usually irregular in shape and readily seen. In some cases, one sees a brownish-yellow discoloration. Digital palpation reveals the presence of borders on the mass. The dissection is begun on the medial side of the gland through the fat layer using Mayo scissors and is continued bluntly with mosquito forceps and sterile cotton tipped applicators. The gland is gently elevated as the dissection is continued. The small blood vessels in the fat generally do not have to be ligated. The adrenolumbar vein runs laterally and caudally from the ventral surface of the adrenal gland. It can be seen as the gland is elevated. This vessel is ligated using 4 0 chromic gut or a surgical clip (Hemoclip). The gland is continually elevated and dissected until a suture can be placed below it. The tissue is then incised, and the gland is removed. Closure is the same as for an ovariohysterectomy. Because this is a major abdominal procedure, patients are hospitalized for 1 to 2 days postoperatively. Amoxicillin oral suspension at a dose of 10 mg/lb is dispensed for 7 days.

Right Adrenalectomy

As mentioned previously, removal of the right adrenal gland is a technically more difficult procedure. After entry into the abdominal cavity, and a general exploratory operation, the spleen and intestines are moved to the left or are exteriorized. The right adrenal gland is located under the caudate liver lobe. The hepatorenal ligament must be incised to elevate the tip of the liver lobe. The lobe is then reflected cranially. The adrenal gland is usually directly adhered to the vena cava (Figure 45-1). One must be careful to avoid lacerating this major vessel. The surgeon begins shelling out the gland by sharp dissection of the surface furthest from the vena cava and continues around the gland using iris scissors, mosquito forceps, and sterile cotton swabs. When the gland is mostly peeled away, a Hemoclip or a ligature using 5-0 absorbable suture is placed between the gland and the vena cava. Any remaining glandular tissue is trimmed using the iris scissors. One should have available 5-0 and 7-0 suture as well as sterile sponges (Gelfoam) in the event that the vena cava is lacerated. When one is certain that all hemorrhage has been controlled, closure is as described earlier.

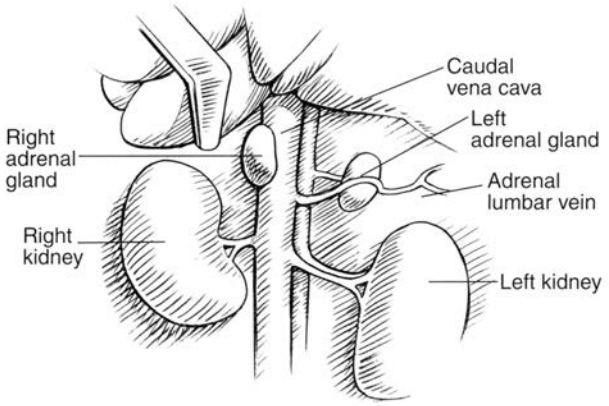

Figure 45-1. Appearance of the adrenal glands. The caudate lobe of the liver has been reflected cranially. The right adrenal gland usually adheres to the vena cava.

Bilateral Adrenal Disease

When both adrenal glands are abnormal, the surgeon removes the left entirely and debulks the right. If incised, the adrenal gland bleeds profusely. One begins Caudal venacava dissecting the gland and places a crushing suture around the part that has been freed, using 4-0 monofilament absorbable or nonabsorbable material. Iris scissors can then be used to cut above the suture. The surgeon removes 50 to 75% of the right adrenal tissue.

Complications

The most common complication of adrenalectomy is prolonged or difficult recovery resulting from hypogly cemia secondary to an undiagnosed insulin secreting tumor of the pancreas. In fact, when ferrets are referred to my practice for postsurgical problems blood glucose concentrations are frequently found. For this reason, a blood glucose determination is performed before the surgical procedure and 1 to 2 hours postoperatively. Many times, fluids containing dextrose are used as a precaution. Ferrets are encouragcd to eat after they are fully awake, and Deliver (Deliver I 2.0, Mead Johnson Nutritionals, Evansville, 'N) is often administered orally within 3 to 4 hours postoperatively. Vomiting has not been a problem.

Another problem commonly encountered is hypothermia. Intravenous fluids should be warmed before administration. We use a warm water heating pad and heat lamp during and after surgery. Ferrets are generally hardy and are good surgical candidates. Postoperative infections appear to be rare.

Even with the removal of the left adrenal gland and part of the right, most patients do not appear to require hormonal supplementation. Vital signs in these ferrets should be monitored closely in the immediate postoperative period. If recovery is prolonged or if the patient is dping poorly, a blood glucose

determination should be made. If the blood glucose level is normal, corticosteroids can be administered, and blood can be saved for a resting cortisol level to ascertain the need for continued cortisone supplementation.

Paraurethral Cysts

One problem encountered with male ferrets with adrenal disease is the presence of paraurethral cysts. Animals with this condition present with dysuria or total blockage along with other signs of adrenal disease. The cysts are thought to arise from prostatic tissue that has been stimulated by the hormones released from the adrenal gland. These cysts are present just caudal to the bladder and can usually be felt by external abdominal palpation (Figure 45-2). If the urinary tract is totally obstructed, the blockage must be relieved. This procedure can be challenging because the penis is difficult to catheterize as a result of the os penis. I have been most successful using a tomcat catheter or 3 French red rubber catheter. At the present time, the best treatment (Figure 45-2). A paraurethral cyst around the neck of the urinary bladder.) appears to be adrenalectomy. In addition, one should attempt to aspirate material from the cyst during the surgical procedure using a 22 gauge needle and a 3 mL syringe. The material in the cysts appears flocculent. Because the cysts are usually multiloculated, a few attempts should be made into different areas. Leakage from the cysts after this procedure has not been a problem. The cysts regress after the adrenal tumor has been removed. The ferret is kept on postoperative antibiotics for 14 days. In a few cases, cysts that have not regressed and that cause reobstruction need to be marsupialized. In severe cases, pre scrotal or perineal urethrostomies can be performed. In these patients, the cysts should regress after 3 to 4 weeks of antibiotic therapy.

Prognosis

The prognosis for patients undergoing adrenalectomy is excellent. It is the treatment of choice for this condition. In females, the swollen vulva may begin to shrink within 1 to 2 days. Hair loss takes longer to resolve. My impression is that the longer the interval between the onset of clinical signs and surgery (and usually the more extensive the alopecia), the longer the hair takes to regrow. Clinical signs return in some patients, and a second surgical procedure will be needed to remove the other gland, which has since become diseased.

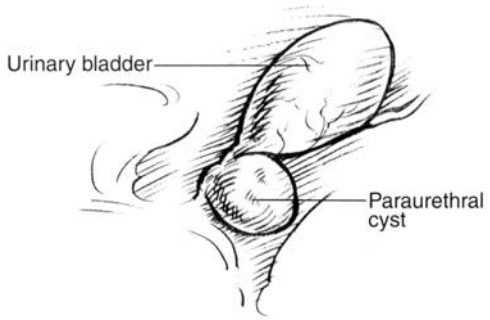

Figure 45-2. A paraurethral cyst around the neck of the urinary bladder.

Insulinoma

As previously mentioned, insulinoma surgery is the second most common procedure performed in my practice. Signs are due to hypoglycemia and range from ferrets who begin to sleep more and seem lethargic, act nauseated, and paw at their mouths, to episodes of "vacant expressions" and staring into space, to hind limb weakness and collapse, to seizures and coma. Signs can be intermittent and can resolve quickly. Because this disease is commonly seen in ferrets over 3 years of age, early signs may be interpreted as normal aging. Diagnosis is based on the demonstration of low blood glucose concentrations and hyperinsulinemia. After a 3 hour fast, normal blood glucose should be above 80 mg/dL. Levels below 65 mg/dL suggest the diagnosis. Prolonged anorexia or starvation can produce a blood glucose level this low, but the presence of an insulinoma is much more common. Many times, the blood glucose level is below 50 mg/dL. Blood glucose levels between 65 and 80 mg/dL are suggestive of this diagnosis, and the fast should be continued for another 1 to 2 hours and an insulin level checked. An abnormally high insulin level along with low blood glucose is diagnostic.

Often, treatment begins with medical intervention. It is effective in the early course of the disease and has been used for 3 months to 2 years. Therapy is begun with prednisone at a dose of 0.5 to 2 mg/kg. The dose can be increased over time to keep clinical signs under control. Diazoxide (Proglycem), at a dose of 5 to 10 mg/kg, can be added to the prednisone regimen. It inhibits insulin release and stimulates hepatic gluconeogenesis.[12] Sometimes, the dose of prednisone can be lowered when diazoxide is added. Side effects in other species include vomiting and anorexia, but these effects are rare in ferrets. The easiest form to adminis¬ter is the suspension, which is expensive.

Owners are instructed to, feed ferrets with insulinomas frequently. Owners are also instructed to avoid high sugar or carbohydrate containing supplements unless treating a hypoglycemic episode. These foods or treats can stimulate insulin secretion and can cause rebound hypoglycemia. These ferrets should be fed a high quality ferret or cat food containing an animal protein source. Brewer's yeast should be added to the diet at a rate of one quarter teaspoon twice daily because it is a good source of chromium, which helps to stabilize blood glucose and insulin levels in humans.[13] Deliver makes an excellent supplement because of its high fat content and acceptance by almost every ferret. Medical treatment is indicated in ferrets that are poor surgical 'candidates or whose owners decline surgery for their pet. Clients should be informed that the /3 cell tumors are almost always malignant, and surgical treatment appears to slow the progression of the disease. Many ferrets become normoglycemic at least for a time after surgery. Clinical impression is that ferrets seem to do better for longer with a combination of surgical and medical treatment. In dogs with insulinomas, surgical treatment prolongs life span over medical management alone.[14]

Surgery is generally recommended in ferrets younger than 5 or 6 years of age. All ferrets should be carefully screened for other diseases, especially cardiac disease. As mentioned in the discussion of adrenal surgery, a cardiac ultrasound study

is recommended as a presurgical screen. Often, surgery is performed concurrently for adrenal disease and insulinoma. Presurgical fasting is usually limited to 3 to 4 hours. An intravenous catheter is placed in all cases, and warmed 5% dextrose is administered during the surgical procedure.

As with adrenal surgery, a midline incision is made, and a standard exploratory operation is performed. I have seen metastasis of β cell carcinoma to the spleen and liver. In patients with splenic metastasis, splenectomy was performed. Most commonly multiple, and infrequently solitary, nodules are present. The entire pancreas should be inspected visually and also palpated. The nodules usually appear as raised areas that may be lighter in color. Sometimes, the nodules are not evident visually, yet they are firmer than the surrounding tissue, so careful digital palpation is imperative. In most cases, blunt dissection enables the surgeon to shell out the affected areas. Some minimal bleeding occurs, but it usually stops with pressure or Gelfoam application. In some cases, 5-0 or 6-0 polyglycolic acid (Dexon), polyglactin 910 (Vicryl), or polydioxanone (PDS) can be used to ligate larger vessels. If numerous nodules are present, a partial pancreatectomy can be performed. The previously listed absorbable suture can be used to ligate the pancreatic tissue in a crushing manner. If the area is small enough, one circumferential ligature can be placed around the area to be removed, or the suture can be placed in the center of the area and transfixed in both directions (Figure 45-3). In this manner, less tissue is included in each tie. Pancreatitis does not seem to be a problem after surgery.

Blood glucose should be measured postoperatively and at reasonable intervals during recovery. Some ferrets become normoglycemic 1 to 2 days postoperatively. In many cases, I observe only a slight increase in measured blood glucose, although the ferrets appear to improve clinically. Often, medical management must be continued. Some patients have Postoperative hyperglycemia, which is usually transient and reso1ves within 3 to 5 days.

The surgeon must inform clients that this is a maiignant neoplasm,[15] and a cure should not be expected. One should also be sure that clients understand that medical intervention may need to be continued or resumed as the disease progresses. Even with these caveats, I believe, based on many cases, that a combination of surgical and medical management yields the best results for the longest period.

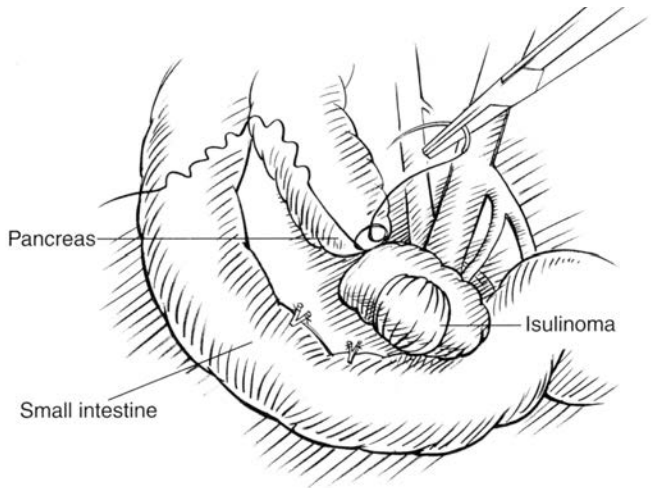

Figure 45-3. Transfixation and removal of a portion of the pancreas containing a nodule of moderate size.

Foreign Body Surgery

Foreign body ingestion by ferrets is common, especially in young animals. The most common materials are pieces of a ferret's plastic or rubber toys. For this reason, I recommend that owners do not provide ferrets with the soft squeaky toys commonly sold for use by ferrets or with toys made of any other material soft enough to be chewed apart. Hard nylon (Nylabone type) toys are acceptable. Other foreign bodies seen include trichobezoar, pieces of foam rubber, cork, the hard ends of shoe laces, and almost anything one could imagine.

Clinical signs include anorexia, vomiting, diarrhea, and weakness. In general, ferrets do not exhibit vomiting as often as dogs and cats, but they appear nauseated by stretching the neck and retching, salivating, and pawing at the mouth.

Diagnosis is made by history, abdominal palpation, and plain and contrast radiography. Ferrets often exhibit pain on abdominal palpation. In my experience, ferrets with trichobezoars exhibit less severe clinical signs. The most common location for foreign bodies is the small intestine, but they may also be located in the stomach or esophagus.[16,17]

In some cases, endoscopy may be helpful to remove esophageal and gastric'foreign bodies. I use a pediatric bronchoscope. The diameter is too large to be useful for the small intestine.

Surgical Procedure

In many cases, ferrets with foreign body ingestion exhibit anorexia and are dehydrated. Therefore, adequate rehydration is important. Surgery should be considered an emergency and performed as soon as possible. A standard midline approach is used, and a complete examination of the intestinal tract is performed to check for multiple foreign bodies. In patients with esophageal or proximal duodenal obstruction, the surgeon should retropulse the material into the stomach and perform a simple gastrotomy. Gastric surgery is similar to that in the dog or cat. Closure is accomlished with a double layer simple interrupted pattern using 4-0 absorbable material.

Because of the small diameter and fragility of the intestines, gentle tissue handling is important, to mini-ize stricture of the surgical site. The incision is made jn the antimesenteric border and is closed with 4-0 or 5-0 monofilament nonreactive suture in a simple interrupted pattern. Because of its handling characterstics, I prefer 5-0 polydioxanone (PDS). If the section:of intestine appears devitalized, an intestinal resection and anastomosis should be performed. The procedure is the same as in dogs and cats. The surgical site and abdomen should be flushed completely with warmed saline solution. The omentum should be placed over the area to aid healing. Closure is routine, and as in all gastrointestinal surgery, care must be taken to avoid contamination.

Ferrets are offered water and Deliver about 12 hours postoperatively, and they are encouraged to eat solid food within 24 hours. Intravenous fluids should be continued until the patient is eating well.

Anal Sac Resection in the Ferret

James E. Creed

Introduction

The ferret is a popular house pet; however, odor emitted from the anal sacs of both sexes is often objectionable. Like nearly all carnivores[1] and all mustelids,[2] the ferret has an anal sac on each side of the anus. The ducts open at 4 o'clock and 8 o'clock positions on the inner cutaneous zone of the anus, adjacent to the mucocutaneous junction. The sacs are interposed between the internal and external anal sphincter muscles. Material stored within the sac is secreted by a glandular complex surrounding the neck of the sac and 3 to 4 mm of the duct. This complex is evident without magnification, but a binocular loupe enhances visualization. The sebaceous gland component surrounding the distal part of the duct is covered asymmetrically by an apocrine gland component.[3] Surgical removal of the anal sacs and their ducts eliminates the odor of anal sac secretions, but some odor from sebaceous and apocrine tubular glands in the perianal region typically persists.

Indications

Client request is the principal indication for performing this procedure. However, veterinarians should recommend this operation for all ferrets at 6 to 8 months of age to make them more acceptable pets. Neutering should be recommended at this age in ferrets of both sexes to reduce odor further. Neutering also prevents development of aplastic anemia in nonbreeding females, which can develop from hyperestrinism associated with prolonged estrus.[3,4] The client must be made aware that anal sac resection and neutering do not eliminate all "musky" odor, because of sebaceous and apocrine glands in the ferret's penrianal skin.

Preoperative Considerations

In addition to a complete physical examination, the patient's packed cell volume of blood and total serum protein level should be determined. One study of 11 healthy male ferrets reported an average packed cell volume of 52.4% and average total serum protein of 6.0 g/dL.[3] Food should be withheld for 12 hours. Anesthesia is induced with oxygen and an appropriate gaseous agent in an anesthesia chamber; it can be maintained with a mask or an endotracheal tube 2.5 mm in inner diameter (12 French outer diameter, Cole, Intermountain Veterinary Supply, N. Kansas City, MO). An alternate method is intramuscular injection of ketamine hydrochloride (26mg/kg) and acepromazine (0.2 to 0.3mg/kg).[5]

The ferret may be positioned for anal gland resection in dorsal or ventral recumbency. Because neutering is frequently performed and is best accomplished in dorsal recumbency, all ferrets should be positioned in this way, to provide consistent orientation of anatomic structures. The ferret is placed at the end of a table on a sandbag or similar pad to prevent loss of body heat, with its pelvic limbs pulled craniad and its tail dropped. The scrotal or ventral abdomen and perianal regions are prepared and draped

for the surgical procedure. Aseptic neutering is accomplished, and then the surgical drape is shifted to expose the anal region.

Surgical Technique

A binocular loupe should be used to locate the minute opening of each anal sac duct and to aid visualization throughout the procedure. The opening of each duct and the surrounding 2 mm of skin and mucous membrane are grasped with mosquito forceps. A circumferential incision is made with a No. 15 Bard Parker scalpel blade immediately distal to the forceps tip; one must be careful not to incise too deeply. Using a gentle scraping action with the blade, skin and mucosa are reflected from the duct (Figure 45-4). The glandular complex surrounding the terminal 3 to 4mm of the duct makes dissection difficult (Figure 45-4C). This complex has a nodular surface, with skeletal muscle fibers inserting into the glandular tissue. One should not attempt to find a fascial plane at this level, and dissection should be superficial with respect to overlying tissue. Shifting the mosquito forceps to clamp them across skin, mucous membrane, and terminal duct should prevent tearing the duct as caudal traction is applied with the forceps (Figure 45-4E). Applying another forceps parallel to the first provides even more support.

A fascial plane is encountered as dissection is carried beyond the glandular complex (Figure 45-4B). The anal sac can be removed readily by reflecting sphincter muscles off the sac wall with a scraping action of the scalpel blade. Staying on the proper fascial plane not only enhances sac removal, but also minimizes hemorrhage and damage to internal and external anal sphincters. If the fascial plane is followed, little muscle will be left on the sac wall. The wall appears yellowish white; it is thin, and glandular secretions are yellow. It is easy to rupture the duct and sac, particularly if the veterinary surgeon is inexperienced. Trying to establish a fascial plane before dissecting beyond the nodular glandular complex is futile and particularly hazardous, because it is easy to cut into the duct lumen. If the duct or sac is incised, surgical extirpation can still be accomplished, but the absence of a distended sac makes the operation more tedious. Odor from an incised or ruptured sac is obnoxious, but not overwhelming.

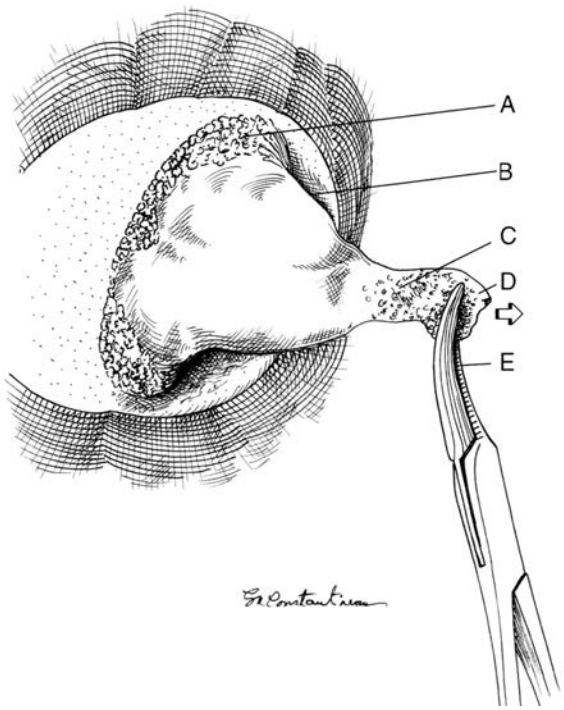

Figure 45-4. *A-C.* Resection of the anal sac. External anal sphincter muscle *A.* Wall of the anal sac *B.* Nodular glandular complex surrounding the duct *C.* End of the anal sac duct *D.* Tip of mosquito forceps grasping skin, mucous membrane, and terminal duct *E.*

Intraoperative hemorrhage is negligible, although sterile cotton tipped applicator sticks work well to clear oozing blood from the surgical field. Placement of sutures and administration of local or systemic antibiotics are not required.

Postoperative Care

The patient is normally discharged when recovery from anesthesia is complete. Although no serious postoperative sequelae have been observed, complications can occur. Persistent minor hemorrhage may develop postoperatively, but this ceases spontaneously. Potential complications include prolapsed rectum and fecal incontinence if trauma to the anal sphincter muscles is excessive. Staying on the proper fascial plane minimizes trauma and the possibility of these serious sequelae.

Soft Tissue Surgery in Reptiles

Steve J. Mehler and R. Avery Bennett

Introduction

In recent years reptiles have become increasingly popular as pets. Veterinarians are called upon to perform a variety of medical and surgical procedures on these animals.[1,2] The anatomy and physiology of reptiles differs from the more familiar mammalian patients and the surgeon must be familiar with these differences. Skin incisions are generally made between scales in the thin softer tissue between them. It is assumed that healing in this skin is more rapid than when an incision is made through the tough scales. A number 11 scalpel blade is particularly useful for skin incision as its fine tip allows the surgeon to incise with more precision in the zig-zag pattern required to cut between scales (Figure 45-5). In a retrospective report there was no difference in healing when the incision for celiotomy in snakes was made through the scutes (large ventral scales) on the midline compared with a lateral incision between scales.[3]

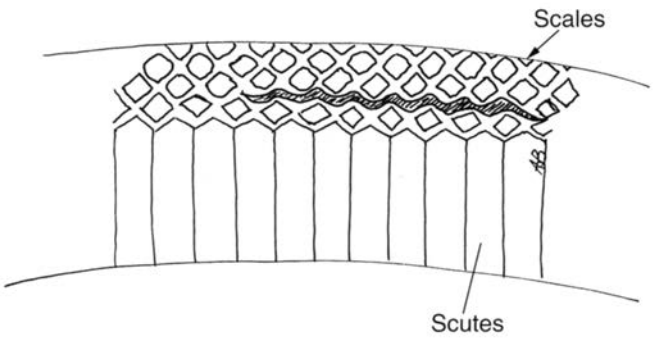

Figure 45-5. The skin incision for a lateral celiotomy in a snake is made between the first two rows of scales dorsal to the large ventral scales (scutes). The incision is made in the soft skin between the scales.

The incised skin of most reptiles has a tendency to invert. Because of this, an everting skin closure pattern, such as an interrupted horizontal mattress, is commonly used. Alternatively, skin staples are designed to slightly evert the skin edges when applied and serve nicely for skin closure in reptiles. Reptiles have very little subcutaneous tissue and most incisions are closed with sutures in the deep tissues and skin only. The skin of reptiles is very tough and is considered the holding layer for wound security. For example, when closing a celiotomy in an iguana, the body wall muscle is very thin and does not hold suture well. No distinct fascia is identified and the muscle does not easily separate from the skin. A two layer closure is used with a simple continuous pattern in the body wall and an everting pattern in the skin recognizing that the skin is the holding layer. Sutures are tightened to gently appose the skin edges. Sutures tightened excessively will cause necrosis of the skin within the suture and dehiscence of the incision. Reptiles do not traumatize their skin incisions or remove sutures.

The tissue reaction to 8 types of suture material and cyanoacrylate tissue adhesive placed between the skin edges in ball pythons (Python regis) has recently been reported. One centimeter skin incisions were made and a piece of suture placed in the wound. The same suture material was used to close the skin over each piece of implanted suture. One wound was left to heal by second intention and served as a control. Cyanoacrylate was not significantly different from the control wound. All suture materials induced an inflammatory response. No suture material was was absorbed at 90 days. In many instances, the inflammatory response progressed with time and in some wounds suture had been or was in the process of being extruded from the tissues. Materials that are more rapidly absorbed such as poligliecaprone 25 and chromic catgut were in the process of being absorbed at 90 days while other sutures with longer absorption times such as polydioxanone may take years to be completely absorbed. In another study polyglactin 910, poliglecaprone 25, and polyglyconate were evaluated in the skin of juvenile loggerhead sea turtles *(Caretta caretta)*. Polyglactin 910 induced statistically significant more panniculus inflammation in juvenile loggerhead sea turtles and poliglecaprone 25 and polyglyconate caused the least cutaneous tissue reaction.[5] Chromic catgut has been observed to induce granuloma formation and was not absorbed 12 weeks postoperative in some reptiles[6] but appears to be less inflammatory in some chelonians.[5]

Given the variety of suture materials on the market that induce less inflammation and have more predictable absorption rates, the use of chromic gut is not advised. Synthetic absorbable monofilament suture materials are preferred but absorption appears to be prolonged in reptiles compared to mammals. If absorbable suture materials are placed in the skin, it should be anticipated that they will require removal.

Skin suture removal is generally not attempted for at least 4 weeks postoperative. At that time incisional healing is assessed by gently teasing the incision edges to determine wound security. Often only every other suture is removed at 4 weeks and the remaining sutures removed 2 to 3 weeks later. Ecdysis (skin shedding) is considered to speed wound healing as during this time the epidermis is metabolically active. Because of this many surgeons prefer to wait for suture removal until after the subsequent ecdysis. Environmental temperature has been shown to have an effect on wound healing in reptiles.[7] The patient is maintained at the upper end of its preferred optimum temperature range during the recovery period to promote healing. Following suture removal, the skin will frequently stick to the incisional scar for several sheds (ecdysis) but this eventually resolves.

Anatomy

Prior to undertaking a surgical procedure in a reptile patient, the surgeon must become familiar with the unique anatomy of the particular family of reptiles to which the patient belongs.[1-3] There is variation in anatomy among families of reptiles; for example, crocodilians are considered to have a 4 chambered heart while squamates (lizards and snakes) and chelonians (turtles and tortoises) have a 3 chambered heart.[8-11] There is also variation within a family of reptiles. In green iguanas, the kidneys are normally located within the pelvic canal while in monitor lizards they are within the coelomic cavity.

Some features are relatively consistent across species of reptiles. In general, reptiles do not have a muscular diaphragm and, as such, have a ceolomic cavity rather than thoracic and abdominal cavities; however, crocodilians do have a relatively well developed septum between the thoracic viscera and the abdominal viscera. Reptiles do not have lymph nodes. They do not store fat in the subcutaneous tissue but have discrete fat bodies within the coelom. In some species the spleen and pancreas are intimately associated with each other forming a splenopancreas.

The urinary system of reptiles is substantially different from mammals. Reptiles have a renal portal system such that, when the portal vein is open, blood from the caudal half of the body passes through the kidney prior to reaching the systemic circulation. Urine leaves the kidneys through the ureters which empty into the cloaca, not the urinary bladder. Urine then travels from the cloaca into the bladder of those species with a urinary bladder (chelonians and some lizards) or into the colon in those species without a bladder (snakes, crocodilians, and some lizards) where water absorption and ion exchange occur.[8-11] Urine does not flow through the reproductive system and the short urethra only connects the bladder to the cloaca.

The cloaca receives excretions from the ureters, colon and urinary bladder in those species with a bladder, and the reproductive system. Chelonians and crocodilians have a single copulatory organ (penis) while squamates have paired copulatory organs called hemipenes (hemipenis, singular). The copulatory organs do not contain tubular structures such as a urethra. Semen travels along a groove in the hemipenis into the cloaca of the female. The female reproductive tract is bilateral in reptiles with each oviduct having a separate opening into the cloaca.

Celiotomy

The approach for celiotomy in reptiles varies with the family of reptile. Because reptiles lack a diaphragm celiotomy can allow access to both thoracic and abdominal viscera.

Lizards and **crocodilians** have a body structure more similar to mammals than chelonians and snakes. A paramedian incision is recommended in these species because of the ventral abdominal vein. This vein receives blood from the caudal abdominal wall and courses along the ventral midline 2 to 3 mm inside the body wall. It is located between the umbilical scar and the pubic bones and is suspended by a short mesovasorum. Some surgeons prefer a midline approach using meticulous dissection to avoid damaging this rather large vein.[3] Making a paramedian incision 2 to 4 mm lateral to midline minimizes the risk of lacerating this vessel. It has been reported that this vein may be ligated without consequence.[2,3]

Closure is accomplished using a simple continuous pattern with a synthetic absorbable material on a fine, atraumatic swaged-on needle. Because the muscle of the body wall is thin and tightly adhered to the skin, care must be taken with suture placement and tension on the suture or tearing through the muscle will occur. Suturing the body wall will pull the skin edges into apposition. Skin staples or an everting pattern of a nonabsorbable material maintain skin apposition.

In laterally compressed lizards, such as chameleons, an intercostal or paracostal approach is more appropriate. The ribs in the species extend caudally close to the hip and femur so there is little space to enter through this approach alone. Exposure can be improved by combining the intercostal or paracostal approach with a ventral midline approach creating a flap on one side or the other. For closure, suture the apex of the triangle of body wall created to the cranial aspect of the ventral midline incision. Then suture the paracostal or intercostal body wall followed by closure of the ventral midline incision. The skin is closed routinely.

Snakes have organs arranged in a linear configuration. In most cases, the specific organ being approached must be identified preoperative as celiotomy will not allow access to all of the viscera. It is essential to know the location of the specific organ being approached.[12]

The coelomic membrane may be closed as a separate layer or incorporated in the body wall closure. The body wall is a thin pale muscle that is tightly adhered to the skin. The coelomic membrane is not attached to the skin. The muscle of the body wall is closed with a simple continous pattern using a synthetic absorbable material on a fine atraumatic needle which will also approximate the skin edges. The skin is closed with either skin staples or an everting pattern such as a horizontal mattress.

Chelonians present a unique challenge for celiotomy because of their shell. For most procedures a plastron osteotomy is required. In species with a small plastron, such as snapping turtles and sea turtles, some procedures can be accomplished through a flank incision. Some procedures, such as cystotomy, can be accomplished through this approach in other chelonians.[3]

The pelvic bones are avoided during plastron osteotomy to avoid injury to the appendicular skeleton. Radiographs are helpful in assessing the location and extent of the pelvic bones. In most species, osteotomy through the femoral and abdominal epidermal shields (Figure 45-6) will allow access to coelomic viscera while avoiding injury to the appendicular skeleton and heart. The osteotomy must be large enough to allow the procedure to be accomplished and located in a position to allow access to the target organ.

Plastron osteotomy is performed using a power or pneumatic bone saw, or a sterile motorized wood working tool with a fine circular saw blade. Standard bur bits are not recommended because they cut an excessively wide osteotomy which will delay bone healing. Standard surgical preparation is performed and the surface of the plastron must be completely free of keratin

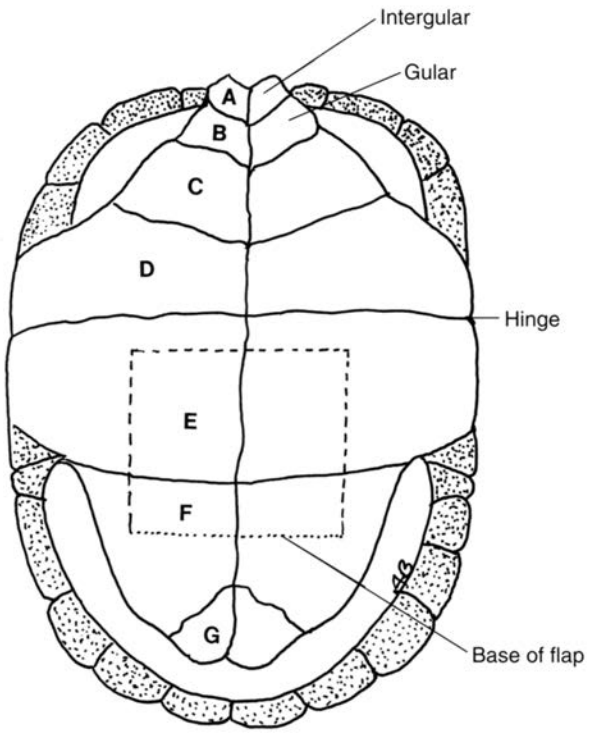

Figure 45-6. The plastron osteotomy for celiotomy in chelonians is generally made in the femoral *F.* and abdominal *E.* epidermal shields. If the osteotomy is made too cranial the heart can be injured and if too caudal the pelvic bones can be damaged. *A.* intergular, *B.* gular, *C.* humeral, *D.* pectoral, *E.* abdominal, *F.* femoral, *G.* anal.

debris and soil. This requires a surgical scrub brush. Alcohol, ether, or acetone is used to remove grease from the surface of the plastron to allow a better bond to form between the keratin and the epoxy resin that will be used to stabilize the plastron osteotomy postoperative.

The plastron is dermal bone and efforts are made to improve the environment for bone healing. The osteotomy cut is beveled slightly and the blade should be as thin as possible so when the segment of plastron is replaced, bone-to-bone contact will be achieved (Figure 45-7). The blade is irrigated while performing the osteotomy to dissipate heat and control bone dust. It is best to make a 3 sided osteotomy in species with a hinge (e.g. box turtles). An osteotomy is made on both sides as well as the caudal margin of the proposed flap. The segment of plastron is then reflected craniad based on the intact hinge which will provide blood supply to the segment of bone. For those species without a hinge (most tortoises), the segment is cut along the cranial or caudal border and the two sides. The fourth side is partially cut with the saw and then, as the section of bone is elevated, it is cracked along the remaining border to preserve some blood supply as well as some stability.

After the bone has been osteotomized, a periosteal elevator is used to dissect the body wall off the plastron preserving the attachments of the pelvic or pectoral musculature. It may be difficult to bend the segment beyond 90 degrees and it may require an assistant to hold the segment up and out of the surgeon's field while the procedure is performed. There are two large venous sinuses within the coelomic membrane located paramedian on each side between the midline and the bridge (junction of the plastron with the carapace). These are generally obvious during the intial approach but once manipulated, undergo vasospasm and become relatively imperceptible. Care is taken not to damage these vessels so when they dilate following closure, hemorrhage does not occur. It has been reported that they can be ligated without consequences.[2,3] The incision into the coelom is made along the ventral midline. The membrane is thin and transparent in the central region where there is no muscle.

Closure is accomplished using a synthetic absorbable material in the coelomic membrane and body wall. The bone flap is replaced and secured using epoxy resin and fiberglass cloth.

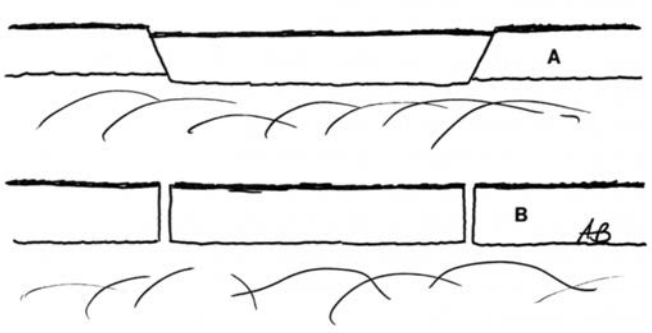

Figure 45-7. A bevel cut is recommended for plastron osteotomy to achieve postoperative bone-to-bone contact for more rapid bone healing. *A.* When the flap is replaced after a bevel cut, the bone contacts bone. *B.* With a vertical cut, a gap is created.

Epoxy is mixed and applied 2 to 3 cm around the periphery of the plastron osteotomy and over the entire bone segment leaving a 3 to 4 mm border around the osteotomy on both sides to prevent the resin from flowing into the osteotomy which would delay healing. A sterile autoclaved piece of fiberglass cloth is placed over the plastron flap with a 2 to 3 cm border extending over the osteotomy onto the plastron. The epoxy already on the plastron is gently worked into the cloth being careful not to allow the resin to seep into the osteotomy. The epoxy is allowed to cure and a second layer is applied over the entire patch. This layer should be thin enough that the resin does not soak through the cloth and into the osteotomy. Enough layers of epoxy are applied to create a completely smooth surface with no texture from the cloth remaining. During the final curing process, a piece of plastic sheeting or wax paper is applied to the patch to prevent paper or soil from adhering to the resin. This will not stick to the epoxy and is removed the following day. Within 24 hrs the resin is completely cured and the turtle can resume normal activity, including swimming. Some surgeons prefer to apply a thin layer of antibiotic cream along the osteotomy site to prevent resin from entering and provide some antibacterial activity.

Healing of a plastron ostetomy requires 1 to 2 years.[3] Patches have remained viable for over 5 years and are generally not removed. Often, the patch will fall off on its own; however if the borders become elevated from the plastron, the patch can be pried off. In young growing chelonians, the patch is cut at the growth rings after bone healing is complete to allow for shell growth. Because the epoxy is potentially carcinogenic, the cuts are best made under a hood or, at least, in a well-ventilated area using a respirator mask. Copious irrigation will help prevent aerosolization of the toxic dust.

Flank celiotomy is used in chelonians with a small plastron or in tortoises with small cystic calculi or a small intestinal foreign body.[3] With the animal in dorsal recumbency, the left hindlimb is pulled caudally exposing the inguinal depression. The skin is incised in either a longitudinal or transverse manner and the muscles are bluntly separated until the coelomic membrane is identified. The membrane is grasped with tissue forceps and incised to allow access to the coelomic cavity. Through this approach the left lobe of the bladder can be accessed and with a digital exploratory, small intestinal foreign bodies can be exteriorized. This approach has not been adequate for access to the entire female reproductive tract for ovariosalpingectomy; however, focal oviductal lesions may be approached through the flank. A two or three layer closure is performed with the coelomic membrane and muscle sutured either as separate layers or together.

Surgery of the Female Reproductive Tract

Female reptiles have a bilateral reproductive tract but their reproductive physiology varies considerably. Some reptiles lay eggs (crocodilians, chelonians, and some squamates) while others deliver live babies (some lizards and some snakes). Dystocia and prevention of reproduction are the major indications for surgery of the female reproductive tract. Surgical management of dystocia is indicated when husbandry changes and medical

management have failed to relieve the dystocia or if there is evidence (such as radiographic) that the eggs are unable to pass because they are too large or of an abnormal shape. Ovariosalpingectomy is performed to treat dystocia or to prevent future problems related to the reproductive tract such as yolk coelomitis, dystocia, and salpingitis.

Preovulatory egg stasis is characterized by the development of yolks on the ovary that are not subsequently released. Postovulatory stasis occurs when the eggs or feti are within the oviduct but do not pass normally. In either case, it is recommended that the ovaries as well as the oviducts be removed.[3] It appears that if the oviduct is removed without removing the ovary, yolks will be released into the coelom potentially inducing yolk coelomitis. If the ovaries are removed and the oviducts left, they simply atrophy and are unlikey to cause problems in the future. Removal of one side of the reproductive tract (unilateral ovariosalpingectomy) for treatment of reproductive disease allows the patient to remain reproductively viable which may be important for herpetoculturists.

The female reproductive tract is relatively mobile within the coelom. In lizards and chelonians it is readily accessible through a standard celiotomy approach. In snakes, the tract is very long and if the entire oviduct contains eggs or feti that must be removed, it is often necessary to make several celiotomy approaches. Generally, 3-5 eggs can be manipulated out of a single salpingotomy incision.

When reproductively active, the blood vessels supplying the ovary and oviduct become engorged and hypertrophied making surgical removal more challenging. For this reason, in pet reptile species with a high incidence of dystocia, prepubertal elective ovariosalpingectomy should be considered. The procedure is much easier when the vessels, ovaries and oviducts are small and the patient is in good metabolic condition.

The oviduct wall is very thin and transparent. When there is salpingitis the wall becomes thicker but more friable making it a challenge to suture closed. Cultures and biopsies should be obtained from the oviduct for diagnostic purposes to guide the postoperative management of the case and determine the prognosis for future reproductive capability. Once the oviduct is identified, an incision is made over an egg or fetus approximately the length of the egg/fetus. If the salpingotomy incision is too small the oviduct will tear while the eggs/feti are manipulated through the incision. The first egg/fetus is generally removed without much effort. Eggs/feti that have been in place a long period of time adhere to the oviduct wall. A 20 ga catheter on a 20 cc syringe filled with saline is inserted between the egg/fetus and oviduct wall and saline is injected to separate the wall from the egg/fetus. This will not only free the egg/fetus from its adhesions to the oviduct but also provide some lubrication. After the first egg/fetus is removed, adjacent eggs/feti are massaged toward the salpingotomy using saline injection, finger dilation, and digital manipulation to separate adhesions between the egg/fetus and oviduct, and to extrude the egg/fetus from the salpingotomy. Once all the eggs/feti have been removed the salpingotomy is closed using a fine (6-0 to 8-0) monofilament, synthetic absorbable material on a fine atraumatic needle in a two layer inverting pattern or a simple continuous oversewn with an inverting pattern. Following a properly performed salpingotomy the prognosis for reproductive viability is good.

In cases where there is irreparable damage to the reproductive tract or where the owner desires to prevent future episodes of dystocia, ovariosalpingectomy is performed. The following discussion applies primarily to green iguanas. Other lizards and chelonians will have some variation in anatomy but the procedure is similar. In snakes with their longitudinal configuration, the ovary is cranial to the oviduct and must be approached through a separate incision or by extending the celiotomy craniad until the ovary is identified.

In iguanas, the right ovary is very close to the right external iliac vein, while the left is more loosely attached with the left adrenal gland interposed between the left external iliac vein and the ovary (Figure 45-8). When the ovary is active, as with preovulatory egg stasis, the ligament is stretched out and it is easy to apply hemostatic clips to the vessels supplying the ovary. Two clips are applied to each vessel and the vessel is transected between the clips. The process is continued until all vessels are clipped and the ovary with its multitude of yolk follicles is removed.

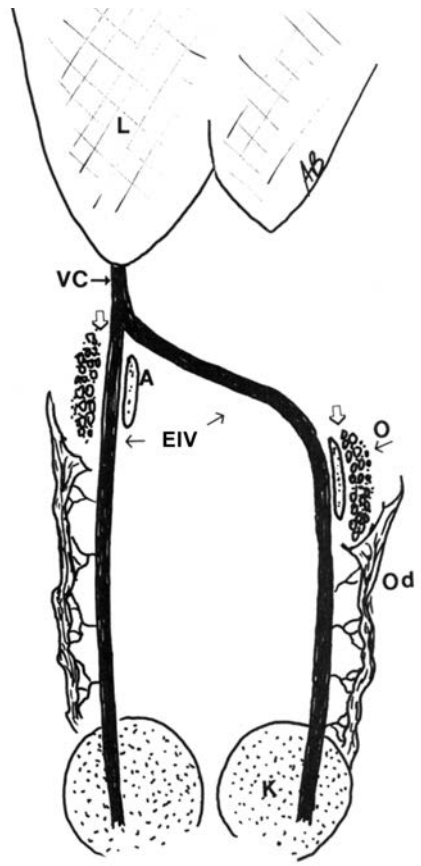

Figure 45-8. Anatomy of the female reproductive tract of a green iguana. Hemostatic clips are applied between the right ovary and the right external iliac vein, and the left ovary and left adrenal gland (*open arrows*). The tissue distal to the clip is incised allowing the ovaries to be removed. *L.* liver, *VC.* vena cava, *EIV.* external iliac vein, *O.* ovary, *Od.* oviduct, *K.* kidney, *A.* adrenal gland.

When the ovary is not active, removal is more challenging. Removal of the right ovary is accomplished by gently elevating the ovary, applying one or two clips between the right ovary and the right external iliac vein, then transecting the tissue distal to the clip to allow removal of the ovary. The left ovary is removed in a similar manner with the clips applied between the ovary and the left adrenal gland. The tissue distal to the clips is transected allowing removal of the ovary without damaging the adjacent adrenal gland.

Following removal of the ovaries, the oviducts are removed. Dissection is initiated at the infundibulum and continued to the cloaca. With preovulatory egg binding, the oviduct is empty and vessels are easily controlled either with hemostatic clips or bipolar cautery. One or two clips are applied to the base of each oviduct at the cloaca prior to their transection and removal.

In cases of postovulatory egg binding where the oviducts are full of eggs, the ovaries are relatively small and inactive as they have already released their yolks. The oviducts full of eggs will obscure visualization of the ovaries and are removed prior to ovariectomy. The vessels to the oviducts are generally engorged and numerous. Each vessel is identified, two hemostatic clips are applied, and the vessel is transected between them. Dissection is initiated at the ovaries and continued caudad until the oviducts can be ligated or clipped at the cloaca prior to transection. After the oviducts are removed the ovaries are visualized as described above. The ovaries are removed as described previously. Closure is routine.

Postoperative care is supportive. Most patients will have been anorectic for 2 to 4 weeks prior to surgical intervention. Fluid therapy is administered through an intravenous or intraosseous catheter. Antibiotics are indicated in the management of bacterial salpingitis. Again, the patient should be maintained at the upper end of its preferred temperature range for proper function of the immune system and the digestive system.

Orchidectomy

Castration is primarily performed in male green iguanas that have become aggressive toward their owner.[3] Castration has been shown to decrease testosterone levels and sexually aggressive behaviors in other lizard species.[13-15] Most commonly, orchidectomy is performed in iguanas after the aggressive behavior has developed and it may be more appropriate to perform the procedure in prepubertal iguanas before the inappropriate behaviors have developed. When performed in an aggressive animal, it appears that the aggression is not ameliorated until the following breeding season. The prognosis for attenuation of the behavior has anecdotally been reported to be around 50% following orchidectomy.[3]

Orchidectomy is performed through a standard celiotomy. As with the ovaries, the right testicle is more closely attached to the right external iliac vein by its short, vascular mesorchium. The right adrenal gland is located on the other side of the external iliac vein. The left testicle is more loosely attached to the left external iliac vein and the left adrenal gland is located between the left testicle and the external iliac vein (Figure 45-9). The adrenals are elongated, granular, pink glands easily distinguished from the smooth, white testicles. The testicles are covered by a capsule that can be ruptured during aggressive manipulation. Rupture of the capsule does not result in hemorrhage but the contents flow out making it difficult to continue with the dissection.

The testicles are removed in a manner similar to that described for removal of inactive ovaries. The right testicle is gently elevated and one or two hemostatic clips are applied between the testicle and the external iliac vein. The tissue distal to the clips is transected allowing removal of the testicle. The left testicle is removed following application of hemostatic clips between the left adrenal gland and the testicle. If hemorrhage from the external iliac vein occurs, one or two hemostatic clip are applied longitudinally along the damaged side of the vessel to control hemorrhage (Figure 45-10). Partial occlusion of the external iliac vein has not been associated with clinical disease; however, if over half of the diameter of the external iliac vein is attenuated, signs of vascular obstruction might be anticipated.

Cystotomy

Urinary calculi can develop in any species of reptile that has a urinary bladder but seem to occur most frequently in desert tortoises (**Gopherus agassizzii**) and green iguanas. Improper nutrition and inadequate access to water or dehydration have been suggested as initiating causes.[3] Clinical signs of

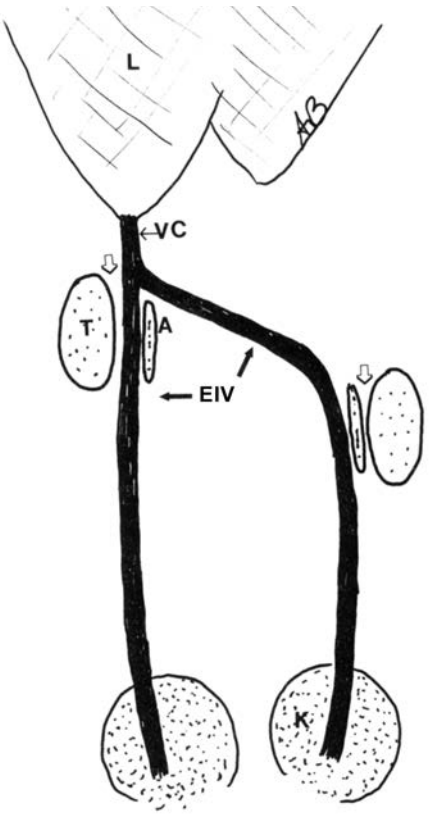

Figure 45-9. Anatomy of the male reproductive tract of a green iguana. The testicles are removed as described for ovariectomy in figure 45-8. *Open arrows* demonstrate the location where clips are applied. *L.* liver, *VC.* vena cava, *EIV.* external iliac vein, *T.* testis, *K.* kidney, *A.* adrenal gland.

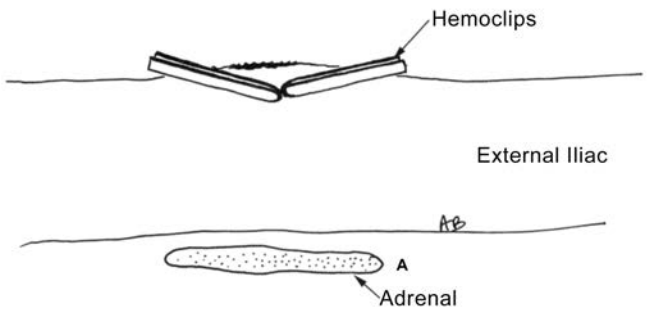

Figure 45-10. Hemostatic clips are applied to the external iliac if there is damage to the vein. Partial occlusion does not generally cause clinical problems. *A.* adrenal gland.

cystic calculi include anorexia, depression, constipation from occlusion of the colon, dystocia from occlusion of the oviduct, cloacal prolapse from tenesmus, and paraparesis secondary to compressive injury to the pelvic nerves.[3] A definitive diagnosis is made based on radiographs or palpation. Calcium urate calculi are radiopaque while ammonium urate calculi can be very difficult to visualize radiographically.

In chelonians, cystic calculi are palpated in the left inguinal fossa. The urinary bladder of chelonians is bilobed and the right liver lobe lays over the right lobe of the urinary bladder. Because the right portion of the bladder is compressed by the right liver lobe, most cystic calculi are present in the left lobe of the bladder. A finger is inserted into the fossa with the chelonian in a sternal recumbency. With the finger left in place, the tortoise is tipped to verticle (90 degrees) and the stone is felt hitting the finger as it falls to the dependent portion of the bladder. In lizards, cystic calculi are easily identified by abdominal palpation.

Cystotomy is performed through a standard celiotomy approach. The bladder is large and easily identified when a calculus is present. The bladder wall is very thin and transparent but becomes somewhat thicker because of the cystitis usually associated with a calculus. The bladder is isolated with moist gauze sponges or laparotomy pads prior to making the cystotomy to minimize coelomic contamination. The urine of reptiles contains mucus and urates giving it a thick, cloudy appearance which may not be easily aspirated through small suction tips. Following removal of the calculus, the bladder is irrigated to remove residual debris. Closure is accomplished using a fine (5-0 to 7-0) monofilament, absorbable material on a small, swaged-on, atraumatic needle in a simple continuous appositional pattern oversewn with an inverting pattern. Celiotomy closure is routine.

Because dehydration may cause dessication of urates within the bladder initiating calculus formation attention must be paid to maintaining adequate hydration. Antibiotics are indicated if bacterial cystitis is present. Husbandry changes (nutrition, temperature, access to water) are made where appropriate.

Reproductive Organ Prolapse

The cloaca of reptiles consists of three compartments: the coprodeum, the urodeum, and the proctodeum. Each of these compartments and their associated structures can, theoretically, prolapse; however, this has never been reported. The coprodeum is the most cranial compartment of the cloaca and is where the rectum enters.[13] This compartment receives urinary and fecal wastes from the terminal colon. The urodeum is the middle section of the cloaca and is where the ureters and the reproductive systems terminate. Urinary wastes of reptiles pass into the urodeum and then into the urinary bladder (chelonians and most lizards), or into the terminal cloaca (snakes and some lizards) where water absorption occurs.[13,14] The proctodeum is the caudal compartment of the cloaca and is a reservoir for fecal and urinary wastes prior to their excretion.

The anatomy and location of the male copulatory organ varies among reptile orders. Squamate reptiles (most lizards and snakes) have hemipenes (paired copulatory organs). Hemipenes in these reptiles are hollow organs that are inverted within the tail. Crocodilians, chelonians, and some lizards have a single phallus or penis. The penis of these reptiles is within the cloaca or coelomic cavity and is a solid organ. It is directed cranially within the cloaca and is everted during copulation. Neither the reptile penis or hemipenis contains a urethra. These organs are not for urination but strictly for the transport of semen.[14]

Paraphimosis occurs more commonly in chelonians than in squamate reptiles. Causes include excitement, stress, infection or inflammation, neurologic deficits, cloacal impaction, trauma to the exposed organ from cage mates or the enclosure substrate, forced separation during copulation, and iatrogenic trauma secondary to probing for sex determination.[13,15]

The prolapsed organ is often edematous from venous engorgement, lacerations from cage mates or the substrate, and may be infected, necrotic, and covered with inflammatory exudates.[13,15] If the tissue is very edematous and necrotic it may be difficult to determine if the prolapsed tissue is penis/hemipenes or another structure. It is simple to ascertain the nature of the tissue in most squamates. If the base of the prolapsed tissue is coming from the caudal aspect of the vent (i.e. coming from the tail) it is most likely a hemipenis or hemipenes. In crocodilians and chelonians, with severely damaged prolapsed tissue, it may be difficult to determine the origin of the tissue without entering the coelomic cavity. The penis/hemipenis is solid and has no lumen, while prolapsed intestine is hollow and has a lumen. If the sex is unknown, the oviduct is also hollow and often contains striations, unlike the intestine.

The reptile is sedated or placed under general anesthesia and the prolapsed organ is cleaned and lubricated. If lacerations are present, attempts are made to suture them, but usually edematous tissues will not hold sutures well. The tissue is then replaced into the tail in squamate reptiles or into the cloaca in chelonians and crocodilians. Moistened cotton-tip applicators are useful in reducing the prolapsed tissue.[13] If the prolapase does not reduce, application of a cold compress or hygroscopic fluids (glycerin or concentrated sugar solution) may help. In addition, stay sutures can be placed in the center of the vent (the opening of the cloaca), both proximal and distal, to help with traction. The vent can also be incised laterally on one or both

sides. Once the prolapse is reduced it is kept in place with a purse string or transverse sutures in the vent. Transverse vent sutures have the benefit of allowing fecal and urinary wastes to be passed more easily than through a purse string suture. In squamate reptiles, a purse string can be placed in the vent at the base of the tail (Figure 45-11). It is best to place a stent into the vent to prevent over-tightening allowing urine and feces to pass while keeping the tissue in place. This technique allows for normal cloacal function.[13] Regardless of the technique used the sutures are removed in 2 to 3 weeks.

If the tissue is necrotic or infected it should be amputated. Amputation of the penis, hemipenis or both hemipenes will not compromise urination. In snakes and lizards, amputation of one hemipenis still allows reproductive viability.[13] Mattress sutures or encircling sutures are placed around the base of the prolapsed tissue, and the organ is amputated distal to the suture (Figure 45-12). The mucosa of the stump is sutured with a simple continuous pattern, and the stump is replaced into its normal anatomic location.

Prolapse of the oviducts has occurred in female reptiles.[15] In some cases it is possible to reduce the prolapsed tissue; however, the viability of the tissue and assessment of damage to the suspensory ligament of the oviduct is limited.[13] Amputation of the exposed tissue has been performed but celiotomy for complete assessment of the prolapsed tissue and repair or removal of the reproductive tract is recommended. If only one side of the reproductive tract is removed, the contralateral side allows for reproductive viability.

Other Procedures

A variety of surgical procedures such as enterotomy for removal of foreign bodies may be performed in reptile patients once the surgeon is familiar with the unique anatomy of and surgical approaches used in reptile patients. Once the approach to the celomic cavity is made, most procedures are analogous to those performed in domestic animal surgery.

Abdominal Surgery of Pet Rabbits

Cathy A. Johnson-Delaney

Introduction

Because of their relative ease of care and their docile dispositions, rabbits are becoming more and more popular as pets in today's transient society. They are now estimated to be found in more than 1% of households in the United States, and represent some 4 million animals. As such, requests to small animal practitioners to provide rabbits with both medical and surgical care are increasing. In many areas, practitioners are responding to the increase in popularity of this animal species, with resulting supplemental income to many practices. In some cases, rabbits comprise a significant percentage of the total number of patients, and the result is that some practices are devoted exclusively to exotic animals. Unfortunately, some clinicians are failing to take advantage of emerging "pocket pet" clientele and to incorporate these patients into their practices. Practitioners' reluctance to provide such veterinary care, especially surgery on rabbits, may, in part, be due to a lack of formal training in the species during their veterinary education and training. It may also be due to a lack of confidence based on clinical experience with the species; no mentor may have been available for guidance. Reference texts recommended for practitioners considering treating rabbits in their practices should include Ferrets, Rabbits, and Rodents Clinical Medicine and Surgery, Quesenberry K and Carpenter J editors, 3rd edition, Elsdevier, 2012, BSAVA Manual of Rabbit Surgery, Dentistry, and Imaging. Francis Harcourt-Brown and John Citty editors. 2013, the current edition of James W. Carpenter's Exotic Animal Formulary, and the 3rd edition of Ferrets, Rabbits, and Rodents by Drs Quesenberry and Carpenter.

The intent of this chapter is to provide veterinary practitioners with basic information necessary to safely perform common abdominal surgical procedures in rabbits. Included are a general overview of anatomy, indications for each type

of surgical procedure, and detailed descriptions of commonly performed procedures: gastrotomy, cystotomy, ovariohysterectomy, orchiectomy (castration), and vasectomy. Because each procedure occurs within the abdominal cavity (castration may also be performed outside the abdominal cavity), several areas are common to all and warrant discussion beforehand: a review of the unique properties of rabbit skin, preoperative considerations, guidelines for preparation of the surgical area, general surgical principles particular to the rabbit, and useful suture patterns for closure.

Anatomy of the Skin

Except for some of the heavy skinned rabbit breeds whose pelts are used in the fur trade, a rabbit's skin is thin relative to body size.[1] The full thickness of the skin, including the hypodermis and panniculus carnosus, is generally only 1.0 to 2.0 mm thick. Except for the tip of the nose and the inguinal region (in both sexes) and a small area on the scrotum in bucks, a rabbit's skin is covered with fine textured hair, and both underfur and guard hairs are present. Rabbits generally molt their hair coats annually, with hair loss starting on the shoulders and moving caudally. Frequently, patterns and rates of hair growth and regrowth (where the hair has been clipped for a surgical procedure) do not appear uniform; this is often a concern of clients. After the rabbit's hair has been clipped, it may not begin to grow back uniformly and may look patchy, with some areas of hair longer and appearing to grow faster than others. This unusual, seemingly abnormal skin coat can be more pronounced in young, white animals when the hair on the animal's flank has been removed. It does, however, represent normal skin responses to variations in rabbit hair growth cycles. The raised, blotchy patches are areas of active hair growth. Beginning with the second coat of hair, waves of hair growth periodically move caudally and ventrally from the neck region. These "growth waves" occur in areas of the skin where all the hair follicles are simultaneously in an active growth cycle. Owners should be informed of this when the rabbit is discharged from the veterinary clinic.

The hair growth cycle has been divided into three main phases: anagen, catagen, and telogen. The anagen, or growing, phase, is the time when the germ cells undergo a burst of mitotic activity, leading to the formation of the sheathed hair bulb and papillary cavity and emergence from the skin surface. The catagen, or transition, phase is a brief period in which mitotic activity slows and the follicle shortens. The hair then passes into the telogen phase, which is a resting period. Changes in the vascularity and thickness of the skin are associated with these phases of the hair growth cycle. The skin thickness is approximately 1.0 mm during the telogen phase and may become 2.0 mm thick during the anagen period. As rabbits become older, the waves become less frequent and more patchy in their distribution.

Preoperative Considerations

Normal rabbit behavior and activity are typically sedentary, and stoic, but nervous or wary of their environment when compared with dogs and cats. As such, they may have preexisting health problems that may not manifest themselves clinically to their owners and can be easily overlooked preoperatively in today's busy veterinary practices. This is typical of species that are prey and they will hold off showing illness. The rabbit should be examined in a quiet setting and therefore, each animal must have a complete presurgical workup including physical examination, history, and, if possible, complete blood count and urinalysis. Diet, eating habits, and volume or consistency of fecal production are important items to be addressed. Clinical or subclinical problems, such as dehydration or emerging septicemia, should be corrected before any surgical procedure, to maximize the potential for a successful outcome. Because rabbits cannot vomit, withholding of food and water before the surgical procedure is not necessary, although 2 to 3 hours of fasting will clear the oral cavity, and may decrease the ingesta within the stomach, intestines, and in particular, the cecum. Assessment of pain requires astute observation. Signs of pain include reluctance to move, sitting in a stiff, hunched posture, rapid, shallow respiration, and tensing upon palpation. An elevated rectal temperature may indicate pain, stress, inflammation or infection.

As in other species, prophylactic antibiotics may be used in rabbits undergoing surgical procedures. Because of the predominance of gram-positive bacterial flora in the rabbit gastrointestinal tract, especially the cecum, any antibiotic that affects those populations, such as oral penicillins, cephalasporins, macrolides, and tylosin, should be avoided. Antibiotics, such as trimethoprim sulfa combinations, or fluorinated quinolones such as enrofloxacin, given either individually or together, can be used effectively with minimal side effects. These drugs are generally started the day before surgery, or they are administered at induction of anesthesia and are maintained for 3 days to ensure adequate blood levels should unexpected contamination occur during the surgical procedure. Clostridial overgrowths can occur in rabbit ceca and large intestine if the diet has been high in carbohydrates and sugars when using fluoroquinolone antibiotics alone. Fluoroquinolones are not effective against clostridial infections. If clostridial populations are suspected due to diet or detection of spores on fecal gram stains, metronidazole may be added to the antibiotic regimen. In the healthy rabbit, cecoliths are ingested and a few make it through the acidic stomach to the cecum to replenish the cecal flora. During illness or antibiotic therapy, this process is interrupted. Orally administered probiotics may not survive transit through the stomach and small intestine. The colon and large intestine of the rabbit sorts materials by particle size. Particles greater than 2 mm are passed into the colon and rectum to form fecal pellets. Smaller particles are moved back to the cecum via retroperistalsis. Thus probiotics administered in small quantities rectally may actually be moved back to the cecum to enable the rabbit to reestablish normal flora. An enema of healthy rabbit cecoliths is advantageous when administered to rabbits with anorexia and diarrhea post operatively. In addition, administration of fluids and gastrointestinal motility stimulants such as metoclopromide may be indicated to enhance intestinal tract motility postoperatively. Since anesthesia and opiate analgesics may slow gastrointestinal motility, use of motility stimulants will often speed recovery of normal intestinal motility. The rabbit should be encouraged to eat soon after surgery.

Preparation of the Surgical Site

For all procedures described in this chapter, the rabbit is placed in dorsal recumbency on heated water blankets with all four limbs fully extended. The animals are preanesthetized with a combination of ketamine hydrochloride (35 mg/kg intramuscularly), xylazine (5 mg/kg intramuscularly), and glycopyrrolate (0.1 mg/kg subcutaneously); they are carefully intubated and maintained on isoflurane and oxygen during the procedure. Alternative regimens include the use of glycopyrrolate, and ketamine at 20 to 30mg/kg IM with diazepam at 1 to 3 mg/kg IM. A number of different anesthetic regimens have been published and should be considered depending on the procedure to be performed. It is important to minimize stress to the rabbit during drug administration and the anesthetic induction phase. The reader is referred to the literature for additional information on anesthetic protocols used in rabbits.[2,3] Intravenous access is established with a 24 gauge catheter (Angiocath) placed in the marginal ear or cephalic vein and maintained by the slow administration of an isotonic crystalloid fluid. As the rabbit has a large and heavy abdomen in comparison with the thoracic cavity, care should be taken to slightly elevate the thorax during surgery and to not tilt the rabbit's head and thorax downward as is sometimes performed with carnivore abdominal surgery. The reader is referred to the literature for additional information on anesthetic protocols used in rabbits.[2,3]

Preparing the rabbit's skin for surgery can be a challenge to a practitioner inexperienced with the species. Removing hair at and around the incision site without damaging the skin can be frustrating. Although many clinicians use traditional clinic clippers with a No. 40 dipper clipper blade to remove hair, variable high speed clippers (e.g., Double K Industries, Inc., Model 401) specifically designed for animals with fine hair, such as rabbits and rodents are recommended. These clippers make hair removal easier and reduce the incidence of accidental cutting or burning of the skin. If possible, hair should be removed at least 5 to 10 cm in every direction from the incision site.

Rabbit skin can be sensitive to alcohol. Care should be taken to avoid excessive scrubbing when preparing the skin for surgery. After clipping the hair, the surgical site is vacuumed to remove any remaining hair and is wiped with a saline soaked gauze. The skin is then surgically prepared using alternating applications of povidone iodine soap and either alcohol or sterile saline for a total of three applications each. Each application begins at the center of the surgical site and works outward in larger and increasing sized circles. Povidone iodine solution should be sprayed over the entire surgical site and allowed to dry. Chlorhexidine surgical scrub has also been used rather than povidone iodine. The author has found that using cosmetic-grade soft cotton rather than gauze sponges causes less irritation to sensitive rabbit skin, particularly the scrotum when preparing the site for castrations. The author performs local blocks of all incisional sites using 2% lidocaine 1:10 dilution with sterile water prior to skin incisions.

General Surgical Principles

The rabbit intestine occupies most of the abdominal cavity. Handling and manipulating the intestinal tract must be minimized as the tissue is fragile. Injury to the intestine may precipitate bacterial migration which may lead to fatal peritonitis and clostridial toxicosis. Rabbits also are highly prone to form adhesions and generous lavage with warm saline should be performed prior to closure of the abdominal wall. Adhesions occur due to multiple microhemorrhages which may occur during tissue handling. Postoperative ileus or intestinal gas formation may be fatal to the rabbit because the intestinal flora is disrupted.

Taking steps to minimize inclusion of foreign materials such as gauze lint, surgical glove powder, and talc also decreases the opportunity for adhesion formation. After donning a surgical gown and gloves and before beginning the procedure, the surgeon should wash the powder and talc off surgical gloves with sterile saline soaked gauze sponges. In addition, any gauze sponges with frayed ends should be removed from the surgical tray because these sponge fragments may fall into the rabbit's abdomen and become a nidus for adhesion formation.[5]

Another important practice for avoiding adhesion formation is performed during closure of the abdomen. The two cut peritoneal surfaces from the incision must be brought into apposition when closing the muscle fascia layer. This maneuver reestablishes continuity of the nonadherent peritoneal surface, which directly contacts the underlying organs. Failure to restore the peritoneal barrier often results in adhesions involving the muscle fascia layer with one or more abdominal organs, often with adverse outcomes.

Wound Closure

Various suture materials can be used to close wounds in rabbits, including absorbable and nonabsorbable materials. Chromic or plain catgut or suture material that increases the inflammatory response should not be used in rabbits. Long-acting synthetic absorbable suture material that is broken down by enzymatic hydrolysis such as polyglactin 910 or polydioxanone suture are preferred. Nonabsorbable sutures for skin include monofilament synthetics and stainless steel. As many rabbits will remove externally placed sutures, it is recommended that skin closure be performed using a subcuticular pattern. Elizabethan collars may be necessary short-term to prevent the rabbit from opening the surgical site, however with adequate post-operative analgesia, the use of physical barriers to the incision site may be minimized. Closure of the abdomen in most rabbits is difficult in more than two layers. The muscle-fascia layer (with underlying peritoneum) is the primary strength layer of the abdomen. As such, this layer should be closed using a tapered swaged on needle and a simple interrupted suture pattern. These sutures should be placed close together. Elevating the muscle fascia layer with towel clamps placed at each end of the incision during the closure is useful and reduces suturing time. The added visualization helps to avoid accidental suturing of an underlying organs and at the same time ensures approximation of the two edges of "glistening" peritoneum with each stitch. When completed, the suture line

should be evaluated for potential herniation using Brown Adson thumb forceps. The tips of the forceps are held together, and the surgeon gently probes between each suture. If the forceps can easily enter the abdomen, a potential for abdominal organ herniation exists, and additional sutures should be placed. This process is continued until sufficient sutures are placed to prevent forcep entry.

The skin may be closed using various different suture patterns and materials. I prefer to close the skin using either absorbable suture material, as mentioned earlier, on a swaged on, reverse cutting needle in a subcuticular pattern or by using surgical staples. Surgical staples are usually reserved for linear skin incisions on flat surfaces. The site and nature of the skin lesion generally dictate which method to use. Surgical glue can be used to close any gaps remaining in the skin after subcuticular closure.

Adjustable Cervical Collars ("Scratch Guards")

Rabbits have an almost compulsive desire to keep themselves well groomed. This behavior is often exaggerated by surgery to a level which, unless they are inhibited, the animals literally lick and bite themselves down to muscle and bone, removing skin, sutures, and anything else in an attempt to eliminate the incision site pain. Post-operative pain control using a combination of opiate and an NSAID, will help to decrease self-trauma to the surgical site. Unfortunately, rabbits usually do not tolerate the traditional Elizabethan collar well postoperatively. Although this device does keep them from removing the sutures or traumatizing the incision, the animals seem frightened and frequently do not eat, drink, or move around. Often, they just stay in one location with their heads down. One soft, adjustable type of cervical collar overcomes many of the problems associated with Elizabethan collars.[6] It can be easily constructed using available clinic materials and is reusable. Preparation begins with an initial circular ring made from a roll of gauze or flexible anesthetic gas tubing approximately 14 inches in circumference. Four by four gauze sponges are next wrapped around the ring to provide both padding to the animal's neck and external diameter enlargement to the collar. The gauze is secured in place by wrapping over it with both surgical adhesive tape and Vetwrap (3M, Minneapolis, MN) applied sequentially. This not only reinforces the gauze ring, but provides for a consistent collar diameter and water resistance. The finished collar is simply placed over the animal's head, and the slack in the ring is compressed until it's snug. The collar can then be secured by adhesive tape so it resembles a yoke (Figure 45-13). It was coined "scratch guard" by staff members because the animals did not scratch the surgical site. When this collar is used, the affected animals seem distracted from surgical site discomfort and appear to resume normal activity and eating and drinking.

In a report of more than 1500 abdominal surgical procedures using the scratch-guard only 2.5% of animals exhibited self mutilation episodes, and those episodes occurred primarily because of the rabbit's ability to remove the scratch guard,[6] Some rabbits however will be depressed with any type of collar restraint. A belly-band wrap using Vetwrap, and taped circumferentially

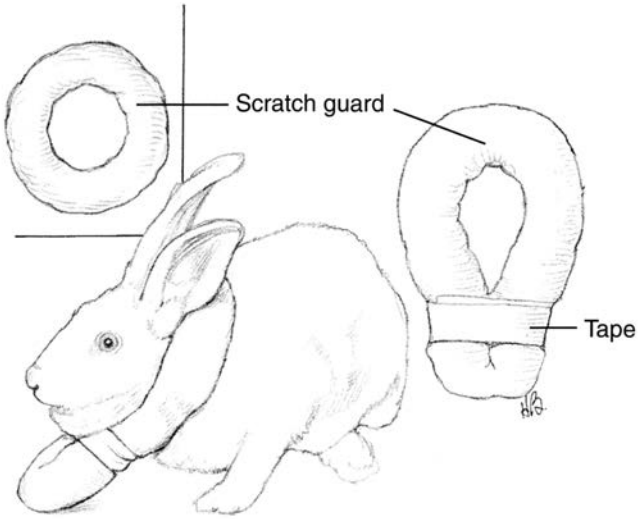

Figure 45-13. Adjustable cervical collar ("scratch guard").

cranially and caudally may be needed for several days. A gauze sponge with a topical anesthetic cream or gel can be placed over the incision. A layer of gauze bandage is wrapped loosely around the rabbit's mid-section, and finished with 2 to 4 layers of Vetwrap, then taped. The bandage needs to be loose enough to not constrict the abdomen, but layered enough to prevent the rabbit from chewing through it.

Postoperative Considerations

Postoperative care plays an important part in successful surgery in rabbits. Postoperative care can be broken down into two time periods: the first 24 hours after the surgical procedure and the next 13 days. After surgery, the animal is allowed to recover in a warmed, intensive care cage where the endotracheal tube is removed (on return of the animal's gag reflex). Once the rabbit is fully conscious, a scratch guard cervical collar is fitted, and food and water are offered. Close monitoring of the animal is important during the first 24 hours postoperatively, and, therefore; the animal should remain where it can be observed frequently by staff members. During this period, the animals should have complete health checks a minimum of twice a day. This examination includes rectal temperature, pulse count, thoracic auscultation, monitoring of fluid and water intake, monitoring of urination (volume) and defecation (amount and consistency), and monitoring of the incision line and the animal's behavior (activity and body language). In addition, the animals are continually evaluated for signs of pain, which may be obvious, such as vocalizations, to subtle, including reluctance to move, abnormal (hunched) postures, anorexia, grinding of teeth, elevated body temperature, increased respiratory rate, and unexpected aggression. If pain is present, pain relief can be provided (buprenorpbine, 0.05 mg/kg subcutaneously twice daily) as needed. NSAIDS such as meloxicam (Metacam, Boerhinger Ingleheim) at 0.2 to 0.5 mg/kg SQ or PO q 24 h or Carprofen (Rimadyl, Pfizer) at 2 mg/kg PO or SQ q 12 h or 4 mg/kg SQ q 24 h can be used with the opiate and greatly enhance the rabbit's return to normal activity. Minimal to no fecal production suggests potential cecal stasis. A "cow patty" stool may indicate bacterial enteritis. The rabbit must resume eating and drinking

as soon as possible following surgery. Rabbits normally have a small amount of ileus in the postoperative period, and the return to voluntary food and water consumption helps to prevent this occurrence from becoming deleterious. Offering the animals hay, either grass or timothy, usually stimulates reluctant animals to eat immediately. Critical Care (Oxbow Pet Products, Murdock NE) can be used to encourage eating, by assist-feeding it directly orally. Many pet rabbits will begin to eat when hand-fed and encouraged by nursing care. If the animal returns to near normal behavior, especially regarding food and water consumption, and normal urination, and defecation within 24 hours of the procedure the surgeon can send it home. To help facilitate a successful outcome, the owner should perform as many health monitoring techniques as possible, especially monitoring body temperature, incision site, food and water intake, urination and defecation (volume and consistency), movement, and overall attitude. Owners appreciate participating in the rabbit's postoperative care and in becoming more aware of their pet's health. A return progress visit should be scheduled for 3 to 5 days following major surgery.

Common Surgical Procedures

The common surgical procedures performed in the peritoneal cavity are discussed in this section. The techniques presented focus on procedures that I believe can be easily learned and are usually successful. No attempt is made to discuss all available surgical techniques. In addition, the description of each technique begins as if the surgeon had already opened the abdomen as discussed previously.

Gastrotomy

Rabbits are hindgut fermenters and have a simple, glandular stomach. The stomach serves as a reservoir for most of the ingested food, and it is never completely empty in a healthy animal. The stomach acids in the rabbit are among the most acidic of those of any species, with a pH of 1.2 to 1.5. This high acidity enables rabbits to use plant proteins more efficiently than most mammals and normally minimizes problems with ingested hair.

Unlike other species with incessant grooming behaviors, such as cats, rabbits physiologically cannot vomit.Consequently, ingested foreign materials, especially hair, which would normally induce a protective emetic reflex in other species, have the potential to become life threatening obstructions, unless sufficient roughage is present from the diet, and the rabbit is active, continually well-hydrated, and maintains normal gut motility. Additional predisposing factors in creating an obstructing trichobezoar may include boredom-associated over-grooming or ingestion of carpet/clothing fibers or other linear-type fabric strings, inadequate dietary roughage, anorexia because of off flavor or off odor feed, inability to smell from rhinitis, pain from sore hocks, malocclusion, lack of fresh water, or other stress factors. Once gastrointestinal motility is altered the rabbit may stop eating and drinking, and critical metabolic problems can result if this problem is not corrected.[4,7-13]

Common presenting complaints include anorexia, lethargy, weight loss, oligodipsia, diarrhea, or conversely, small or scant, dry feces. Other frequent clinical signs are dehydration, depression, hunched posture, tense abdomen, hypothermia, and bloating. Although definitive diagnosis of trichobezoar cannot be made without surgical exploration, a tentative diagnosis can be made based on history, clinical signs, palpation of an abdominal mass in the vicinity of the stomach, and contrast radiography, especially with fluoroscopy. Care should be taken when palpating the upper abdomen because the liver in these animals is often friable.

Rabbits with trichobezoars are frequently dehydrated and cachectic and should be treated as medical emergencies. Initial efforts should be directed at reestablishing normal homeostasis, including aggressive parenteral fluid administration before definitive therapy is pursued. Initial medical therapy involves the administration of intravenous or subcutaneous fluids, oral electrolyte fluids, and assist-feeding of a fiber-rich formula such as Oxbow's Critical Care. Fluids such as fresh pineapple juice or crushed papain tablets in water are promoted in many publications, but other than the fluid content, and possibly the sugar content of the pineapple juice, these have not been shown to dissolve or break-up a trichobezoar. These fluids should be given in small amounts (10 to 20 mL) four to six times a day for up to 3 to 4 days. Often, this oral fluid administration both "refloats" the hair mass in the stomach and aids in quickly rehydrating the animal. Refloating allows the proteolytic enzymes and stomach acids to penetrate the trichobezoar and to begin digesting the hair. The fiber-rich roughage is necessary to encourage gut motility. A valuable tool in assessing the efficacy of medical treatment is the production of fecal pellets in increased quantities. Radiographs are useful in assessing the size of the trichobezoar and its movement. Barium as a contrast agent must be used cautiously in animals that depend on cecal digestion. If the cecum becomes coated with barium, crucial metabolism and gut flora will be altered. Because of this, the author does not utilize contrast studies in rabbits with gastrointestinal motility disorders.

Other medical treatment strategies for treating trichobezoars, formerly a strictly surgical condition, have been successful in recent years, including the use of metoclopramide.[4,8-10] These newer regimens have reduced the number of animals that ultimately require surgical treatment. As a general rule, if no improvement is seen with medical therapy for trichobezoars after 3 days, these animals become surgical candidates for an exploratory gastrotomy. Animals presented for gastric foreign bodies other than trichobezoar are surgical candidates for gastrotomy (Figure 45-14). All animals having a gastrotomy are given prophylactic antibiotics, as previously mentioned, which are generally maintained for 5 to 7 days. Postoperatively, these rabbits resume food and water consumption as soon as possible. I recommend maintaining these rabbits in the hospital for several days until they return to normal eating, drinking, and defecating.

Orchiectomy (Castration)

Orchiectomy (castration) is one of the most common surgical procedures performed in companion rabbits. The usual indications for removing testicles are for birth control or to modify or eliminate certain offensive behaviors intact male rabbits (bucks) often develop when they reach sexual maturity. These behaviors include: urine spraying, territory marking with both urine and feces, and aggression toward their owners or other rabbits.

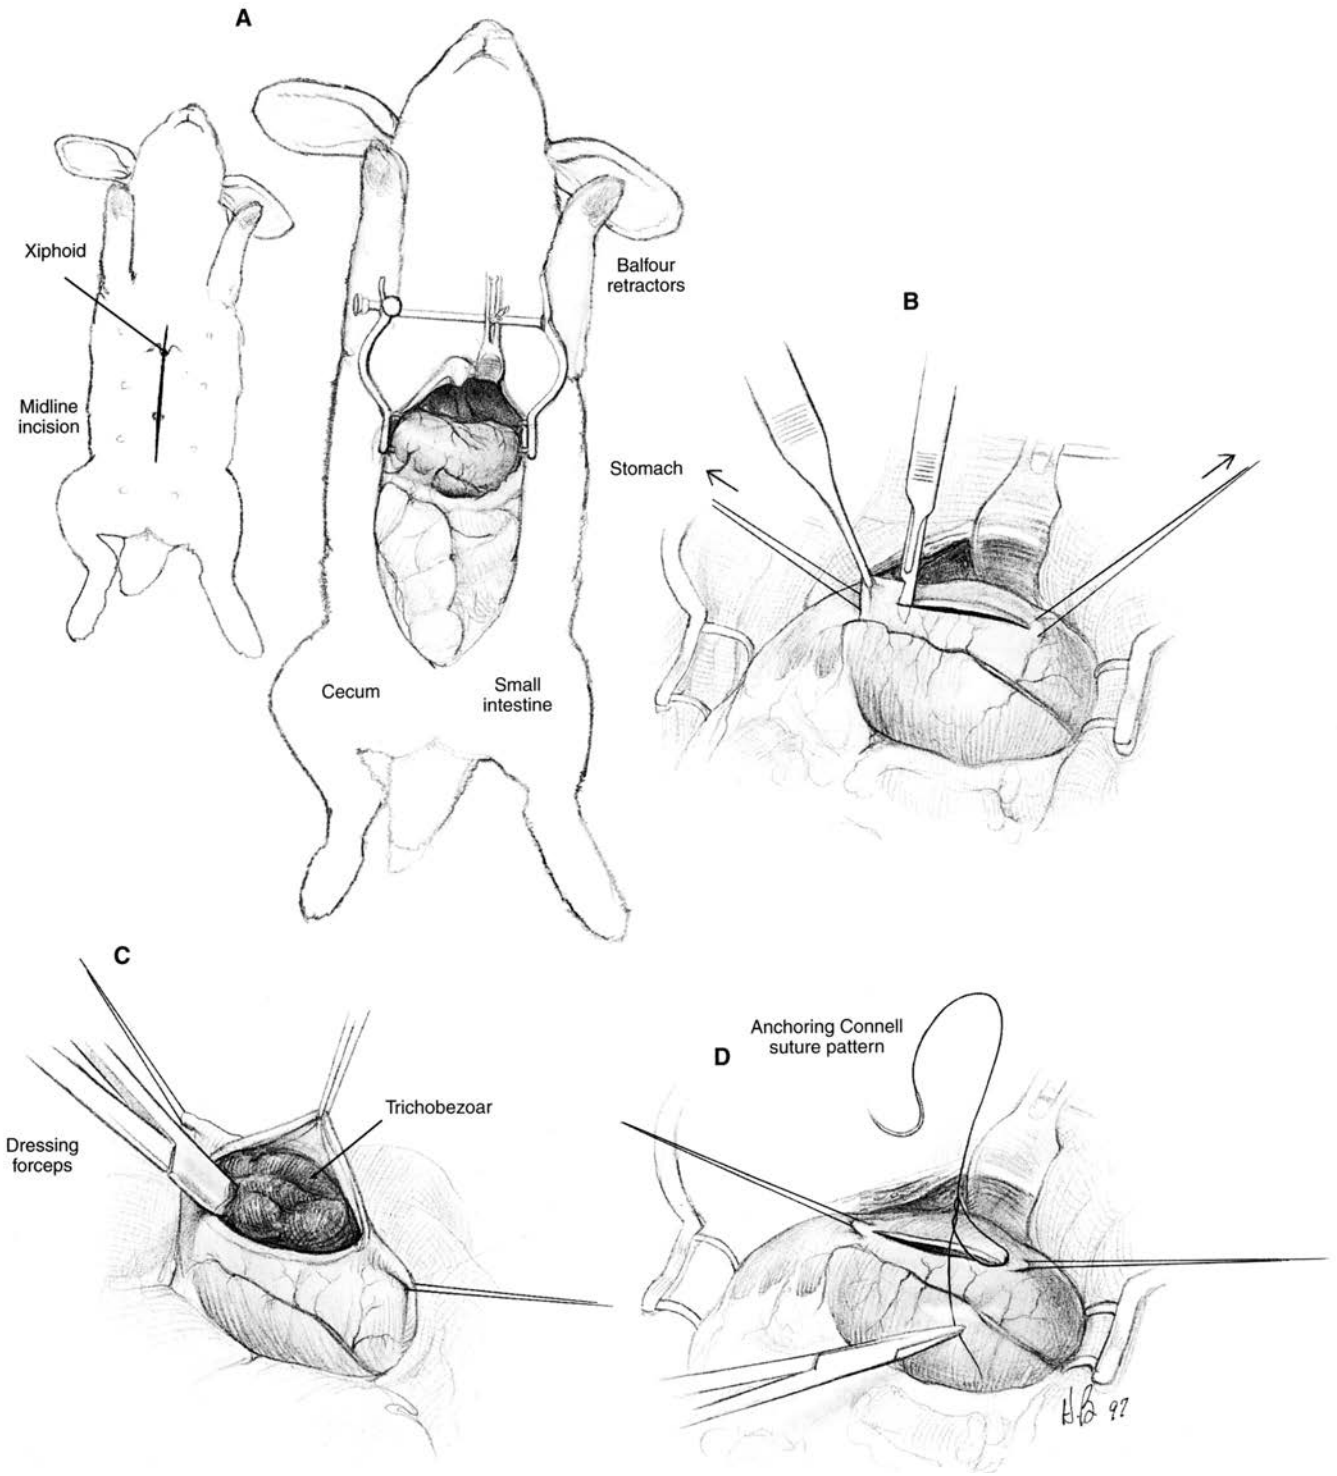

Figure 45-14. A. The animal is placed in dorsal recumbency, and the surgical site draped from 4 cm anterior to the xiphoid cartilage to 5 cm caudal to the umbilicus. A midline skin incision is made extending from 2 cm cranial to the xiphoid cartilage to 3 cm caudal to the umbilicus. Using thumb forceps and Metzenbaum scissors, the incision is continued through the linea alba through the muscle fascia layer into the abdomen. The surgeon must identify and avoid cutting the xiphoid cartilage when cutting the muscle cranially. When reaching the caudal edge of the xiphoid, the surgeon redirects the scissors and continues cutting the muscle along the edge of the cartilage for the remaining 2 cm. Both sides of the abdominal incision are lined with moistened laparotomy sponges. Exposure is maximized by placing pediatric self retracting Balfour abdominal retractors just caudal to the xiphoid. The two fenestrated retractor blades are spread laterally, and the xiphoid cartilage is elevated gently with the center Balfour blade to visualize the stomach, the cecum, and portions of the small intestine. **B.** Two stay sutures are placed 5 to 6 cm apart midway between the greater and lesser curvature of the stomach in a visibly avascular area. The sutures are lifted in opposite directions to elevate the stomach out of the abdomen and to provide a taut area for entering the stomach. The surgeon packs off the elevated portion of the stomach from the rest of the abdomen with moistened laparotomy sponges. Waterproof drapes are placed over the laparotomy sponges to prevent abdominal contamination from gastric contents when the stomach is opened. In addition, separate instruments should be available for entering and closing the stomach. A stab incision is made with a scalpel into the stomach.

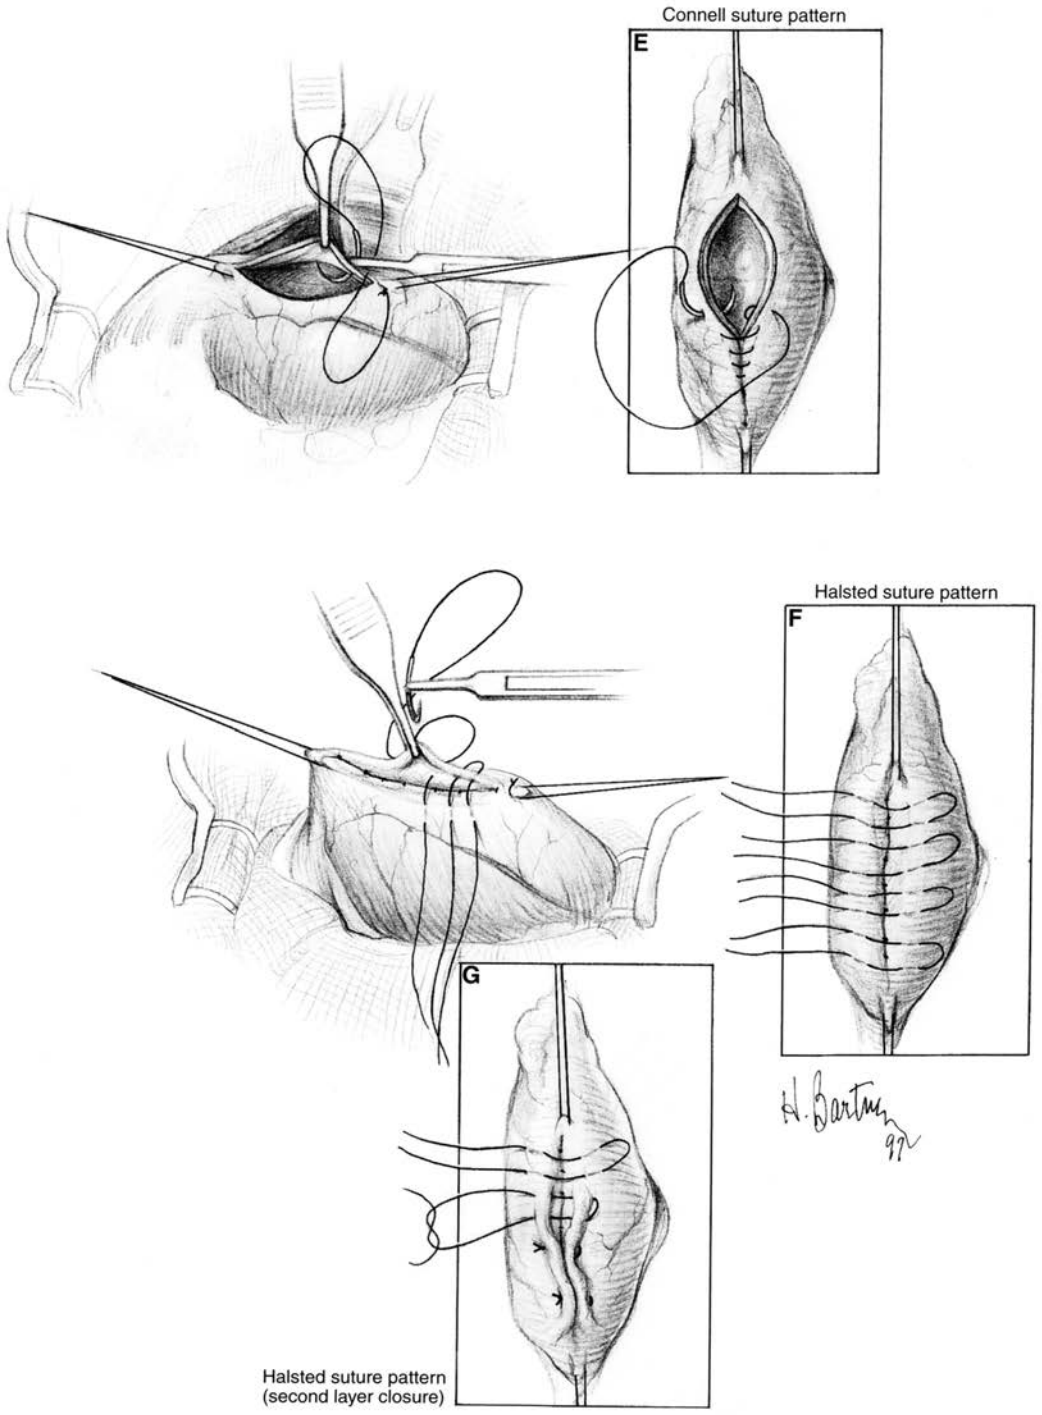

Figure 45-14 (continued). Suction is used to prevent accidental spillage of gastric juices onto the stomach serosal surface. This incision is extended as needed with a scalpel or with Metzenbaum scissors until a desired opening is achieved. **C.** The stomach contents are examined. If a trichobezoar is present, the hair mass is broken up and is removed with a pair of dressing forceps. The stomach is lavaged with warm saline solution and is suctioned. All instruments involved with entering the stomach are discarded. The surgeon should reglove, change or discard drapes, and begin closing the stomach with clean instruments. **D** and **E.** Closure of the stomach is accomplished with two inverting suture patterns using 3-0 polyglactin 910 or polydioxanone on a tapered needle. The first layer is a Connell pattern followed by a Halsted oversew. When performing the Connell pattern, full thickness bites should be placed from the edges of the incision, and the anchoring knots should be placed 2 to 3 mm from the incision at both ends. **F** and **C.** The second layer is closed using a Halsted suture pattern, which further inverts the incision and helps to ensure a complete seal. Each suture should be preplaced before being tied, to provide for even tissue inversion and tension distribution. Once the second layer is completed, the closure is checked for any leakage. The abdominal cavity should be lavaged with warm saline and suctioned if one sees evidence of gastric spillage. The stomach is returned to its normal anatomic position, and the abdomen is closed routinely.

Although not a panacea, castrating bucks generally makes them more docile, reduces fighting, and diminishes urine spraying. Other indications for castration are related to scrotal injury, including trauma from fighting or severe urine scalding.[4]

Male rabbits have two separate scrotal sacs, rather than one, as found in other placental mammals. These hairless structures lie slightly cranial to the penis. The testes are found in the abdomen at birth and descend into the scrotal sacs at approximately 3 months of age. Bucks reach sexual maturity between 4 and 5 months of age, depending on the breed of rabbit. Dwarf breeds mature more quickly than giant breeds. Castration is usually performed after the testicles descend. In addition to their peculiar scrotal anatomy, rabbits have open inguinal canals that allow the testicles to move easily between the scrotal sacs and the abdomen.[8] In intact bucks, epididymal fat, which lies cranial and medial to the inguinal canal on each side is normally inhibited from entering the scrotal sac by each testicle. Because this fat lies on the abdominal side of the inguinal ring, it, in turn, inhibits intestinal herniation through the canal. Castration techniques involving incision of the scrotal sac and removal of the testicle could potentially lead initially to epididymal fat herniation and, subsequently, herniation of the intestine into the scrotum unless the inguinal canal is closed surgically following castration.

Most of the techniques described for castrating male rabbits are adaptations of techniques used in dogs and cats: scrotal approach open castration with incised tunica albuginea and preservation of the epididymal fat; scrotal approach closed castration without incising the tunica albuginea; and the prescrotal approach over the inguinal rings with inguinal ring closure.[4,6,10,12] From experience, each technique is easily learned and has minimal complications. However, the scrotal perineal area can be traumatized or irritated either by the surgical procedure or by surgical preparation using any of these techniques. This trauma or irritation potentiates iatrogenic injury and the opportunity for subsequent bowel herniation or infection. Pre-surgical scrubbing should be gentle and the author prefers the use of chlorhexidine-based surgical scrubs delivered with cotton rather than gauze, and irrigated with sterile saline rather than scrubbed. The rabbit is positioned in dorsal recumbency with the thorax elevated. The incision is made on the midline just cranial to the scrotal sacs and penis. The incision should be as small as feasible (1-2 cm in length) to allow protrusion of the testicle. Ligation of the testicular vasculature is the same as in other species. For most bucks, a single suture applied through the inguinal ring and through the spermatic cord is adequate for hemostasis and closure of the inguinal ring. In this manner, the inguinal ring is closed, and no herniation can occur. The incision in the scrotum can be closed with a drop of tissue adhesive. The procedure is repeated on the opposite side. The use of manual pressure to elevate each testicle may cause bruising of the scrotal tissue, and therefore is not recommended. After both testicles have been removed, and the incisions glued, the author applies a topical anesthetic lidocaine gel to the scrotal tissue. Recently, the author has been applying Penetran ointment to the surgical area. This is an organic ammonia-based ointment that decreases pain and inflammation. It is absorbed into the skin completely so there is no residue for the rabbit to ingest. Healx Soother (Harrison's Pet Products, West Plam Beach, Fl). Post-operative analgesics and NSAIDS are continued for 2 to 4 days. With gentle tissue handling, the scrotum is not bruised or irritated, and with systemic pain control, most bucks seem unaware of the surgery.

An abdominal castration technique has also been described, and although it avoids the potential trauma to the scrotal or penile area, it does require post-operative use of a cervical collar and is more invasive. This method must be used in cryptorchid bucks (Figure 45-15).

When the animal is discharged from the clinic the owners must be advised that the desired effects of castration are not instantaneous. Although the animal's testicles have been surgically removed, male hormone levels have not been eliminated. Urine spraying, territory marking, and aggression may continue for a few weeks. In addition, libido and probably viable sperm (remaining in the vas deferens) are present for a month, and thus the potential for impregnating intact females does exists during that time.

Cystotomy

Urinary calculi (urolithiasis) are commonly encountered in clinical practice in pet rabbits, particularly in rabbits on an alfalfa-based pelleted diet. A healthy adult rabbit produces an average of 130 mL/kg of urine each day; this urine is usually turbid and varies in color from white to yellow to brown to orange to bright red.[8-11,14-16] The turbidity of the urine is due primarily to mineral precipitates. Because urine is the primary route for calcium and magnesium excretion in rabbits, various crystals, including ammonium magnesium phosphate, calcium carbonate monohydrate, and anhydrous calcium carbonate precipitates, are normally found on urinalysis.[8] The wide spectrum of colors and intensity is related to dietary pigments and the animal's hydration status; higher alkalinity and dehydration are usually associated with brighter, more intense colors.[8] The etiology of urolithiasis is still not clear, but several predisposing factors have been proposed, including urine stasis, genetic predisposition, dietary imbalances or diets high in calcium such as alfalfa-based diets and concurrent hypercalcemia), chronic urinary tract infections, and inadequate water intake.[8,9,14] Normal urine pH in rabbits is around 8.2, but at 8.5, calcium carbonate and phosphate crystals precipitate. Urine sludge is frequently seen and may or may not exacerbate the formation of calculi. The sludge itself can be irritating to the mucosa of the bladder and urethra, and add to the discomfort of the rabbit, reluctance to urinate, and with urine retention, increase the probability of ascending infection and stone formation. The most common presenting complaint in rabbits with urolithiasis is hematuria. As mentioned previously, rabbit urine may be any of several colors, depending on urine pH and diet. Diets high in calcium, such as alfalfa, can cause the urine to become bright red orange to red. Hematuria should, therefore, be confirmed by urinalysis or urine dipstick. This condition is often diagnosed after the animal has been presented for other problems. Hematuria was reported as the chief complaint in only one of seven rabbits with urinary calculi.[10] Other signs may include polyuria, perineal irritation from urine scalding, stranguria, lethargy, anorexia, hunched posture, abdominal distension, and chronic or intermittent

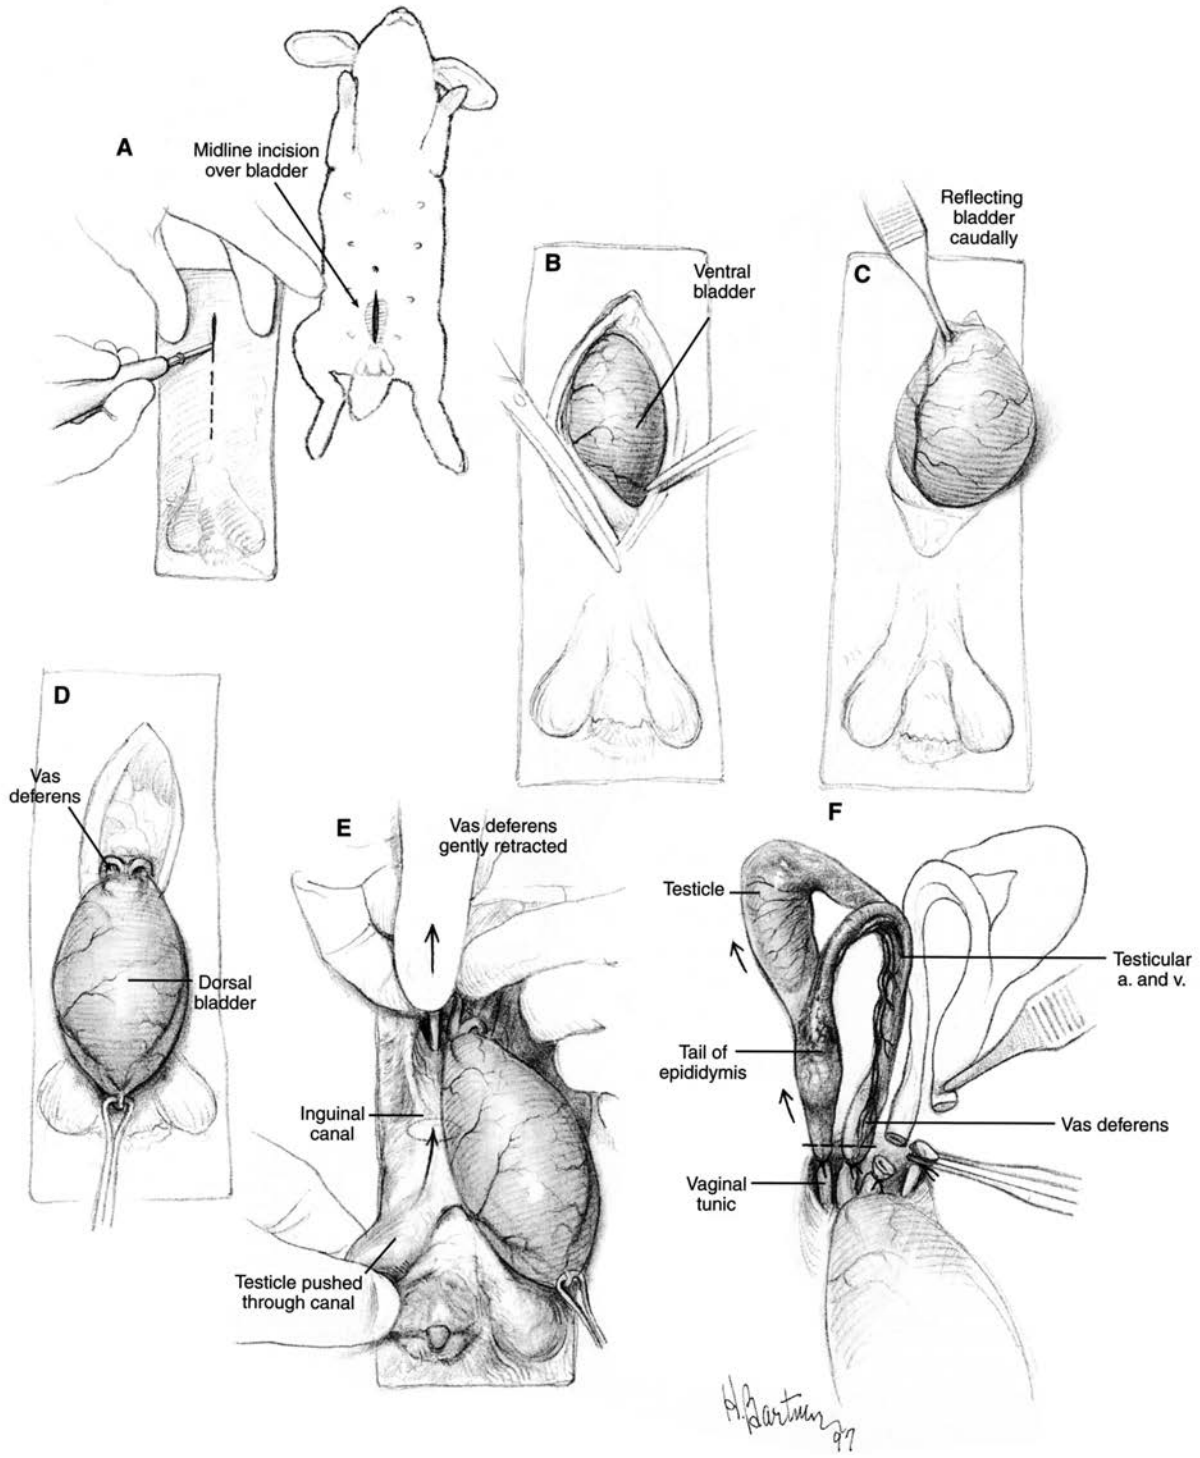

Figure 45-15. Abdominal orchiectomy (castration). **A.** The animal is placed in dorsal recumbency, and the surgical site is draped off to include the scrotum and penis. A midline skin incision is made extending from 5 cm caudal to the umbilicus to the level of the pelvis or 2.5 cm anterior to the genitalia or to the level of the last set of nipples. **B.** Using a pair of thumb forceps and Metzenbaum scissors, the incision is continued through the linea alba through the muscle fascia layer into the abdomen, exposing the ventral surface of the bladder. **C.** The apex of the bladder is grasped with a pair of Babcock (or other atraumatic) forceps and is reflected caudally, exposing the dorsal aspect of the bladder. **D.** Further gentle caudal retraction of bladder with Babcock forceps exposes the two vasa deferentia emerging near the base of the bladder. **E.** Removing the testicle involves performing the two procedures almost simultaneously: each vas deferens is gently retracted cranially (either with a spay hook or manually) while one gently pushes the testicle (often located within the scrotal sac) through the inguinal canal into the abdomen. **F.** This retraction continues until the entire testicle and blood supply are removed from the scrotal sac. These procedures are repeated for the other testicle. A ligature is placed around both vasa deferentia and their associated blood supply near the base of bladder. A second ligature is then placed between the head of the epididymis and its scrota attachment (at the vaginal tunic). The testicle can now be removed by cutting above both ligatures. After removal of both testicles, each side of the invaginated scrotal sac and its associated epididymal fat is pushed back to its normal position. The bladder is returned to its anatomic position, and the abdomen is closed routinely.

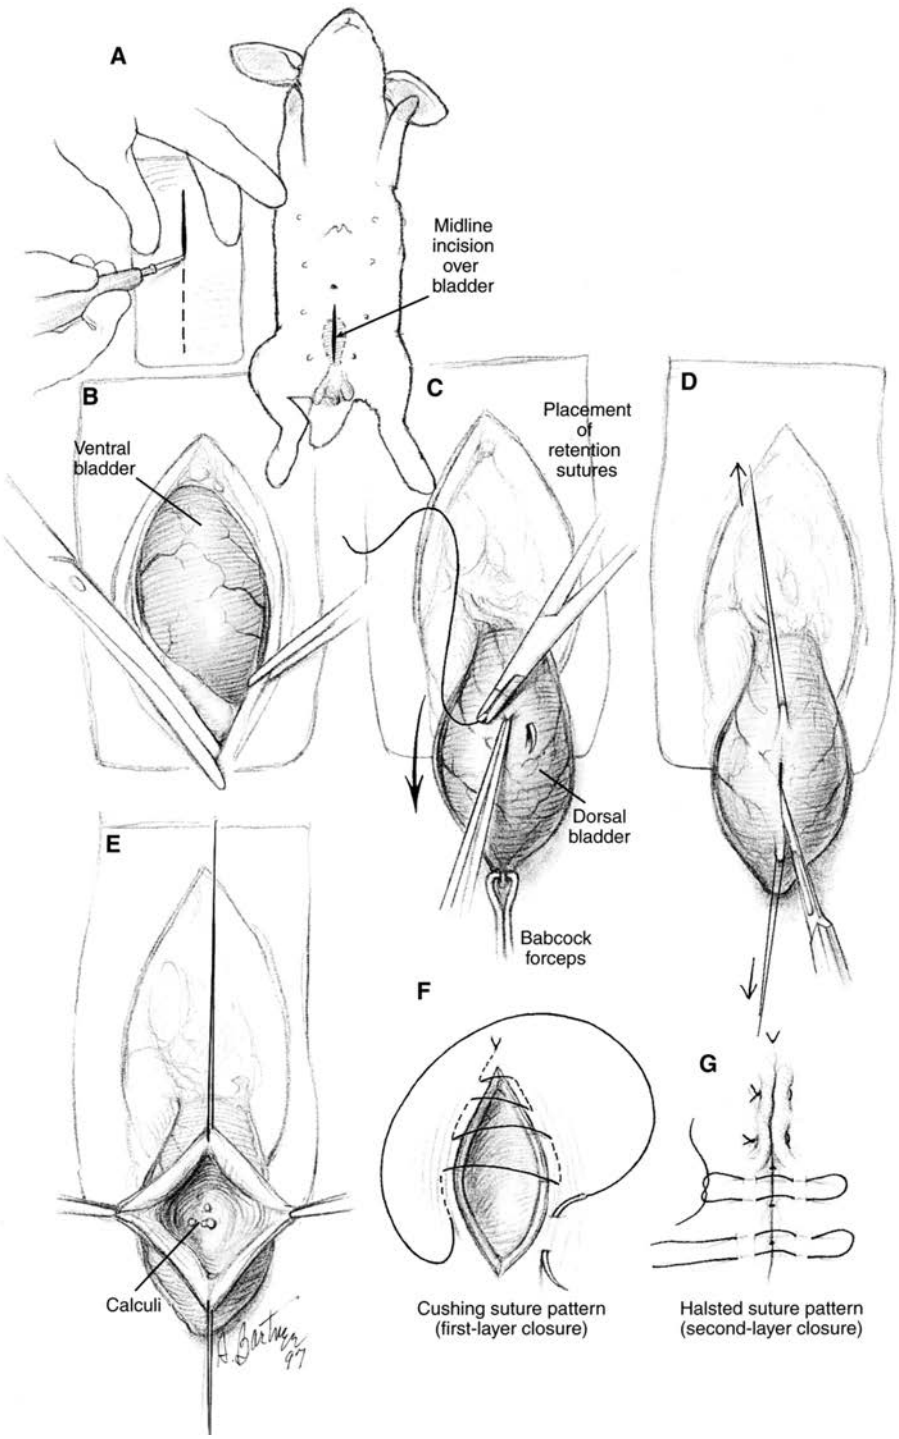

Figure 45-16. Cystotomy. **A.** With the animal placed in dorsal recumbency, a midline skin incision is made extending from a point 5 cm caudal to the umbilicus to the level of the pelvic brim. **B.** Using Metzenbaum scissors and forceps, the incision is continued through the thin linea alba and through the muscle fascia layer into the abdomen, exposing the ventral surface of the bladder. **C.** The apex of the bladder is grasped with a pair of Babcock (or other atraumatic) forceps and is reflected caudally, exposing the dorsal side of the bladder. The bladder is then isolated from the abdomen with moistened laparotomy pads. Then, using 3-0 polyglactin 910 or polydioxane suture on a taper needle, two retention sutures are placed 3 cm apart in an avascular location of the bladder. The bladder is then emptied by cystocentesis using a 25 gauge needle on a 20 mL syringe in a visibly avascular area of the fundus of the bladder. **D.** Lifting both retention sutures in opposite directions further elevates the bladder out of the abdomen and provides a taut area between them for entering the bladder. A stab incision is then made into this taut area with a scalpel. This incision is then extended cranially and caudally with Metzenbaum scissors. **E.** The bladder incision is then spread to allow inspection of the bladder contents. Any urinary calculi are removed with forceps or irrigation and suction. A specimen of bladder mucosa may be obtained for culture. **F.** The bladder is then closed in two layers using 3-0 polyglactin 910 or polydioxanone suture on a taper needle. The first layer is a Cushing suture pattern which inverts the suture line when completed. The suture should not penetrate the lumen of the bladder. **G.** The second layer is closed using a Halsted suture pattern, which further inverts the incision and helps to ensure a complete seal. Each suture should be preplaced before being tied, to provide for even tissue inversion and tension distribution. Once the second layer is completed, the closure is checked for any leakage. The bladder is returned to its normal anatomic position, and the abdomen is closed routinely.

cystitis.[4,9-11] Diagnosis can be confirmed through physical examination, palpation, and radiography.

The treatment of choice for urinary calculi is cystotomy (Figure 45-16). A urine culture should be taken by cystocentesis during the surgical procedure, before entering the bladder, and submitted for culture and antibiotic sensitivity testing. Any calculi removed should also be analyzed for possible dietary adjustment as part of the postoperative treatment.

The animals should undergo diuresis for 2 to 3 days postoperatively with either intravenous or subcutaneous fluids, and appropriate antibiotic therapy should be instituted, if indicated. An opiate analgesic along with an NSAID should be used for 3 to 5 days post surgery. The opiate is usually used for 24 to 48 hours, but the NSAID may be continued for 5 to 7 days, depending on the degree of inflammation noted in the bladder wall during the surgery. Acidifying the urine as is done with carnivorous animals is not indicated. Changing the rabbit's diet to one based

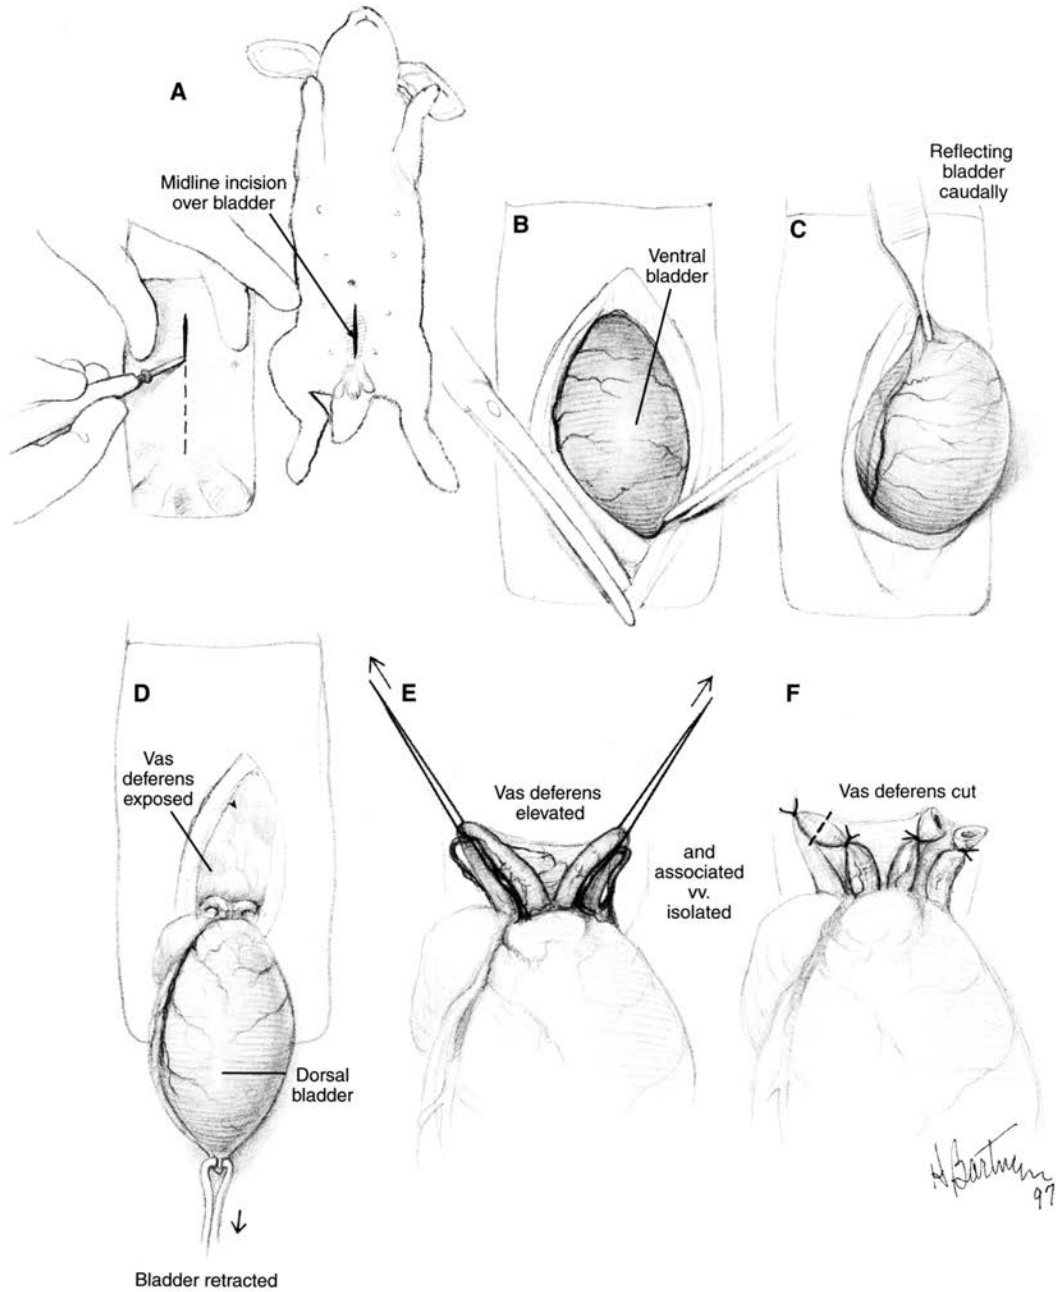

Figure 45-17. Vasectomy. **A.** With the animal placed in dorsal recumbency, a midline skin incision is made extending from 5 cm caudal 9 to the umbilicus to the level of the pelvis or 2.5 cm cranial to the genitalia or to the level of the last set of nipples. **B.** Using a pair of Metzenbaum scissors and forceps, the incision is continued on the linea alba through the muscle fascia layer into the abdomen exposing the ventral surface of the bladder. **C.** The apex of the bladder is grasped with a pair of Babcock (or other atraumatic) Orceps forceps and is reflected caudally, exposing the dorsal aspect of the bladder. **D.** Further gentle caudal retraction of the bladder with the Babcock forceps exposes the two vasa deferentia emerging near the base of the bladder. **E.** A ligature is placed around each vas deferens with care taken not to include the adjacent associated blood vessels. Each ligature is retracted to allow more exposure of each vas deferens for placement of second ligatures approximately 3 mm from the first **F.** Each vas deferens is divided between the two ligatures with Metzenbaum scissors to complete the vasectomy. The bladder is returned to its normal anatomic position, and the abdomen is closed routinely.

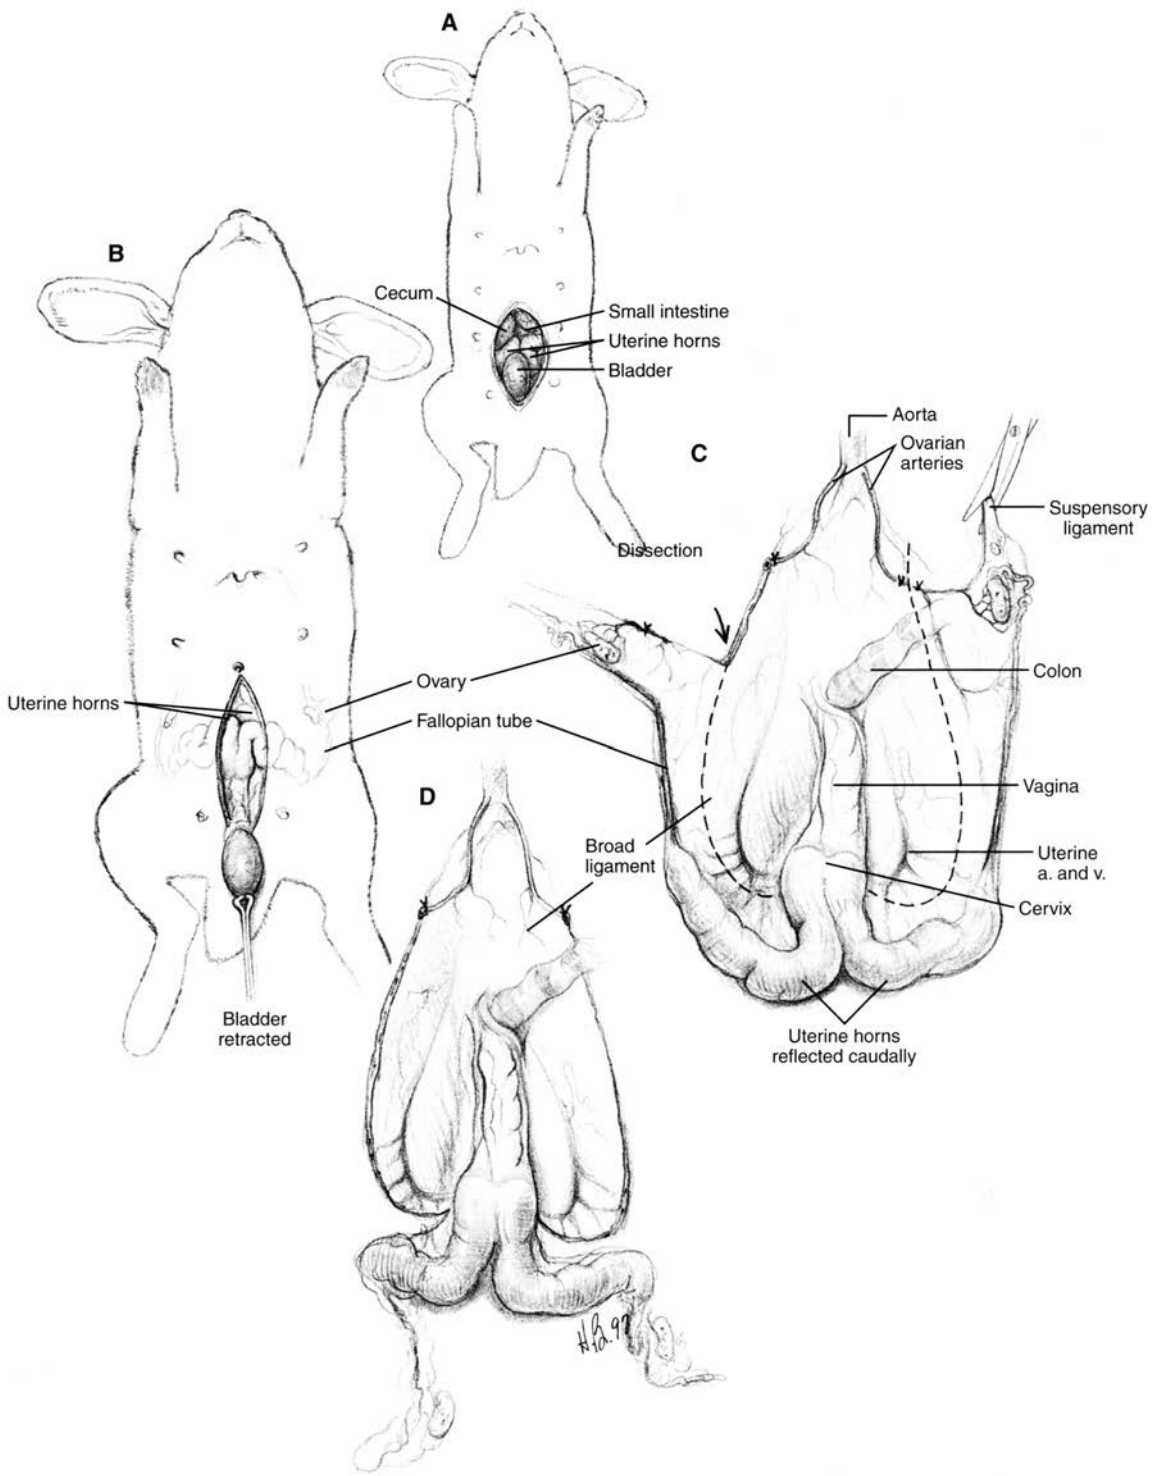

Figure 45-18. Ovariohysterectomy. **A.** With the animal placed in dorsal recumbency, a midline skin incision is made extending from the umbilicus to the level 2 cm caudal to the last pair of nipples. Using Metzenbaum scissors and forceps, the incision is continued through the linea alba through the muscle fascia layer into the abdomen, exposing small portions of cecum, small intestines, uterine horns and the bladder (if distended). Gentle retraction of the cecum laterally exposes the uterus. **B.** The bladder is retracted caudally with Babcock forceps to aid in visualizing the cervix and vagina. Using either Balfour or malleable retractors, the surgeon spreads the abdominal incision to aid in exposing the complete reproductive tract. **C** and **D**. Retracting the uterus caudally helps to expose the complete reproductive tract vagina, cervix, two uterine horns, both fallopian tubes and ovaries, and the major blood supplies. With moistened cotton tipped applicators, the fat is dissected gently to expose the abdominal aorta and the two ovarian arteries. Each ovarian artery is followed to the point where it branches to the ovary and the rest of the uterus. The surgeon places two ligatures around the vessel 3 mm apart above the branching and transects between them. The ovary is elevated, and the suspensory ligament identified and cut. The long fallopian tube and uterine horn are bluntly dissected from the broad ligament to the level 5 mm above the cervix, with care taken to control any hemorrhage from the many small vessels within the broad ligament supplying the uterine horn. This process is repeated on the opposite side.

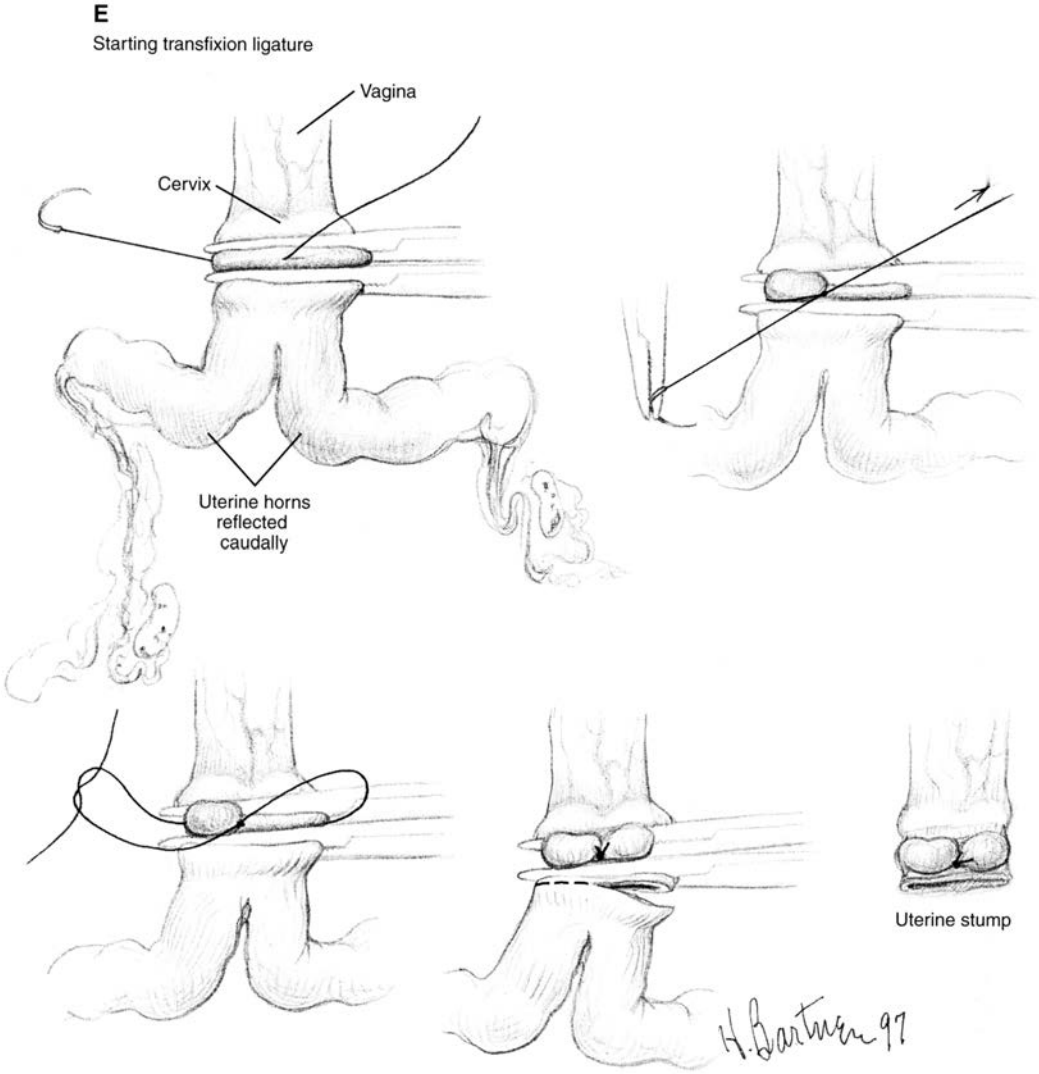

Figure 45-18 (continued). E. Continuing (with the uterus reflected caudally), the cervix is identified and is palpated to identify its anatomy. Kelly forceps are placed 4 mm apart on the uterus just below the cervix. Using 3-0 absorbable suture on a taper needle, a transfixion suture is started midway between the clamps. The transfixion ligature is completed, and the uterus is transected below the most distal clamp from the cervix with a scalpel. The uterine stump is examined for hemorrhage and is allowed to retract into the abdomen. The bladder is returned to its normal position, and the abdomen is closed routinely.

on timothy or grass hays, along with increased fluid intake, and appropriate NSAIDS and antibiotics if indicated will usually prevent recurrence of calculi. However, some rabbits may have a genetic predisposition to calculi formation, and despite corrections of dietary calcium levels, correcting any hypercalcemic conditions, and adequate fluid intake and exercise, some rabbits repeatedly form calculi. Affected animals should be periodically monitored radiographically for recurrence.[10]

Vasectomy

Vasectomy is generally performed on male rabbits for birth control purposes only.[12] However, unlike castration, the adverse side effects of an intact buck remain, including libido, urine spraying, aggressiveness, and hormonal urge to mark territory with urine and feces. The technique involves resection of a portion of each vas deferens just cranial to the bladder after a midline laparotomy (Figure 45-17). This surgical technique is currently gaining more use in biomedical research because of interest in producing transgenic animals. Bucks that have undergone vasectomy are used to induce ovulation in embryo recipient does at the same time as the embryo donor female is mated to an intact male.[17] As previously suggested in the discussion of orchiectomy, bucks that have undergone vasectomy should be separated from intact does for at least 30 days postoperatively to prevent possible pregnancy resulting from viable sperm remaining in the vas deferens.

Ovariohysterectomy

Ovariohysterectomy (OVH) is a commonly performed procedure in small animal practice and involves the surgical removal of the ovaries, fallopian tubes and the uterus. Performing an OVH on female rabbits (does) is similar to the procedure performed on dogs and cats and only requires a knowledge of the anatomic differences of rabbits for the procedure to be adapted. One major difference is that rather than having two uterine horns, a uterine body and one cervix (uterus bicornis bicollis) as in dogs and cats, rabbits have two uteri, each opening into the vagina through

a separate cervix (duplex uterus) and no uterine body. These anatomic peculiarities, at first glance, appear to complicate the traditional OVH surgery techniques taught for cats and dogs where excision of the uterus is completed at the level of the uterine body. Carefully placing a transfixion ligature just anterior to the cervix (analogous to placement in the uterine body of a dog or cat), however, enables the complete removal of the doe's reproductive tract (Figure 45-18).

Like cats, rabbits are induced ovulators with ovulation occurring 10 to 13 hours following copulation or after orgasm induced by another doe.[8,10] The gestation period is from 30 to 32 days. Female rabbits normally reach sexual maturity at 4 to 5 months, but it is best to wait until they reach at least 6 months of age before performing an OVH. Indications for performing OVH in rabbits are: (1) to prevent or treat uterine adenocarcinoma (a very common neoplasia found in 50 to 80% of does over the age of 3); (2) to correct repeated false pregnancies; (3) to prevent pregnancy; (4) to treat pyometra or uterine hyperplasia; (5) to modify aggressive behavior and biting; and (6) to decrease urine spraying.[4,8,10-12] Timing of the OVH may vary as puberty and seasonality varies with breed of rabbit and whether or not it is kept indoors or outside. Owners must be aware that cessation of some of the behaviors associated with estrus will not subside instantaneously, but may take place over several weeks. Owners are advised to launder any bedding, clean the cage well before returning the rabbit to its environment as urine scents and pheromones may still be present in the environment. Environmental pheromones may trigger undesirable behaviors. As mentioned for other abdominal surgeries, adequate pain control post surgery is critical to keeping the rabbit from opening the surgical incision. I (CJD) prefer to schedule a recheck incisional appointment 7 to 10 days postoperatively to ensure the incision has healed appropriately and to remove skin sutures if used.

Skull and Mandible

Surgical Repair of Fractures Involving the Mandible and Maxilla

Mauricio Dujowich

Introduction

Fractures of the mandible and maxilla are fairly common in dogs and cats. They are usually of traumatic origin, occurring with vehicular trauma, gunshot wounds, horse kicks, bite wounds and "high-rise syndrome" in cats. Non-traumatic causes include severe periodontal disease, oral neoplasia, radiation therapy induced osteonecrosis and metabolic derangements. Recently, the increased use of recombinant bone morphogenic-2 (rhBMP-2) protein has allowed surgeons to repair challenging fractures or non-unions, fix critical defects, and perform aggressive oncologic maxillofacial surgery that would have otherwise failed with conventional therapy. When repairing mandibular and maxillary fractures the primary goal is to permanently restore proper dental occlusion. The secondary goal of obtaining anatomical reduction of the fracture is achieved when possible.

Maxillary fractures do not require surgical intervention as often as mandibular fractures. If displacement of a maxillary fracture is not severe, occlusion is appropriate, oronasal communication and facial deformity are minimal, and no obstruction of airflow through the nasal cavity is appreciated, then conservative management is an option. Although most fractures of the oral cavity are open and may have substantial soft tissue trauma, they generally heal quickly due to abundant vascularization.

Anatomy

The mandible is made up of two halves which are firmly, but not rigidly united at the mandibular symphysis. Each half is then composed of a horizontal body and a vertical ramus (Figure 46-1). The alveoli of the lower teeth lie within the mandibular body, with the tooth roots occupying approximately two-thirds of it. The ventral third of the mandible contains the mandibular canal, through which the alveolar nerve, artery and vein course. Several mental foramina lie within the rostral aspect of the mandible. These foramina are the exit points for the mental branches of the inferior alveolar nerve and vessels, providing sensory innervation to the teeth. Typically one foramen is larger than the others.

Figure 46-1. Lateral image of the canine mandible. *A.* mental foramina, *B.* angular process, *C.* condylar process, *D.* coronoid process.

The ramus of the mandible consists of three distinct processes, the most dorsal being the coronoid process. It projects into the temporal fossa and provides an area for attachment of the temporalis muscle. The condylar (or condyloid) process is just ventral and slightly caudal to the coronoid process. This process is a point of articulation between the maxilla (retroarticular process) and mandible. Disruption of this region will result in temporomandibular joint luxation. The most ventral process is the angular process. This structure provides an area for attachment of the digastricus muscle. The masseter muscle inserts laterally on the mandible, while the pterygoid muscle inserts medially. The mandibular foramen is also located medially on the caudal aspect of the mandible.

The masseter, temporalis, and pterygoid muscles are responsible for closing the jaw and will contribute to dorsal displacement of caudal mandibular fractures. An appreciation of mandibular muscle biomechanics is important as this may influence treatment options. For example, an oblique caudo-ventral fracture of the mandibular body will be particularly unstable compared to an oblique caudo-dorsal fracture or a transverse fracture (Figure 46-2).

The maxilla is a slightly more challenging structure to understand from an anatomic standpoint (Figure 46-3). For a complete review the author refers you to the suggested reading list. Although not entirely correct, most veterinarians consider the incisors as part of the maxilla. However, these are actually housed by the incisive bone. Adding confusion, fractures of the frontal, palatine, zygomatic and nasal bones are often considered part of a maxillary fracture. In reality, the maxillary bone itself sits between all these structures. Fractures of the maxillary region may require additional evaluation due to the potential for penetration into the nasal cavity, the close proximity of the orbit, and potential damage to cranial nerves.

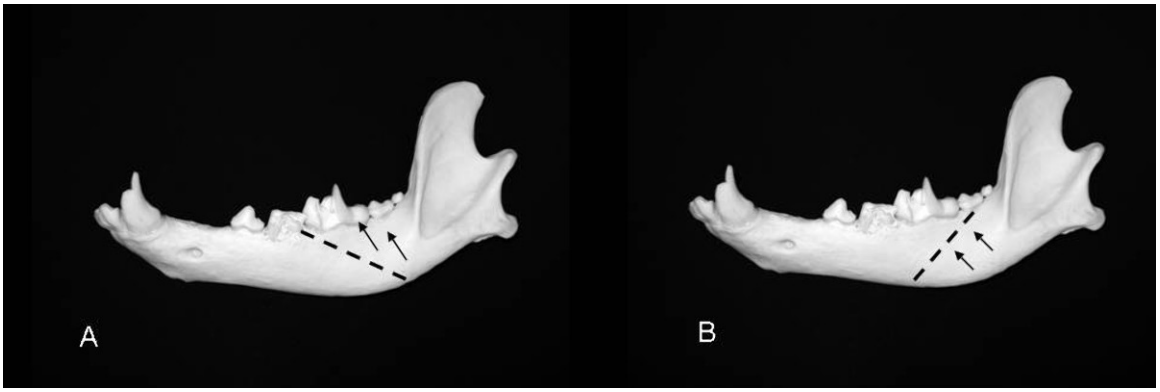

Figure 46-2. Image **A** depicts the typical muscle forces associated with a caudo-ventral mandibular fracture. The dashed line represents the fracture line. The arrows represent the pull of the muscles. Note the subsequent displacement that would occur as a result. Image **B** illustrates the beneficial effects exerted by the muscles of the jaw when dealing with a caudo-dorsal mandibular fracture. The pull of the muscles will result in a natural compression of the fracture.

Clinical Presentation

As mentioned above, most dogs and cats will present subsequent to trauma. It is critical to perform a complete evaluation of the patient prior to focusing on non life-threatening oral trauma. On presentation, stabilization of the patient is the top priority. Assess the airway for patency. Evaluate the patient for thoracic trauma via auscultation and perform thoracic chest radiographs if indicated. As with all trauma patients, it is important to rule out concurrent traumatic conditions such as pneumothorax, diaphragmatic hernia, pulmonary contusions, cardiac arrhythmias and hemothorax. Ensure that there is no abdominal trauma requiring immediate surgical intervention (hemoabdomen, uroabdomen, perforated intestine etc.). Finally, do not overlook the patient's neurological and mental status. Did head trauma result in brain injury? Stabilize the patient adequately prior to managing the fracture repair.

Diagnosis

Examination of the oral cavity with the patient under sedation or short term anesthesia will provide a great deal of information and cannot be underestimated. Evaluate for gingival lacerations and trauma as this may indicate the location of the fracture. Each individual tooth should be palpated for instability. In dogs, fractures of the mandible will most commonly occur in the premolar, molar and symphyseal regions. In cats, over 70% of fractures occur at the level of the mandibular symphysis. Assess the patient's occlusion as part of your examination. Many fractures will be open and easy to diagnose. Additionally, one can palpate for crepitus and instability of the mouth. A mandibular symphyseal fracture will allow movement of one hemimandible in relation to the other.

Traditionally, radiographs have been the first line of diagnostics for viewing mandibular and maxillary fractures. A thorough knowledge of skull radiography is needed to properly interpret the more complex oblique and intraoral views that are sometimes necessary. Radiographs are ideally performed under general anesthesia. Radiographs are excellent for evaluation of multiple tooth roots. Evaluating radiographs of the head can be challenging due to the plethora of overlying bony structures. As computed tomography (CT) has become more widely available and affordable, many surgeons opt to augment conventional radiography with this imaging modality in situations where fracture evaluation is more difficult. Fractures of the ramus, caudal mandibular body and mandibular condyle are key areas that may be difficult to interpret radiographically. CT allows certain advantages for surgical planning such as greater detail, rapid acquisition of images and the ability to create three dimensional reconstructions of the fracture site. CT is particularly desirable when dealing with pathologic fractures due to neoplasia in which resection rather than fracture repair is the treatment of choice.

Conservative Management

The mainstay of medical management of maxillary and mandibular fractures is the tape muzzle. This option is acceptable in situations where the fracture is minimally displaced, there is proper dental occlusion, and the patient has good healing potential. Tape muzzles usually remain in place for approximately 6 to 8 weeks or until there is clinical union. There are a few important considerations when placing a tape muzzle. The muzzle must allow enough slack for the patient to be able to drink water and eat soft foods or a gruel. Additionally, the patient should be kept

cool and restricted as heat dissipation via panting is compromised. Placement of a tape muzzle is seldom a viable option for brachycephalic dogs and cats.

To place a tape muzzle simply cut a length of the appropriate size tape to go around the muzzle of the patient (Figure 46-4A). The "sticky" side of the tape should be up. A spacer (a pencil or a pen) should be placed between the upper and lower incisor teeth to ensure that a small gap is present after the tape muzzle is applied. This gap is not large enough to jeopardize proper alignment, but is sufficient to enable the patient to lap fluid or gruel. The next piece of tape is placed behind the neck and along both sides of the muzzle (Figure 46-4B). This piece of tape is also placed with the "sticky" side up. The ends of the tape on both sides should extend past the nose for an equal distance to that from the nose to the middle of the patient's back. The third piece of tape is placed "sticky" side down around the muzzle. Then the long ends of the second piece can be folded back onto itself. A caudo-ventral mandibular support strap may also be incorporated if desired (Figure 46-4C). It is strongly recommended to apply a tape muzzle under heavy sedation or anesthesia. An alternative to a tape muzzle is a pre-fabricated restraint muzzle. This can be conveniently swapped out with another muzzle and washed periodically. The same considerations mentioned above will apply to sizing of pre-fabricated muzzles. One of the drawbacks to muzzles is their propensity to cause a moist dermatitis. This typically resolves without complications once the muzzle is removed.

Bonding of the mandibular and maxillary canine teeth (Figure 46-5) is a conservative repair technique that may result in less morbidity than stabilizing the fracture with a tape muzzle. In order for this technique to be successful, it is necessary for all canine teeth to be present and healthy. These teeth must first be cleaned, pumiced, and acid etched. The acid etching allows the bonding agent (acrylic) to adhere more reliably to the teeth. The teeth are then aligned with the mouth open enough to allow for drinking and eating as described above and the acrylic is then applied. If the patient is unlikely to eat due to the severity of trauma or an inability to lap food, a temporary esophagostomy tube should be placed. After application, any rough or sharp edges of the acrylic are smoothed with a dental burr. The fixation is removed with a dental burr once the fracture has healed. Although application is easy, this conservative option will require two anesthetic events and the risk of anesthesia should be weighed against the benefits of intraoral bonding in each individual patient.

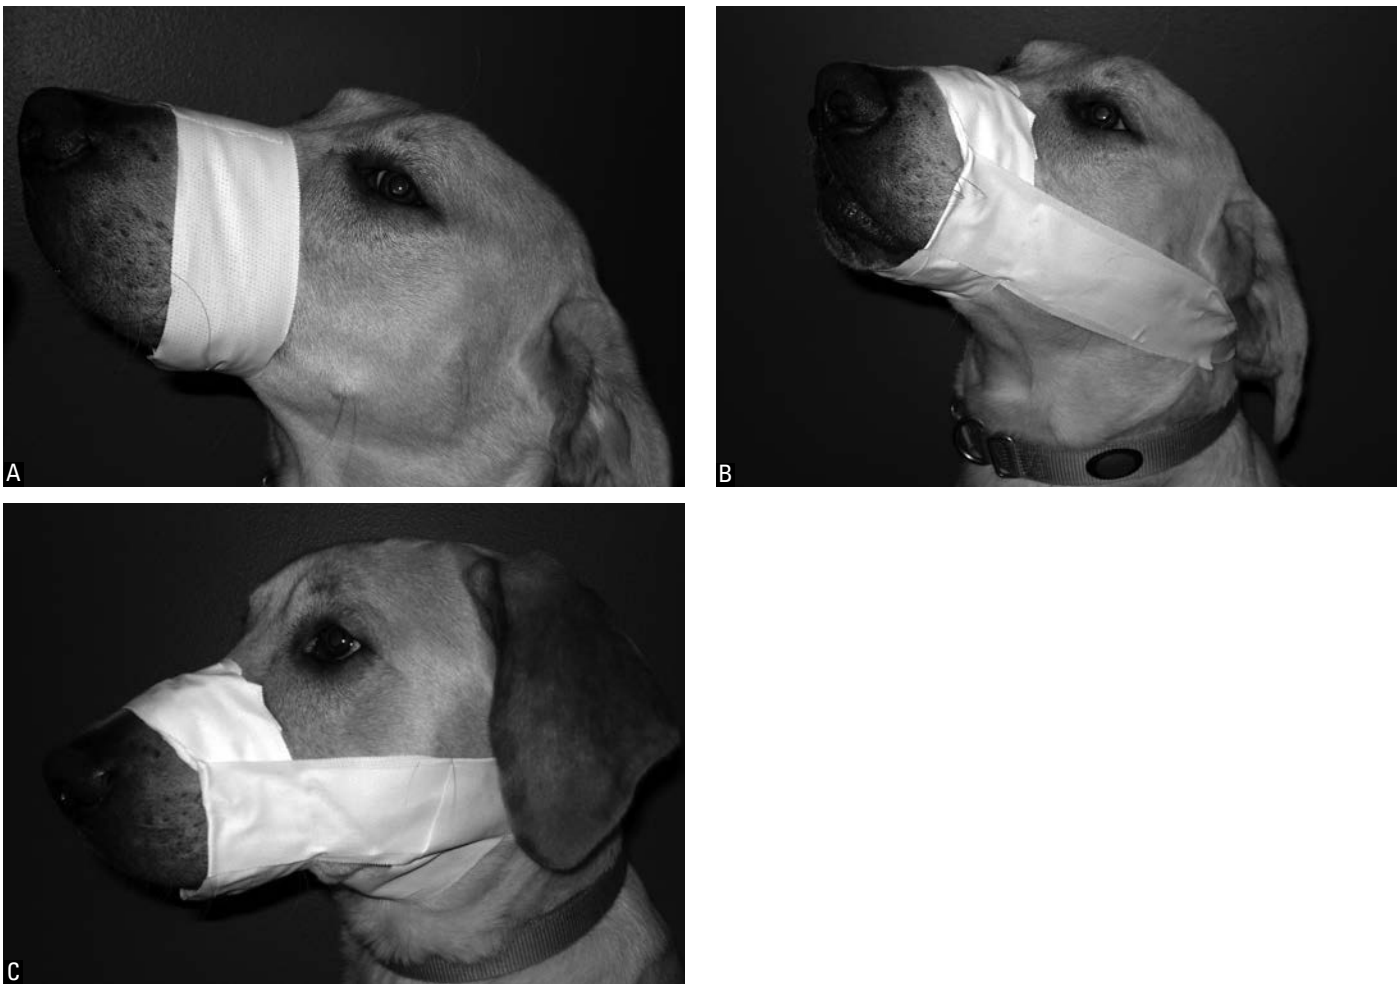

Figure 46-4. Image **A.** depicts the placement of the first length of tape. This is placed "sticky" side up. Image **B.** illustrates the application of the neck strap "sticky" side down followed by another length of tape around the muzzle ("sticky" side down). The excess length of the neck strap was then backed over onto itself. Image **C.** is showing the tape muzzle along with an optional caudo-ventral mandibular support strap.

Figure 46-5. Dental bonding of a feline patient after sustaining a mandibular symphyseal fracture along with multiple fractures to the maxilla and zygomatic arch which were contributing to a malocclusion after reduction of the symphyseal fracture. This prompted placement of a temporary esophagostomy tube and dental bonding in proper alignment.

Anesthetic Considerations

Understanding the potential ramifications of inducing anesthesia on a patient with possible head trauma is important and the anesthetist should plan accordingly. When repairing a mandibular or maxillary fracture that has compromised occlusion, it is challenging to assess proper occlusion if the patient is intubated in the customary manner. It is recommended to translocate the endotracheal tube to a pharyngostomy incision in these situations. Once the patient is anesthetized and intubated in the usual fashion, locate the lateral pharyngeal region of the patient just cranial to the hyoid apparatus, with a curved Carmalt forceps inserted through the mouth. Incise over this region through the skin, subcutaneous tissues, and mucous membrane. Make the incision large enough to reroute the endotracheal tube. Grasp the endotracheal tube through the incision and feed it retrograde through the incision. Once the patient is extubated the incision is left open to heal by second intention.

Another anesthetic consideration that is commonly overlooked is the application of local nerve blocks in the oral cavity. Mepivicaine, lidocaine, and bupivicaine are all commonly used agents in small animal dentistry. Of these, bupivicaine will have the longest duration of action (approximately 6 hours). Nerve blocks are relatively simple to perform, may help prevent "wind-up" of pain receptors and decrease the amount of inhalant anesthesia required.

There are several nerve blocks that are commonly utilized in oral procedures and these should be considered when repairing fractures of the maxilla or mandible. The mental nerve block is performed apical to the mesial root of the second mandibular premolar (Figure 46-6). This block will result in anesthesia of all ipsilateral incisors and canines of the mandible. A caudal mandibular nerve block can be performed when regional anesthesia of all the ipsilateral teeth of the mandible is necessary. The injection is made near the mandibular foramen on the lingual aspect of the mandible (Figure 46-7).

Figure 46-6. Image of mandible illustrating location for application of a mental nerve block.

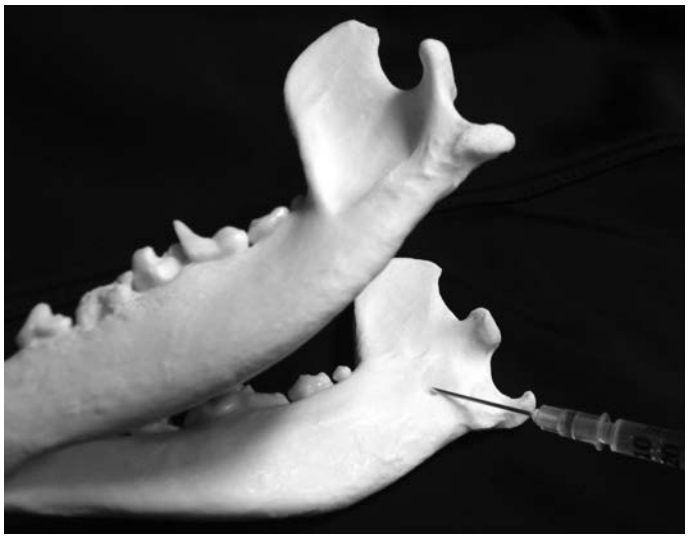

Figure 46-7. Medial aspect of the mandible depicting the location of a caudal mandibular nerve block. The mandibular foramen is the exit point for the alveolar nerve and vessels.

If regional anesthesia of the maxillary incisors, canines and premolars is desired then a palatine nerve block should be performed (Figure 46-8). This block may only be partially effective as some of the innervation of the region comes from the infraorbital nerve. For this reason, it is not uncommon to perform a palatine nerve block in conjunction with an infraorbital nerve block in dogs. To perform a palatine nerve block an injection is made at the midpoint between the mesial aspect of the maxillary carnassial tooth and midline of the palate. The cranial infraorbital block will result in anesthesia of the ipsilateral incisors and canine teeth of the maxilla. To perform this block, an injection is made apical to the distal root of the maxillary third premolar. This corresponds to the opening of the infraorbital foramen (Figure 46-9). Once the foramen is localized by palpating through the oral mucosa the syringe is advanced approximately 1 mm into the foramen prior to injection. In cats it is not recommended to advance the needle because the infraorbital canal is short and orbital trauma may result. For anesthesia of all the ipsilateral teeth of the maxilla, a caudal infraorbital block may be performed by advancing the needle 2 to 3 mm into the infraorbital canal. Again, this is not recommended in the cat.

Figure 46-8. Ventral aspect of the maxilla illustrating the proper location for application of a palatine nerve block.

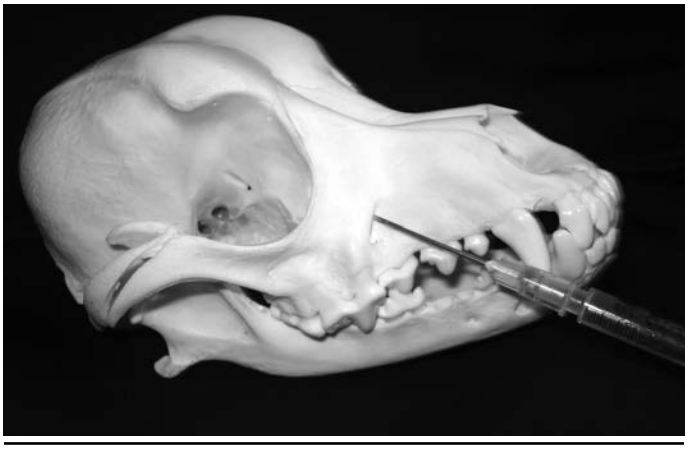

Figure 46-9. Lateral view of the skull depicting the appropriate location for placement of an infraorbital nerve block.

Surgical Considerations

There are multiple structures that must be considered when performing surgery of the mandible and maxilla. These structures are frequently compromised prior to surgical intervention, making it that much more important to limit additional iatrogenic trauma. Use of an intranasal Folley catheter may assist with reduction and controlling nasal bleeding. The maxillary nerve passes through the alar canal and should be avoided during maxillary fracture repair.

Tooth roots must be avoided when drilling into the mandible or maxilla. Damage to the nerve root may necessitate additional intervention at a later time. The teeth should be thoroughly evaluated for damage and viability. If a fractured tooth root is present with weak periodontal ligament attachment, the tooth should be removed. If the viability of the tooth is questionable then adequate follow-up is necessary to minimize future complications. When approaching the caudo-lateral aspect of the mandible, the parotid duct and gland must be avoided. Positioning will depend on the region that is fractured. Typically, mandibular body fractures are repaired with the patient in dorsal recumbency, mandibular ramus fractures in lateral recumbency, and maxillary fractures in ventral recumbency.

External Fixation

External methods of mandibular and maxillary fracture stabilization include external skeletal fixation, interdental wiring and interdental fixation. These techniques offer the potential advantage of being less invasive than internal fixation methods. Decreased morbidity, avoidance of iatrogenic trauma to important structures of the mandible and maxilla, and preserving blood supply are all potential benefits of external fixation.

Interdental Wiring

Wires that are placed around teeth adjacent to a fracture are called interdental wires. Placement relies on a solid tooth-bone interface and any loose teeth incorporated into the wire may result in instability and subsequent failure of the repair. For placement, drill a hole on the superficial aspect of the mandible or maxilla between the two teeth closest to the rostral fracture fragment and then do the same on the caudal fracture fragment (Figure 46-10). An alternative method is to use a hypodermic needle or Kirschner wire passed through the gingival line at the level of the neck of the tooth. The cerclage wire is then fed through the holes and contoured around the teeth in a figure eight fashion. Twist and tighten the wire evenly. Bend the wire ends into the mucosa to avoid damaging surrounding surfaces. Twenty to 24 gauge wire is appropriate for most dogs and cats. Interdental wiring is commonly bolstered with interdental fixation.

Interdental Fixation

Similar to interdental wiring, healthy, intact teeth are required rostral and caudal to the fracture line when applying an interdental fixation. As mentioned above, interdental wires are commonly applied prior to interdental fixation in dogs. Doing so results in a stronger, more stable repair. Interdental fixation involves placement of an acrylic layer over prepared teeth to act as an intraoral splint (Figure 46-11). The teeth must first be cleaned, polished and acid etched. The acrylic is then applied, usually spanning at least two teeth rostral and caudal to the fracture. The acrylic splint is left in place for approximately 6 weeks or until healing has been confirmed. The splint may then be removed by sectioning it with a dental burr.

External Skeletal Fixation

The advent of positive profile pins for use in external skeletal fixation has allowed greater versatility and success. Highly comminuted mandibular fractures (i.e. gunshot wounds) are ideal candidates for repair with external skeletal fixation. Type

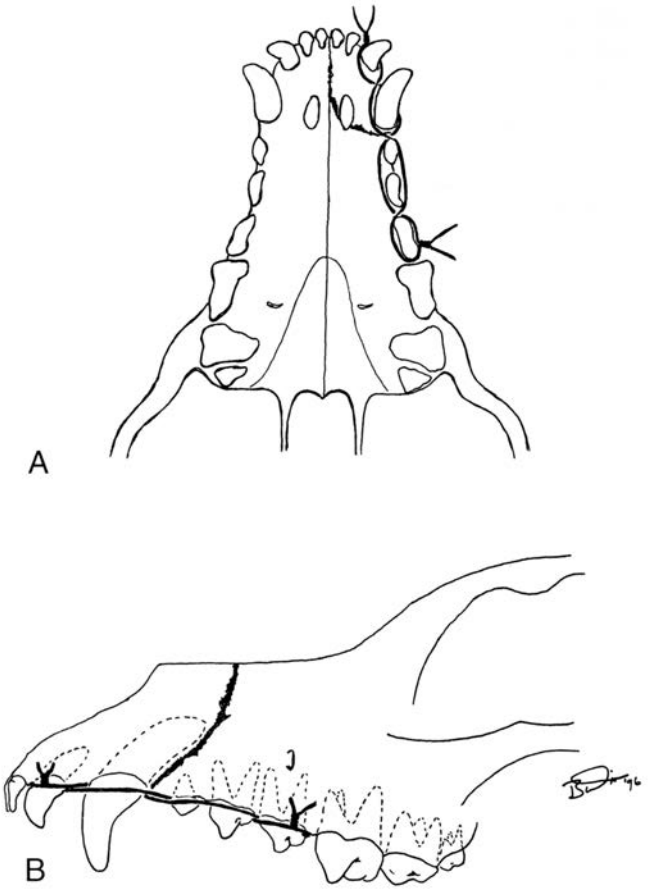

Figure 46-10. A. and **B.** Figure of eight interdental wire used to stabilize a transverse maxillary fracture. Wire loop is twisted from both ends to ensure uniform tension.

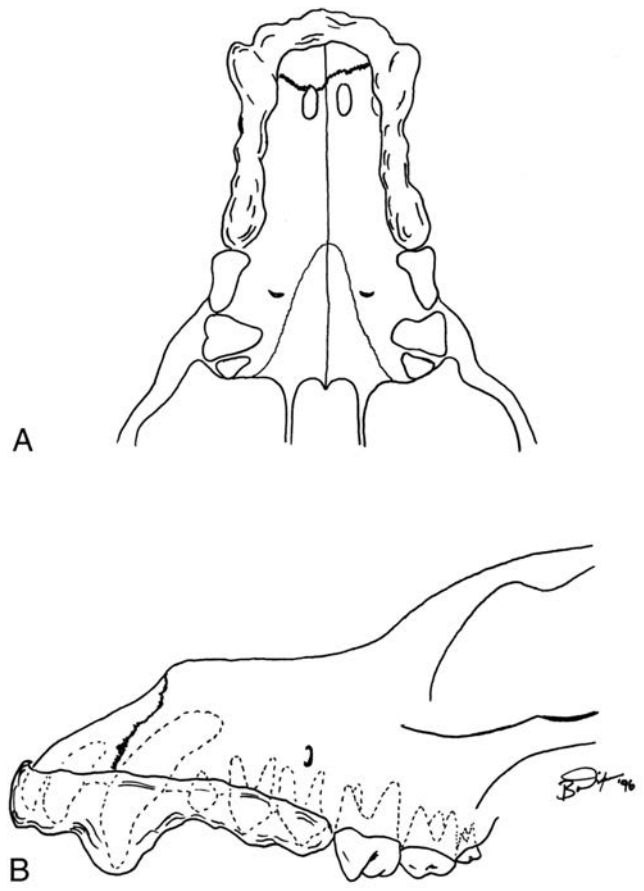

Figure 46-11. A. and **B.** Rostral maxillary and incisive bone fracture stabilized with an acrylic dental splint.

1-a fixators are used for mandibular fractures (Figure 46-12). Typically, all fixation pins are half-pins, but a centrally-threaded full-pin can be applied across the mandibular symphysis. The fixator is applied percutaneously by making release incisions through the skin, pre-drilling the bone, and placing positive-profile end-threaded pins. The pins are placed in the ventro-lateral aspect of the mandible to avoid tooth roots. Ideally, three pins are placed on either side of the fracture, but there may only be enough room for two pins on either side. This varies depending on patient size and fracture extent. The fixation frame can be built with clamps and rods, or acrylic.

Premature pin loosening is one of the major limiting factors of the external skeletal fixation system. Thermal osteonecrosis is thought to contribute to premature pin loosening. To avoid thermal osteonecrosis and subsequent premature loosening of fixations pins, pin sites should be pre-drilled prior to insertion of a fixation pin with a low speed (< 200 RPM) power drill. Acrylic fixators are discussed later in this chapter and add yet another level of versatility to external skeletal fixation. This method of fixation may be a superior alternative in certain comminuted fractures of the mandible in which pins need to be placed on the rostral aspect of the mandible. An acrylic column can be molded to any shape desired around the mandible (Figure 46-13). Alternatively, epoxy putty found at hardware stores may be substituted for acrylic to form the fixation frame.

Internal Fixation

Internal fixation of mandibular and maxillary fractures may include interfragmentary wiring and bone plating. An advantage of internal fixation is the ability to achieve excellent reduction and stabilization. It is important to remember, however, that proper dental occlusion takes precedence over apparent "anatomic reduction" of the internally fixated oral fracture. Additionally, post-operative morbidity may be reduced with internal fixation compared to external skeletal fixation. This is attributable to the absence of percutaneous implants.

Interfragmentary Wires

Interfragmentary wires involve using cerclage wire to reduce relatively simple fractures (Figures 46-14 and 46-15). They should only be used in situations where anatomical reconstruction can be achieved. Placement of two interfragmentary wires is recommended as this will help counter shear and rotational forces. Always drill and pre-place all wires prior to tightening. Wire size will depend on the animal; sizes between 16 to 22 gauge are typically used. Holes are pre-drilled into the bone for application of the wire. The holes are drilled with Kirschner wires perpendicular to, and 5 to 10 mm away from the fracture line. As with all other drilling of the mandible or maxilla, care must be taken to avoid drilling through tooth roots. Slight angling of the holes toward the fracture line will allow for easier tightening of the wire once it is applied.

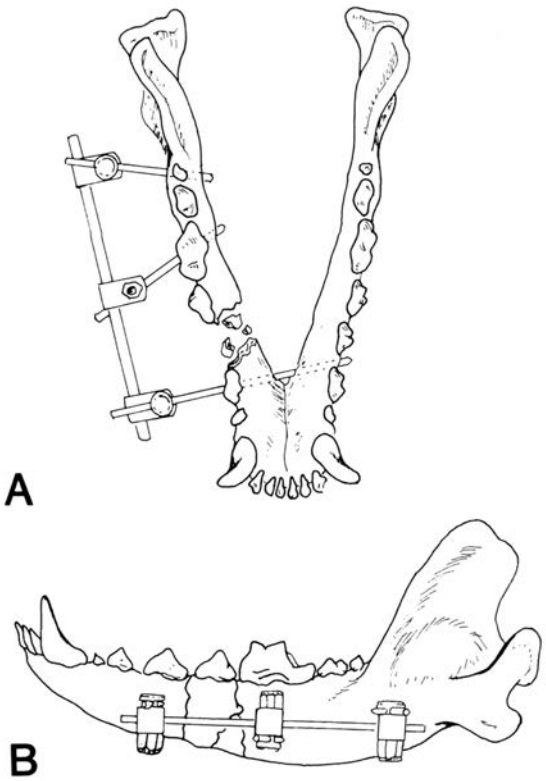

Figure 46-12. Application of an external fixator using positive profile pins to repair a comminuted mandibular fracture. **A.** Dorso-ventral view. **B.** Lateral view.

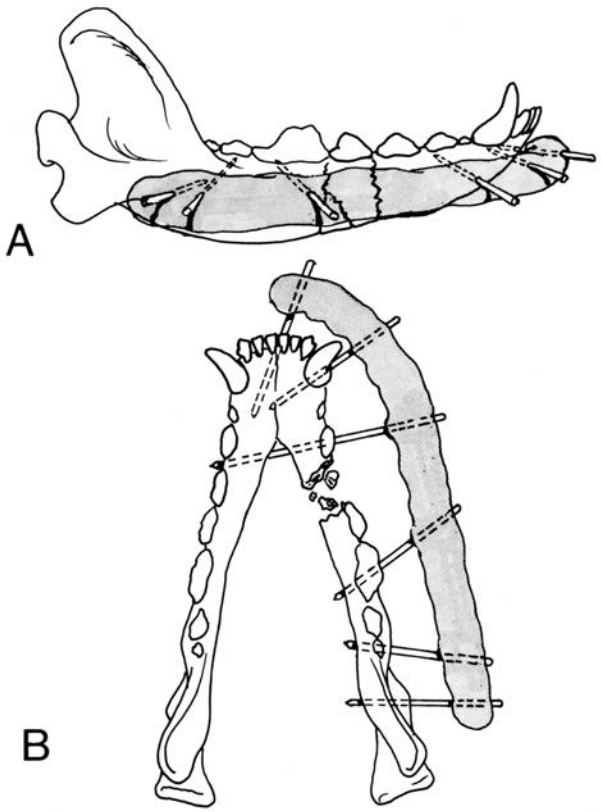

Figure 46-13. An acrylic external fixator applied to a comminuted mandibular fracture. **A.** Lateral view. **B.** Dorso-ventral view.

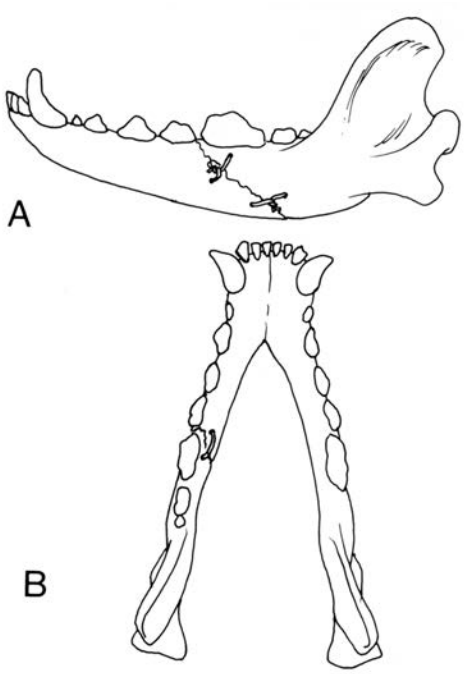

Figure 46-14. Hemicerclage wires used to repair an oblique mandibular fracture. **A.** Lateral view **B.** Dorso-ventral view.

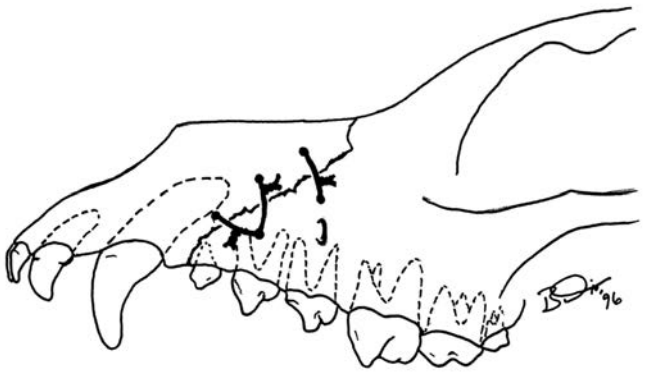

Figure 46-15. Oblique fracture of the maxilla repaired with three interfragmentary wires. All wires should be preplaced before tightening. The two rostral wires are placed using a triangulated wiring technique which may be used for oblique fractures.

After the wires are passed through the drill holes they are tightened with wire twisters. Pull evenly on both wires and twist; with unequal tension, one wire will twist around the other and the fixation will fail due to knot slippage. It is important to ensure that the wire is tight to avoid any unnecessary instability. The ends of the wire are bent toward the bone and away from the gingival margin to avoid damage or irritation of nearby structures. This is done by twisting and bending the wire at the same time to prevent any loosening of the wire while it is being bent. Care must be taken to ensure that the wire is not over- or under-twisted. As the wire is over-twisted and becomes tighter, its color will become dull instead of shiny. Many surgeons twist the wire until the point at which it starts to dull. Once the wire is appropriately bent it is then cut with wire cutters. Three twists are typically left behind to ensure knot security of the tightened wire. Interfragmentary wires are used frequently with maxillary fractures since other fixation methods are either difficult to apply in the presence of the

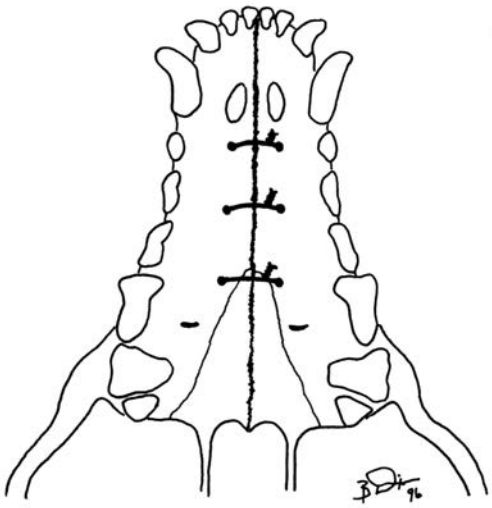

Figure 46-16. Interfragmentary wires used to stabilize a longitudinal split of the palatal bone.

nasal passages or cost prohibitive. Sometimes a Kirschner wire is incorporated into a figure eight wire fixation to help prevent collapse of a maxillary fracture into the nasal passages.

Interfragmentary wires have also been used successfully for the treatment of midline palatal fractures (Figure 46-16).

Symphyseal Fracture of the Mandible

Symphyseal fractures are the most common type of mandibular fracture encountered in cats and they typically occur as a component of "high rise syndrome". Diagnosis can usually be done on initial physical examination by palpating instability at the level of the symphysis (Figure 46-17). The clinician should be able to appreciate one side of the mandible moving in relation to the other. However, once the patient's overall status is evaluated and confirmed stable, a sedated exam is likely to be much less stressful for the patient and the clinician. This will also help to avoid missing other oral cavity injuries.

Figure 46-17. Image of mandibular symphyseal fracture in a cat. Note the step defect associated with the mandible.

Proper reduction of the symphyseal fracture is accomplished through placement of a wire around the rostral mandible just caudal to the canine teeth (Figure 46-18). To do this, make a small incision ventral to the symphysis that is large enough to insert two 16 or 18 gauge hypodermic needles. Insert one needle just caudal to the canine tooth along the lateral aspect of the mandible, as close to the mandible as possible to avoid iatrogenic damage to soft tissues. Next, thread an appropriately sized cerclage wire through the needle (usually 18 or 20 gauge). Place another hypodermic needle in the same fashion as described above on the contralateral side. Thread the cerclage into this hypodermic needle and out the ventral aspect of the mandible. The result is encircling of the symphyseal fracture with cerclage. The cerclage can now be tightened with wire twisters, being sure to achieve proper reduction while tightening. The excess wire can then be cut while leaving at least three twists with the patient. The wire ends are bent down and the small incision is closed or left to heal by second intention.

After the fracture has healed, the wire is usually removed by cutting it with wire cutters. This is best done by cutting the wire intraorally and then either pulling the wire through ventrally or cutting the wire twists to create two separate wires. This latter approach may allow easier passage of the wires. Once the wires are removed, palpate the symphysis to verify that it is stable. Heavy sedation of the patient is recommended as this greatly facilitates wire removal.

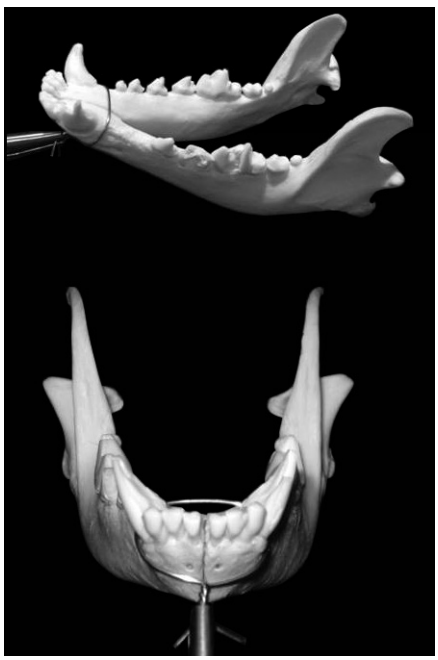

Figure 46-18. Application of interdental wire around a symphyseal fracture. The cerclage wire is placed just caudal to the canine teeth and tightened on the ventral aspect of the mandible.

Bone Plates

With recent advancement in plating technologies there are several different options depending on the repair goals. Bone plates have a distinct advantage of allowing the surgeon to apply them in compression, neutralization, or buttress. For easily reconstructable fractures a limited contact plate (LC), dynamic

compression plate (DCP), or even better, LC-DCP is recommended. Small locking plates like a 2.0 mm string of pearls plate (SOP) can also be very versatile as the plate behaves as an "internal" external fixator and allows the surgeon the ability to contour the plate in almost any direction (Figure 46-19). Miniature maxillofacial reconstruction plates are also available and are very easy to work with from a contouring standpoint. Their main disadvantage is weakness in comparison to other plating options. In human maxillofacial surgery it is common practice to use resorbable plates, however, the high cost of these plates generally precludes their use in veterinary medicine.

When bone plates are applied on the mandibular body they are placed on the ventro-lateral aspect of the mandible. The tooth roots should be avoided when drilling and placing screws. This may be a disadvantage as a result of the "tension band" effect on the alveolar surface. Due to the pull of the muscles of mastication there is a bending force at the alveolar surface causing separation of the fracture at the tooth surface and compression at the ventral aspect of the fracture. To counter this "tension band" effect an interdental wire may be applied or a miniature plate placed more dorsally on the mandible that will allow screw placement between the tooth roots. Lastly, when applying bone plates care must be taken during contouring of the plate to avoid iatrogenic malocclusion.

Postoperative Care

In the immediate postoperative period, the patient should be monitored carefully for any airway obstruction secondary to the fracture repair. Adequate intravenous analgesia should also be provided. Patients should be transitioned to oral analgesics and maintained on these for 5 to 10 days. If substantial discomfort is expected when trying to administer oral medications then a feeding tube (e.g. esophagostomy tube) should be used. These are relatively easy to place and require minimal care. When placing an esophagostomy tube, always check proper placement into the distal third of the esophagus with a lateral radiograph. Initiate an appropriate feeding regimen according to the patient's needs. If oral intake is possible, easily swallowed soft foods are recommended. The ideal food item is nutritionally complete, requires minimal chewing and does not adhere to the repair site. Recheck examination will depend on the type of fracture, repair method used, and patient age. In general most fractures of the maxilla and mandible will heal by 6 to 8 weeks. Once clinical union is achieved implants may be removed if necessary. Potential complications of fracture repairs include sequestra, osteomyelitis, implant failure, malocclusion, nonunion or malunion, tooth root injury and periodontitis.

Acrylic Pin Splint External Skeletal Fixators for Mandibular Fractures

Dennis N. Aron

Acrylic pin splints are external skeletal fixators that use acrylic as both the connector rod and linkage. This fixation method can be accomplished in numerous ways, using either homemade materials or commercial kits (Acrylic Pin External Fixation System, Innovative Animal Products, Rochester, MN). Use of an acrylic pin splint has several advantages over standard metal external skeletal fixators for the mandible. The acrylic pin splint is lightweight, radiolucent, and versatile. The acrylic pin splint enables the surgeon to position pins to avoid tooth roots and vital structures easily and to combine pins of various sizes in a singular frame (Figure 46-20). The acrylic pin splint is easy to contour to the shape of the mandible (Figure 46-20). The advantage of using a homemade acrylic pin splint is that the surgeon can purchase specifically needed components from different sources. The commercial kit provides convenience of application because it contains all materials in a single package.

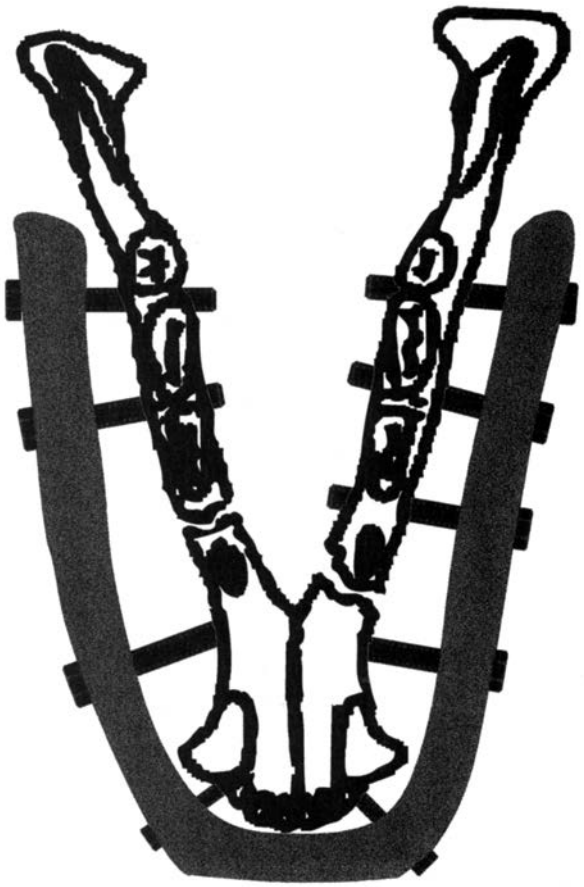

Figure 46-20. Acrylic pin splint is easy to contour. Normal occlusion is a high priority in splinting.

The homemade splint consists of methylmethacry-late, which can be obtained as either hoof repair (Tech-novit Hoof Acrylic, Jorgensen Laboratories, Loveland, CO) or dental molding acrylic (Orthodontic Resin, L.B. Caulk Co., Milford, DE). The acrylic column can be free-formed or injected into a tube to serve as a mold. When free-formed, the acrylic is molded by hand to the required shape. The free-form method is easiest with most applications to the mandible, especially for smaller dogs and cats. The tube method may be best for larger dogs. The commercial kit uses a tube method. Research has shown that a 3/4-inch acrylic column diameter provides fixation strength comparable with or greater than that of the medium Kirschner 3/16-inch connector rod. Given this guideline, the surgeon can extrapolate the needed width of the acrylic column to various sizes of animals.

Two considerations are important to predictable and consistent success when using acrylic pin splints for mandibular fractures. First, the surgeon needs to establish normal occlusion and mastication for the patient. Failure to accomplish this goal predisposes the patient to abnormalities of the temporomandibular joint and pain, with the possibility of negative consequences on nutritional balance. Normal occlusion in the dog is seen when the mandibular canine teeth are positioned between the maxillary incisors and canine teeth and the mandibular fourth premolar is situated between the maxillary third and fourth premolars. Achieving normal occlusion is always a higher priority than accomplishing accurate reduction at the fracture site (See Figure 46-18). When performing surgical correction of mandibular fractures, placement of the endotracheal tube through a pharyngostomy enables the surgeon to assess occlusion during the operative procedure. When the endotracheal tube is positioned routinely, it interferes with normal closure of the mouth and prevents the surgeon from assessing accurate occlusion.

The second important consideration is the need to use screws or positive profile end-threaded pins (fasteners) for attachment of the acrylic column to the mandible. The mandible is a relatively flat bone without two nicely separated dense cortices. This configuration predisposes nonthreaded pins to premature loosening, which leads to discomfort and, possibly, to delayed healing with the fixation of mandibular fractures. Because of this situation, screws or threaded pins, which provide a screwed-in anchorage, are advantageous when used for treating fractures of the mandible with external skeletal fixation. Bone screws work well for this purpose because they can be obtained in varied sizes corresponding to patient size. The head of the screw and exposed thread provide a secure linkage to the acrylic column. For use in particularly small animals is a small-diameter (0.9, 1.1, 1.6, 2.0, and 2.4 mm) positive-profile end-threaded pin (Miniature Interface Fixation Half Pins. IMEX Veterinary, Inc., Longview, TX) that is an excellent fastener designed to be used with acrylic. One end is intended to provide screwed-in fixation with the bone, and the opposite end is a roughened thread to allow for strong linkage with the acrylic column. The pin is remarkably stiff, given its diminutive size, a positive mechanical property not found in most small-diameter pins. Fully threaded Steinmann pins or negative-profile threaded pins should not be used with the acrylic pin splint because they are mechanically weak and are predisposed to loosening or breakage. The threaded pins

and screws should be inserted by first drilling a hole with a sharp drill bit sized to approximate the core diameter of the fastener. This gives maximum stability to the fastener-bone interface. The tip of the threaded pin must exit the transcortex completely to engage thread throughout the bone.

Often, a combination of threaded and smooth fasteners is used together. When this method is used, at least one threaded fastener needs to be positioned in each bone segment on either side of the fracture. By combining smooth and threaded fasteners, the surgeon gains both stability and ease of application, especially when using a biphase technique (see later). At least two fasteners need to be positioned in each bone segment on either side of the fracture. Frequently, more fasteners are placed in each individual bone segment, a maneuver that enhances the strength of the construct. It is possible, and advantageous, with the acrylic pin splint to stabilize fractures involving both hemimandibles with a singular acrylic column (See Figure 46-20). The vertical ramus of the mandible is a poor location for securing fasteners because this soft, flat bone does not hold a fastener well. Because of this limitation, caudal mandibular fractures do not lend themselves well to fixation with the acrylic pin splint.

Free-Form Acrylic Pin Splint

The patient is administered a perioperative antibiotic regimen. The appropriate number of fasteners is placed into each bone segment. Aseptic technique is always used when applying the fasteners and during fracture manipulation and closure of the soft tissues, when using an open reduction technique. Aseptic technique is not necessary for application of the acrylic connector when this procedure is done after closure of the wound. Fasteners can be wedged between tooth roots, but they should not be drilled through these roots, and mandibular vessels and nerves need to be avoided. If smooth pins are used in the configuration, they need to be bent to lie parallel to but elevated from the skin, to allow secure adherence to the column and room to accommodate the acrylic mass (Figure 46-21). Fasteners should be positioned so, after the acrylic column is in place, distance of 1 to 2 cm will be present between the acrylic column and the skin. This distance is necessary to avoid thermal damage to the soft tissues and bone while the acrylic sets. Moistened gauze sponges can be placed to protect the skin and to cool the pins, thereby impeding conduction of excessive heat to the bone. All methylmethacrylate products use two components, a liquid (monomer) and a powder (polymer). For the Caulk orthodontic dental resin, three parts powder are mixed with one part liquid. For Technovit Hoof Acrylic, two parts powder are mixed with one part liquid. A disposable cup and wooden tongue depressor can be used to mix the acrylic. These two portions are mixed until they become doughy (3 to 4 minutes). The acrylic is hand molded to form a column long enough to incorporate all the preplaced fasteners and wide enough to provide adequate strength for the particular size of the animal. Approximate occlusional alignment and fracture reduction are achieved. The acrylic column is placed on the fasteners and is conformed to the appropriate shape; then final occlusional alignment and fracture reduction are completed and held. The acrylic is adequately hardened 8 to 12 minutes after mixing, to enable the surgeon to abandon temporary holding of occlusion and reduction.

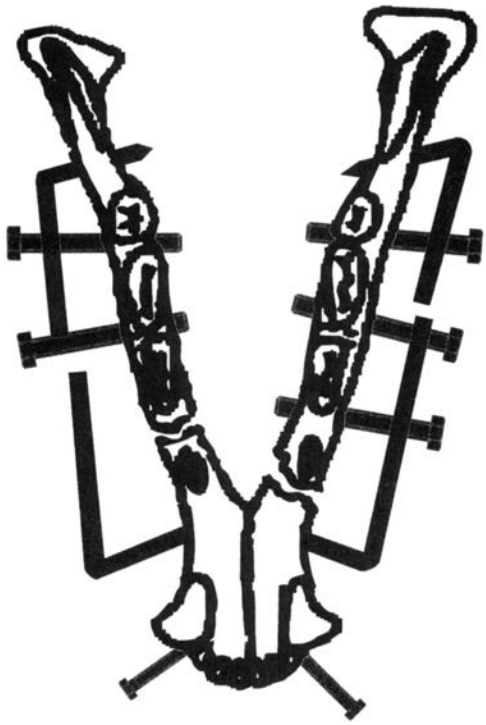

Figure 46-21. Free-form acrylic pin splint.

A biphase technique can be used to facilitate application of the acrylic pin splint. With this technique, the surgeon applies a temporary adjustable reduction device such as Kirschner clamps and connector rods (phase 1) separate and external to the acrylic column, to hold occlusional alignment and fracture reduction temporarily (Figure 46-22). The acrylic is mixed and molded to all fasteners and is allowed to set (phase 2); then the external device is removed. The long pins are cut short once the acrylic has hardened; alternatively, the long pins can be bent over to lie flush with the acrylic column, and more acrylic can be mixed and

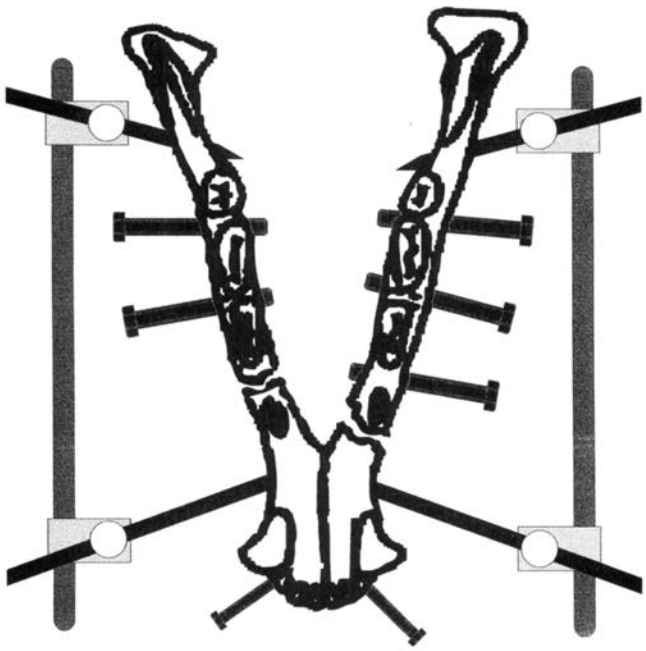

Figure 46-22. Biphase technique using Kirschner clamps and connector rods.

added to the column to incorporate the bent pins (Figure 46-23). This technique enhances the stability of the smooth pin acrylic linkage. The surgeon must bend the pins over using one pair of pliers as a lever positioned at the point of bend and another pair of pliers or hand chuck to exert bending of the pin. This prevents the formation of high stresses at the fastener-bone interface when bending over the pin.

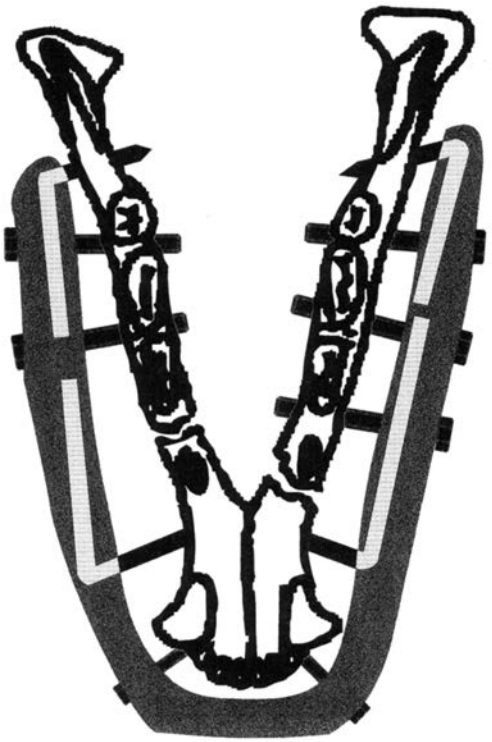

Figure 46-23. Long pins cut short and bent to lie flush with acrylic.

Tube Acrylic Pin Splint

For this splint, either a commercial device or a homemade tube can be used. A homemade method is described here. The patient is administered a perioperative antibiotic regimen. The appropriate number of fasteners is placed into each bone segment using sterile technique, and surgical wounds are closed. Plastic tubing is pressed over the ends of the fasteners and is positioned 1 to 2 cm from the skin. Corrugated plastic anesthetic tubing (anesthesia breathing circuit, 1/2-inch for small frames and 3/4-inch for large frames, King Systems Corp., Nobelsville, IN) or Silastic tubing works well, serving as an injection mold for the acrylic. The most dependent end of each tube is plugged with cotton, and modeling clay is used at each junction of the tube and fastener to prevent excessive leakage of acrylic at these sites. Approximate occlusional alignment and fracture reduction are achieved. The powder and liquid components of the acrylic are mixed and are poured into the top end of the plastic tube. This maneuver can be facilitated by using a large-dose syringe to inject the acrylic into the plastic tube. Accurate occlusional alignment and fracture reduction are maintained until the acrylic sets. The acrylic must fill the tube completely, and no air bubbles can be present to weaken the acrylic column. If large air bubbles are noted, holes can be made in the plastic tube and more acrylic can be injected into the area before or after the acrylic sets. The biphase technique can easily be adapted to the tube acrylic pin splint, with considerations and technique similar to that described for the free-form method. A frame alignment kit (Innovative Animal Products, Rochester, MN) is available and is advantageous because it allows phase 1 reduction equipment to be placed either above or below the plastic tubes.

The fracture reduction or the splint can be adjusted after the acrylic has set by removing a short segment of the acrylic column with a hacksaw blade, obstetric or Gigli wire, or a cast cutter. A portion of the tubing is peeled back, and several channels are drilled into a portion of acrylic on either end of the cut column to provide an anchor for the new acrylic patch. A small amount of acrylic is mixed and hand molded to fill the gap and to overlap a portion of the exposed acrylic containing the channels. Occlusional alignment or fracture reduction is then manipulated, while the acrylic is still soft, and is held until the acrylic hardens. New fasteners can be placed to add additional strength to the configuration or to replace fasteners that are loose. Fasteners are placed adjacent to the existing acrylic column using aseptic technique. The fasteners are then incorporated into the column with the addition of a new patch of acrylic.

Chapter 47

Cervical Spine

Cervical Disc Fenestration

M. Joseph Bojrab and
Gheorghe M. Constantinescu

Indications

Ventral fenestration for cervical disc disease is advocated in animals demonstrating pain, stiffness of the neck, or foreleg paresis. This technique is effective when degenerating discs protrude and cause nerve fiber and rootlet disorders, which account for most cervical disc problems. This procedure accomplishes intervertebral disc decompression by opening the ventral annular fibers for removal of the nucleus pulposus.

Cervical fenestration is not effective if foreleg paralysis or tetraplegia results from the presence of disc material within the spinal canal. These circumstances indicate a decompressive procedure.

Surgical Technique

The animal is placed in dorsal recumbency with a sandbag under the neck to produce dorsal flexion of the cervical spine, facilitating exposure. A ventral midline skin incision is made from the larynx to the thoracic inlet. The paired bellies of the sternohyoid muscle are separated (Figure 47-1), and the trachea is displaced laterally and is held with a self-retaining retractor. Blunt dissection of the deep fascia reveals the V-shaped longus colli muscle (Figure 47-2), which lies on the midline. Locating this muscle is essential to ensure midline identification. The ventral tubercles of the first and second cervical vertebrae is located at the level of the wings of the atlas (Figure 47-3A) for orientation. Because a disc is not present at this interspace, it is not fenestrated. The remaining ventral tubercles are midline projections that are directed caudally from the caudal ventral aspect of the vertebrae and provide the insertion site for the two bellies of the longus colli muscle (Figure 47-3B). The ventral entrance to the intervertebral space is covered by these bellies and their tendinous attachment. The muscle attachment is snipped with scissors, exposing the ventral longitudinal ligament. A No. 10 scalpel blade is used to cut the longitudinal ligament and ventral annular fibers (Figure 47-4A). A tartar scraper (SCLB Miltex Tartar Scraper, Victor Medical, Irvine, CA) (Figure 47-5) is used to fenestrate the disc (See figure 47-4B). All readily accessible cervical discs (C2-3, C3-4, C4-5, C5-6) are fenestrated.

The self-retaining retractor is removed, and the sternohyoid muscle bellies are sutured with a 3-0 polydioxanone (PDS, Ethicon, Somerville, NJ). The skin is then closed.

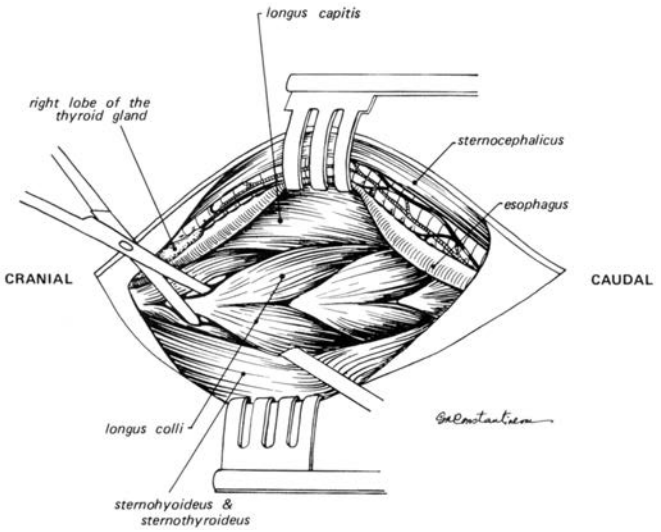

Figure 47-2. Trachea and esophagus are retracted to the left, and the longus colli muscle insertions are identified and cut with scissors.

Postoperative Care

Antibiotics are given for 5 to 10 days postoperatively. Corticosteroids (dexamethasone, 1 mg/lb body weight) are administered intramuscularly once or possibly twice each week. Buffered aspirin is given for 7 to 10 days if pain persists. After 10 to 14 days, complete remission of signs is expected.

Ventral Slot for Decompression of the Herniated Cervical Disk

Karen Kline and Kenneth A. Bruecker

The ventral approach to the cervical spine allows for direct access to the vertebral bodies and intervertebral disks. The ventral slot procedure requires minimal dissection through normal tissue planes and minimal disruption of normal anatomic structures. Minimal manipulation of the spinal cord is necessary, and recovery is usually rapid with few complications.[1-5]

Patient Position

The patient is placed in dorsal recumbency with the forelimbs secured caudally. The cervical spine should be supported by placing a vacuum positioner or rolled towel beneath the neck. Excessive dorsiflexion (hyperextension) should be avoided. The head can be secured by placing one inch tape on the rostral third of the mandible and securing it to the sides of the table. Gentle traction can thus be applied to the cervical spine resulting in distraction of the intervertebral disk spaces and enhanced access to the spinal canal (Figure 47-6).

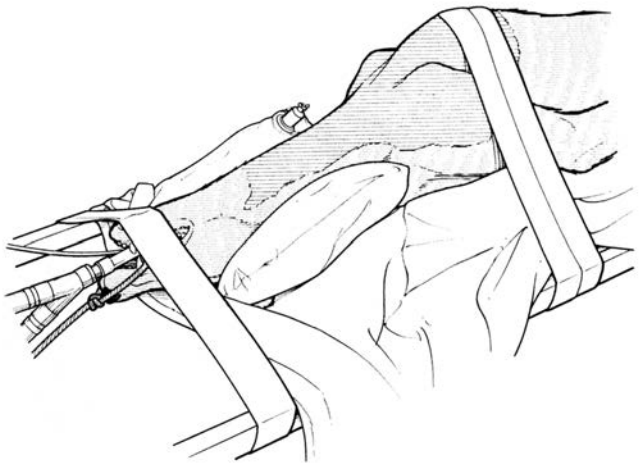

Figure 47-6. Proper position of patient with head and neck stretched for ventral decompression. (From Bruecker KA, et al: Clinical evaluation of three surgical methods for treatment of caudal cervical spondylomyelopathy of dogs. Vet Surg 1989; 18: 197.

Approach to the Cervical Vertebrae and Intervertebral Disks[1-5]

A cutaneous incision is made from the larynx to the manubrium. The paired muscle bellies of the sternocephalicus muscles are sharply separated. The paired sternohyoideus muscles are sharply separated on the midline exposing the trachea. The thyroid ima, a single unpaired blood vessel, lies between the left and right sternohyoideus muscles. If the branches of the thyroid ima are ligated and transected on the right, then this vessel can be reflected with the left sternohyoideus muscle.

Blunt dissection along the right side of the trachea allows retraction of the trachea to the left and retraction of the right

carotid sheath to the right. Care should be taken to identify and protect the right recurrent laryngeal nerve. The endotracheal tube must be of sufficient length to avoid collapse of the trachea during retraction. The esophagus should also be retracted to the left exposing the longus colli muscle. An esophageal stethoscope or soft rubber tube placed in the esophagus will enhance palpation of the esophagus during retraction. Care should be used when retracting these tissues. This retraction can be aided with the use of 4x4 surgical sponges or laparotomy pads if the patient is a large breed canine. These tissues can be retracted digitally and held in place by paired self-retaining retractors that are placed cranial and caudal to the affected interverbral disk spaces once the paired longus colli muscles have been identified and bluntly dissected along the median raphe.

The tendons of insertion of the longus colli muscles are transected from their origins on the caudoventral midline aspect of the affected cervical vertebral bodies, thus exposing the underlying intervertebral disk. This can be done at each disk space intended for surgery. The location of the intended intervertebral disk can be determined by palpating the large, prominent transverse processes of C6. The C5-6 intervertebral disk lies on the midline at the cranial aspect of the C6 transverse processes. Palpating along the midline, the large ventral prominence of the caudal aspect of each vertebral body and the origin of the tendon of the longus colli muscle can be palpated. The transverse processes of C1 can also be used as a point of reference. The ventral process of C1 is particularly prominent and sharp ventrally; this also can or may be palpated. (Sharp/Wheeler). There is no intervertebral disk at C1-2.

Technique[2,3]

Further elevation of the longus colli muscle with a periosteal elevator should be performed in preparation for the ventral slot. The retractors can be repositioned between the muscle bellies of the longus colli muscles. The prominence of the point of origin of the longus colli muscle on the caudoventral midline aspect of the cervical vertebral body can be removed with rongeurs and the intervertebral disk fenestrated.

Using a #11 or # 15 blade to fenestrate, a defect is made in the ventral anulus fibrosus. Starting on the midline of the cranial aspect of the vertebral body caudal to the disk, with the cutting edge of the blade directed towards the surgeon, the blade is gently advanced until the disk is reached. Alternatively, a hypodermic needle can be used to localize the intervertebral disk space. With the blade directed in a slightly cranial direction, the blade is inserted to the level of the dorsal anulus fibrosus, against and parallel to the vertebral end plate. This distance can be estimated from the lateral radiographic view of the cervical spine. The blade is advanced to no more than 1/2 the width of the intervertebral disk. The cutting edge of the blade is then directed cranially and advanced up to the caudal end plate of the cranial vertebra. The blade is then directed to left lateral and advanced to no further than 1/2 the width of the disk space. Again, the blade is angled cranially such that it is against and parallel to the caudal end plate of the cranial vertebral body. The blade is directed caudally and advanced up until the cranial end plate of the caudal vertebral body is reached. The blade is then directed and advanced towards the midline to complete the rectangular shaped excision (window) (Figure 47-7). This portion of excised ventral anulus fibrosus can then be removed with rongeurs and the nucleus pulposus gently removed with curettes or dental scraper (Figure 47-8). Care must be taken such that additional disk material is not forced dorsally into the spinal canal. This can be accomphished by directing the curette or dental scraper in a direction parallel to the plane of the patient's body instead of ventrodorsally.

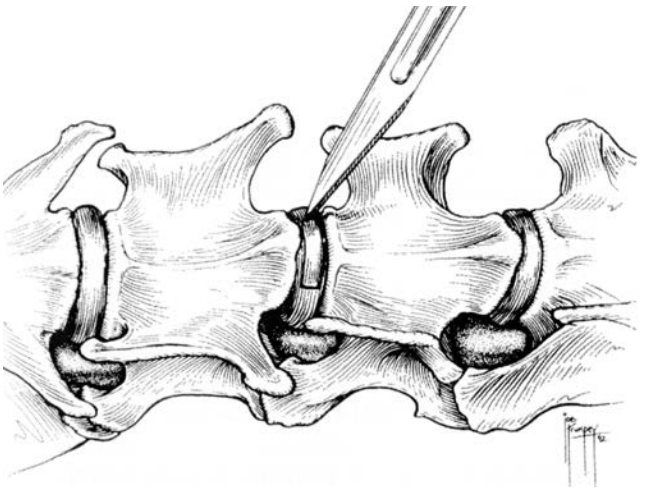

Figure 47-7. Creation of fenestration window in the ventral aspect of the cervical disk. (From Wheeler SJ and Sharp NJH: Small Animal Spinal Disorders, Diagnosis and Surgery. Mosby 1994; 76, Fig 156.)

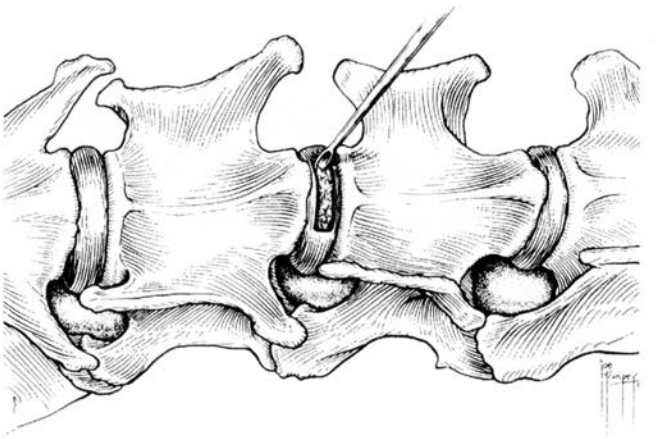

Figure 47-8. Removal of nucleus pulposus to complete the fenestration in preparation for ventral slot. (From Wheeler SJ and Sharp NJH: Small Animal Spinal Disorders, Diagnosis and Surgery. Mosby 1994; 76, Fig 157.)

Following fenestration, a high speed 4-5 mm carbide burr is used to create a slot in the vertebral bodies cranial and caudal to the intervertebral disk. Overheating of the burr can be prevented with saline lavage. We prefer a long, narrow slot for removal of herniated disk material. The slot should be no wider than 1/3 the vertebral body width and no longer than 1/3 the vertebral body length (Figure 47-9). Since the disk space angles craniodorsally, the caudal aspect of the slot can begin at the endplate of the caudal vertebral body (Figure 47-10). The slot can be deepened to the level of the cortical bone of the ventral spinal canal. The depth of the defect can be determined by identifying the difference in bone density of the cortical and cancellous bone.

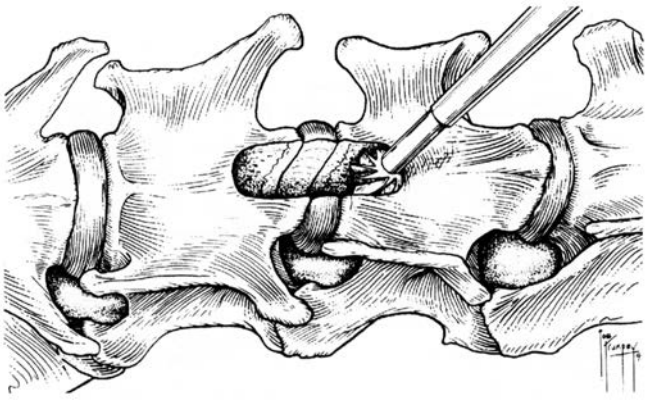

Figure 47-9. Long, narrow slot created with a high speed bur. (From Wheeler SJ and Sharp NJH: Small Animal Spinal Disorders, Diagnosis and Surgery. Mosby 1994; 79, Fig 167.)

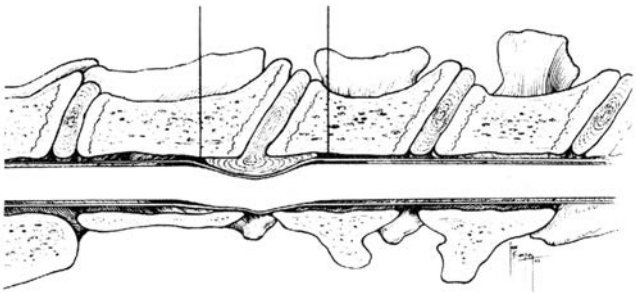

Figure 47-10. Sagittal section of cervical spine indicating the orientation of the slot with respect to the disk space and spinal canal. (From Wheeler SJ and Sharp NJH: Small Animal Spinal Disorders, Diagnosis and Surgery. Mosby 1994; 78, Fig 165.)

Cortical bone is white and hard whereas the cancellous bone is red to purple in color. The inner cortical bone tends to have a pearl color and can appear transparent as it becomes thinner with drilling. Once the burr has penetrated the inner cortical layer, a small bone curette can be used to enlarge the slot. The remaining dorsal anulus fibrosis and dorsal longitudinal ligament can be removed with rongeurs, forceps, curettes or hemostats. Small instruments such as ophthalmic spatulas, loop curettes, fine curved forceps and suction can be used to retrieve herniated disk material from the canal (Figure 47-11). Disk material on the midline should be removed first and then laterally extruded disk material can be removed to avoid damage to the venous sinus.

Damage to the venous sinus results in excessive hemorrhage and obstruction of visualization of the spinal cord. This can be controlled with suction and hemostatics, such as Gelfoam[a] or Surgicel.[b] Suction can be used to evacuate the blood. A small piece of precut Gelfoam[a], presoaked in saline, can be placed at the site of the hemorrhage. Cottonoid[c] or sponge is placed over the Gelfoam[a] to prevent inadvertent aspiration of the hemostatic. Suction of the overlying sponge or Cottonoid[c] is performed until hemorrhage has stopped. The sponge or Cottonoid[c] can then be removed. The hemostatic can be removed after 5 minutes and disk material retrieval can be resumed. In some cases, a small remnant of either Gelfoam or Surgicel can be left at the site to aid in hemostasis. Monofilament absorbable suture material

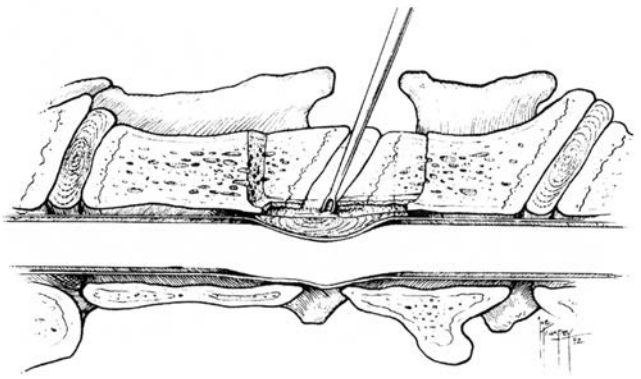

Figure 47-11. Sagittal section depicting removal of disk material from the spinal canal via the slot. (From Wheeler SJ and Sharp NJH: Small Animal Spinal Disorders, Diagnosis and Surgery. Mosby 1994; 81, Fig 174.)

such as 3-0 or 2-0 PDS is used to close the sternohyoideus and sternocephalicus muscles. Closure of subcutaneous tissues and skin is routine.

Post-operative Management

Analgesics such as opiods or NSAIDS should be continued for 24-48 hours postoperatively. Corticosteroids are not indicated in the post-operative period. A thoracic harness should be used instead of a neck collar.

Post-operative management of cervical decompressive slot patients is generally divided into ambulatory or non-ambulatory convalescence. Patients with an ambulatory status post-operatively are generally managed in the following manner: cage confinement, brief exercise 2 to 3 times a day for 2 to 3 weeks, and home on restricted exercise and/or passive range of motion exercises 2 to 3 times a day. Non-ambulatory patients are managed in the following manner: elevated padded cage rack or waterbed, turned every 2 to 4 hours to prevent decubital ulcers and passive lung congestion or pneumonia, bladder expressions to 3 times a day, passive range of motion exercises at least 2 to 3 times a day, and frequent hydrotherapy until return to an ambulatory status is achieved. Non-ambulatory patients will require support to be held in a sternal position to eat and drink and to avoid aspiration pneumonia.

Crate or pen confinement is recommended for 6 to 8 weeks with gradual return to normal activity to follow.

Neurologic recovery is generally very rapid. Neck pain usually subsides within 24 to 48 hours. Tetraparetic patients may begin to show improvement within days, as well. Owners, however, should be counseled as to the unpredictabilty of spinal surgery and its complications to include delayed return to function and recurrent neck pain.

Surgical Treatment of Caudal Cervical Spondylomyelopathy in Large Breed Dogs

Karen L. Kline and Kenneth A. Bruecker

Introduction

There are two separate philosophical approaches to the surgical treatment of caudal cervical spondylomyelopathy (CCSM) in large breed dogs, direct decompression versus decompression by distraction and stabilization. In general, patients with malformation/malarticulation or static compressive lesions benefit from direct decompressive surgical techniques whereas patients with dynamic compressive lesions such as cervical vertebral instability (CVI) require distraction and stabilization. As witnessed from a review of the literature on the subject, no one technique for repair of dynamic lesions is considered the gold standard. Repair of these compressions is contingent upon the patient's demeanor, general overall health, surgeon experience, and owner expectations for recovery.

Treatment by Direct Decompression using an Inverted Cone Modified Ventral Slot[1]

The inverted cone modified ventral slot is a direct decompressive technique for the removal of hypertrophied dorsal anulus fibrosus associated with cervical vertebral instability. This technique is most useful in patients with a static lesion, unchanged by distraction. The hypertrophied dorsal anulus fibrosus can be difficult to remove from the canal using the classic ventral decompressive slot technique.[1,2,3,4] This technique or a combination of this technique with the classic approach may have merit in allowing better retrieval of anulus from the canal. The slot resembles an inverted cone wherein the base of the cone is at the ventral spinal canal.[1] (Figure 47-12).

Technique

The approach to the affected intervertebral disk space is the same as described for ventral cervical slot. Using a high speed bur, the slot is created from the caudal aspect of the intervertebral disk to involve the caudal 1/4 of the cranial vertebral body. The width of the slot is limited to 1/5 the width of the vertebral body. The slot is enlarged as it is deepened by moving the bur in a sweeping motion laterally, creating an elliptical slot. The slot is carried to the level of the inner cortical layer while preserving the dorsal anulus fibrosus. The dorsal anulus fibrosus can then be retracted back into the slot and excised (Figures 47-13 and 47-14). The inner cortical bone layer is removed with the high speed bur and additional anulus and dorsal longitudinal ligament can be excised (Figure 47-15). Closure is routine.

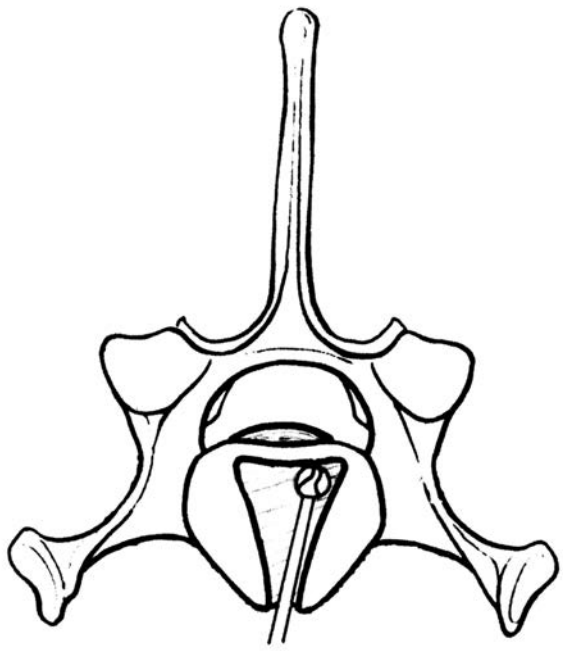

Figure 47-12. Diagramatic cross-sectional representation of the inverted cone decompressive slot at the level of the intervertebral disk space.

Treatment by Distraction and Stabilization Utilizing Pins or Screws and Polymethyl Methacrylate[5,6]

Distraction and stabilization utilizing Steinmann pins or bone screws and polymethyl methacrylate has been described. Advantages of this technique include: adequate spinal cord decompression without entering the spinal canal, reduced risk of iatrogenic cord trauma and bleeding, as well as improvement in the percent, rate and duration of recovery as compared to other techniques. In addition, a neck brace is not required. This technique is used most commonly for dynamic lesions that involve both the annulus fibrosus and the dorsal longitudinal ligament.

Technique[5]

A ventral approach, as described for the ventral decompressive slot, is performed to expose the vertebral bodies and intervertebral spaces cranial and caudal to the affected intervertebral space. The patient is positioned in dorsal recumbency such that the cervical spine is distracted, as described for the ventral slot. The affected intervertebral space is then pulled into additional linear traction by one of two techniques. A Gelpi retractor, modified by blunting the tips, can be used as a vertebral retractor. A defect is created in the vertebral bodies cranial and caudal to the affected vertebral bodies with a high-speed surgical bur. The defects are created just large enough to accept the tips of the modified Gelpi retractor. The retractor is engaged, and the affected intervertebral space spread an additional 2 to

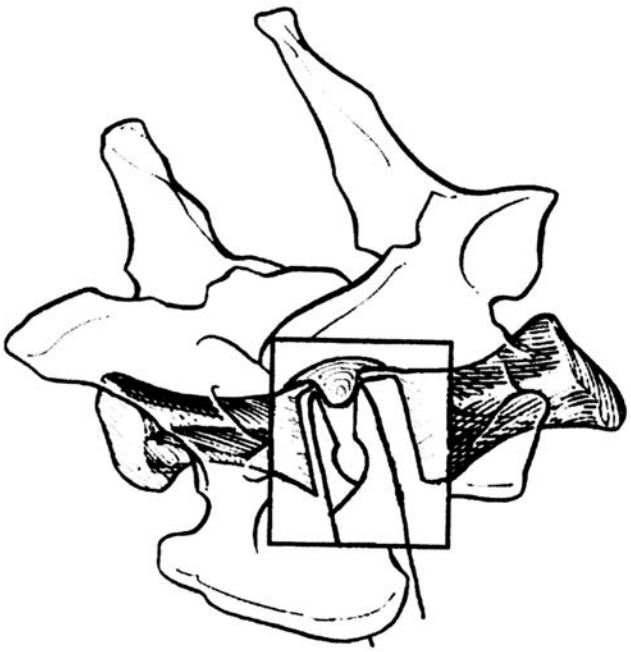

Figure 47-13. The dorsal anulus fibrosus (DAF) is retrieved into the slot by applying traction prior to removal with a rongeur.

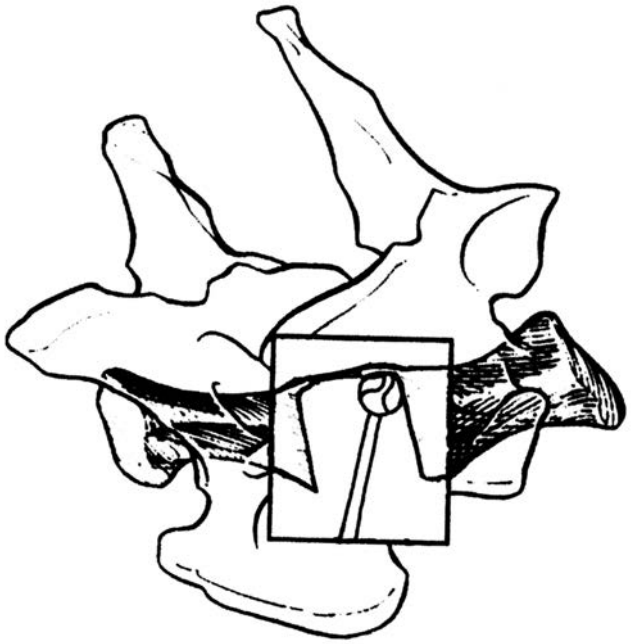

Figure 47-15. A high speed bur is used to remove the dorsal cortical bone shelf providing surgical access to the spinal canal.

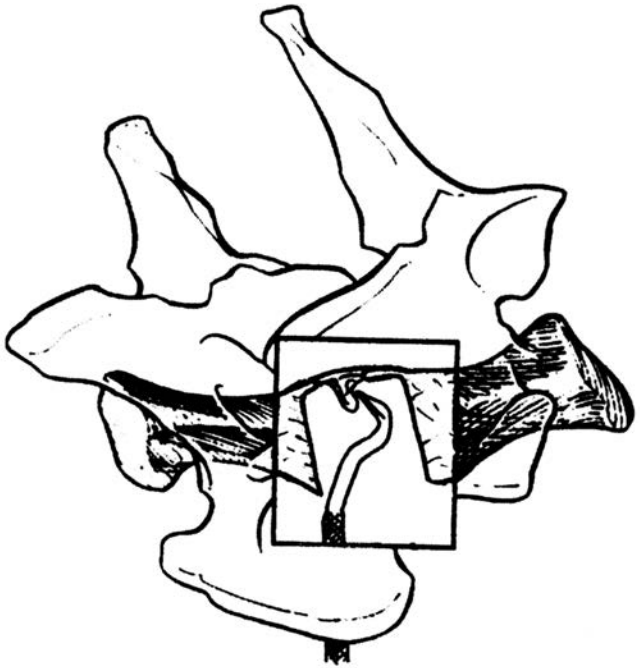

Figure 47-14. Retrieval of additional compressive material into the slot. Note retention of dorsal cortical bone shelf and progressive spinal cord decompression.

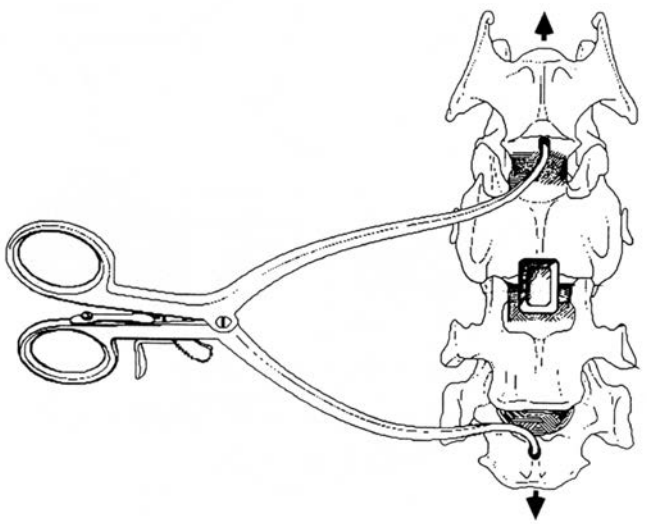

Figure 47-16. Gelpi retractors, modified by blunting the tips, is inserted into the slots created in the vertebral bodies adjacent to the affected disk spaces. (From Bruecker KA, Seim HB. Caudal cervical spondylomyelopathy. In Slatter, Textbook of Small Animal Surgery. 1993: 1064.)

3 mm (Figure 47-16). This technique of vertebral spreading may have merit over insertion of the tips of the Gelpi retractor into fenestrated disk spaces. Fenestration of the intervertebral disks may predispose them to degenerative changes and collapse.[7] Distraction results in decompression of the spinal cord.[8,9]

A ventral slot is performed at the affected intervertebral space, however the slot is wider and shorter than a classic ventral decompressive slot. The depth is carried only to the level of the inner cortical bone layer. The spinal canal is not entered. The width of the slot should be no more than 1/2 the width of the vertebral body. The length of the slot is determined by the thickness of the vertebral endplates. Once the cortical endplate on each vertebral body has been removed, burring should cease. Autogenous cancellous bone is harvested from the heads of the humeri and placed into the distracted slot. Two 7/64 or 1/8 inch Steinmann pins are inserted into the ventral surface of the vertebral body cranial to the affected intervertebral space and two similar size pins are inserted into the vertebral body caudal to the affected intervertebral space. The pins are inserted on the ventral midline of the vertebral body and directed 30-35 degrees dorsolaterally to avoid entering the spinal canal. It is important that two cortices

are engaged by each pin. The pins are cut leaving approximately 1.5 to 2 cm exposed. The exposed portion of each pin is notched with pin cutters allowing the bone cement to grip and prevent pin migration. Bone screws 3.5 to 4.0 mm in diameter long enough to engage both cortices may be used instead of Steinmann pins. Sterile polymethyl methacrylate powder is mixed with liquid monomer until it reaches a doughy consistency and can be handled without sticking to the surgeon's gloves. The cement is then meticulously molded around each pin (Figure 47-17). Irrigation with sterile saline solution for 5-10 minutes dissipates the heat of polymerization. The vertebral spreaders are removed once the cement has hardened. Closure of the longus colli muscle is performed cranial and caudal to the cement mass. The remainder of the closure is routine. Postoperative care includes strict confinement for 4-6 weeks.

Treatment by Distraction and Stabilization utilizing a Polymethyl Methacrylate Plug[11]

Another technique utilizing an intervertebral plug of polymethyl methacrylate to accomplish distraction and stabilization has been described.[11] There is no apparent advantage in rate of recovery and overall success rate as compared to distraction and stabilization using pins and polymethyl methacrylate, however risk of implant failure or iatrogenic spinal cord trauma from improperly placed pins is less with this technique. In addition, this technique can be performed at multiple disk spaces if necessary.[11]

Technique[11]

A ventral approach, as described for ventral decompression, is performed to expose the vertebral bodies and intervertebral spaces cranial and caudal to the affected intervertebral space(s). The affected intervertebral space is then pulled into additional linear traction as previously described in the pins and polymethyl methacrylate technique. The original authors of the PMP technique have successfully used other vertebral spreaders as well. The affected disk material is removed to the level of the dorsal anulus fibrosus. Troughs are cut into the endplates using a high speed drill and a 2 to 4 mm bur to anchor the PMP. These anchor troughs should be made approximately 5 to 10 mm in lateral width, 4 mm in depth and 4 mm in dorsoventral height (Figure 47-18). An angled attachment will allow better access to the caudal vertebral endplate. One gram of sterile cefazolin powder can be mixed with the sterile polymethyl methacrylate. The polymethyl methacrylate powder is mixed with liquid monomer until it reaches a liquid consistency and can be infused into the intervertebral disk space to the level of the ventral aspect of the vertebral bodies and gently packed digitally. Irrigation with sterile saline solution for 5 to 10 minutes dissipates the heat of polymerization. The vertebral spreaders are removed once the cement has hardened. Autogenous cancellous bone is harvested from the heads of the humeri and placed ventral to the vertebral bodies and PMP to stimulate osseous fusion (Figure 47-19). Closure of the longus colli muscle is performed over the cancellous bone graft. The remainder of the closure is routine. A neck brace may be used post-operatively to limit excessive movement, but may not be required (Dixon). The Synthes Locking Plate (Syncage-C intervertebral implant and cervical spine locking plate) may prove to be a viable option in the future. The Synthes locking plate has been discussed in the treatment of dynamic lesions to include single lesions (as repaired with the cement plug), or as a rescue technique after a failed ventral slot decompression or with multiple lesions. To date, the use of the Locking plates on multiple lesions is still undergoing further evaluation.[18] Preliminary results with this technique are encouraging. A swivel ring in the plate hole means that the screws may be inserted at any angle within a range of +/- 20 degrees and the screw holes lock in the plate via a unique locking mechanism. This device (the Syncage) is designed to maintain distraction. It stays within the intervertebral space and is packed with

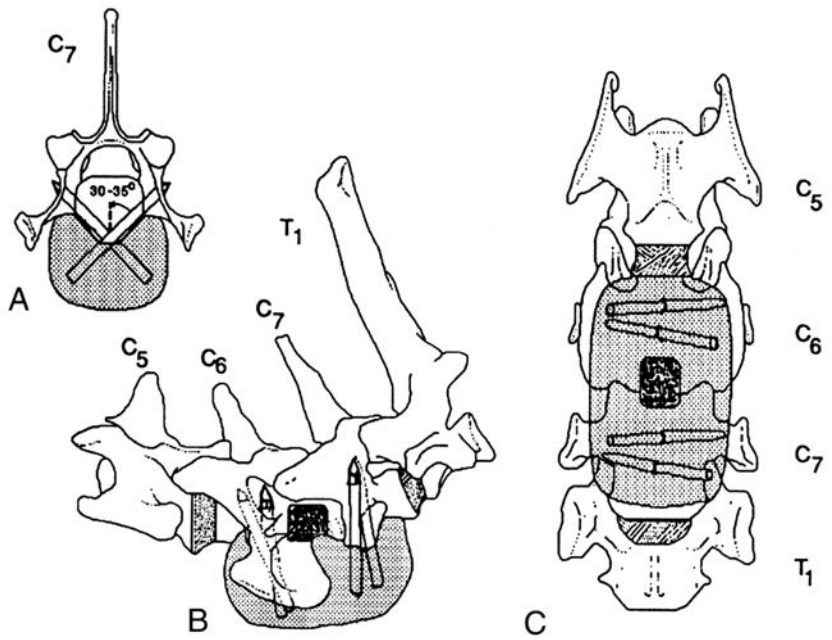

Figure 47-17. Placement of the cancellous bone, pins and bone cement to treat CVI. (From Bruecker KA, Seim HB. Caudocervical Spondylomyelopathy in Large Breed Dogs. In, (ed)Bojrab, Current Techniques in Small Animal Surgery, 3rd ed. Lea & Febiger. 1989: 583).

cancellous bone. This device adds strength and bridge greater than one space.[18] The utility of this device for multiple lesions in the canine is yet to be elucidated. Limitations of this technique can include cost of the implants and the lack of case numbers that support further use and feasibility of this technique.

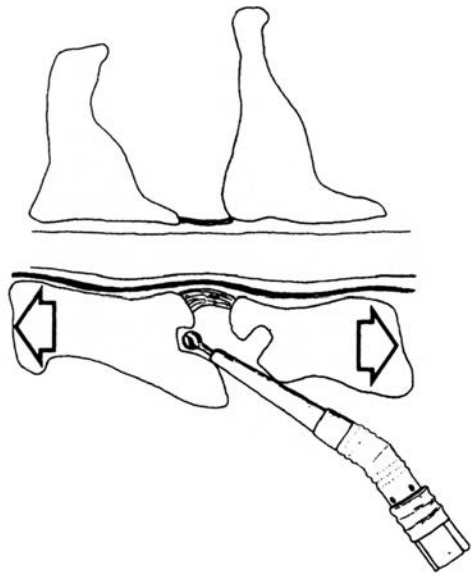

Figure 47-18. Partial diskectomy is performed leaving only a thin layer of dorsal anulus fibrosus (DAF). Creation of anchor holes is accomplished with a high speed bur and angle attachment. (From Dixon BC, Tomlinson JL, Kraus KH. Modified distraction-stabilization technique using an interbody polymethyl methacrylate plug in dogs with caudal cervical spondylomyelopathy. J Am Vet Med Assoc 1996; 208: 63).

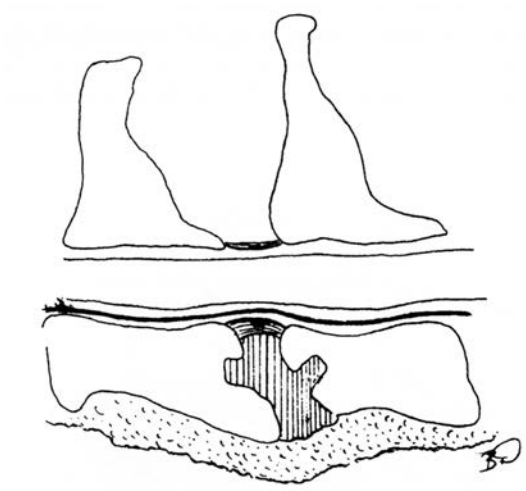

Figure 47-19. The PMP is placed into the prepared disk space while traction is maintained. After the PMP hardens, the traction device is removed and cancellous bone graft (CG) is liberally packed along the ventral aspect of the vertebral bodies. The remaining thin layer of DAF protects the spinal cord from the PMP. (From Dixon BC, Tomlinson JL, Kraus KH. Modified distraction-stabilization technique using an interbody polymethyl methacrylate plug in dogs with caudal cervical spondylomyelopathy. J Am Vet Med Assoc 1996; 208: 63).

Treatment by Direct Decompression using a Continuous Dorsal Laminectomy[12]

Continuous dorsal laminectomy is a decompressive technique. This technique is most useful in patients with multiple lesions and dorsal lesions. Although this technique does not address the underlying pathophysiologies associated with CCSM, relief of spinal cord compression is achieved. Dorsal laminectomy is advocated for single or multiple, dorsal, traction non-responsive (static) lesion(s).[18] The major disadvantage of this procedure is the significant, short-term morbidity with deterioration in neurological status, which can be substantial in the giant breed dogs who most likely require this technique. The most common lesions associated with the use of this technique are bulbous articular facets, ligamentum flavum hypertrophy or a combination of both.

Approach[13]

With the patient in sternal recumbency the front feet are secured cranially and the head and neck elevated from the surgical table. Tape placed over the muzzle and thorax help secure the neck. A midline incision is made in the skin over the dorsal processes of the cervical spine from the poll of the cranium to T3. After the subcutaneous fascia and aponeurosis of the platysma muscle are incised, an incision is made through the median fibrous raphe. The origins of the splenius and serratus dorsalis muscles can be incised from the raphe and reflected to expose the nuchal ligament, dorsal spinous processes of the thoracic vertebrae and the long spinal muscles. These muscles are separated from the midline and reflected form the dorsal spinous processes to expose the dorsal laminae.

Technique[12]

After exposure of the cervical vertebrae, the dorsal spinous processes of the affected vertebrae are removed with rongeurs and the dorsal lamina is carefully removed using a high speed surgical bur. The length of the laminectomy may be from 3/4 the length of each vertebrae up to a continuous laminectomy extending from C4 to C7. The width of the laminectomy is limited by the medial aspect of the articular facets of the cranial vertebra. The initial depth of the laminectomy defect is to the periosteum of the inner cortical layer of the laminae. Following penetration into the spinal canal, the remaining laminae and ligamentum flava are gently excised and removed en bloc (Figure 47-20). Kerrison rongeurs can be quite useful for this procedure. If needed, resection of the lateral aspects of the vertebral arches can be continued to the level of the ventral vertebral veins using rongeurs. It is important to preserve the articular facets. Hypertrophied joint capsule and ligamentum flavum is resected to achieve decompression of the spinal cord. Transarticular hemicerclage wires or lag screws may need to be placed through the facets for additional stability. If stabilization is required, an appropriate sized hole is drilled through the articular facet. Removal of the articular cartilage is achieved using a high speed surgical bur. An 18-gauge stainless steel wire is placed through the hole and twist tightened or, alternatively, the hole is tapped and a lag screw placed. Cancellous bone is placed around the joint to promote arthrodesis.[14,15,16,17,18] An autogenous fat graft placed over the laminectomy site will

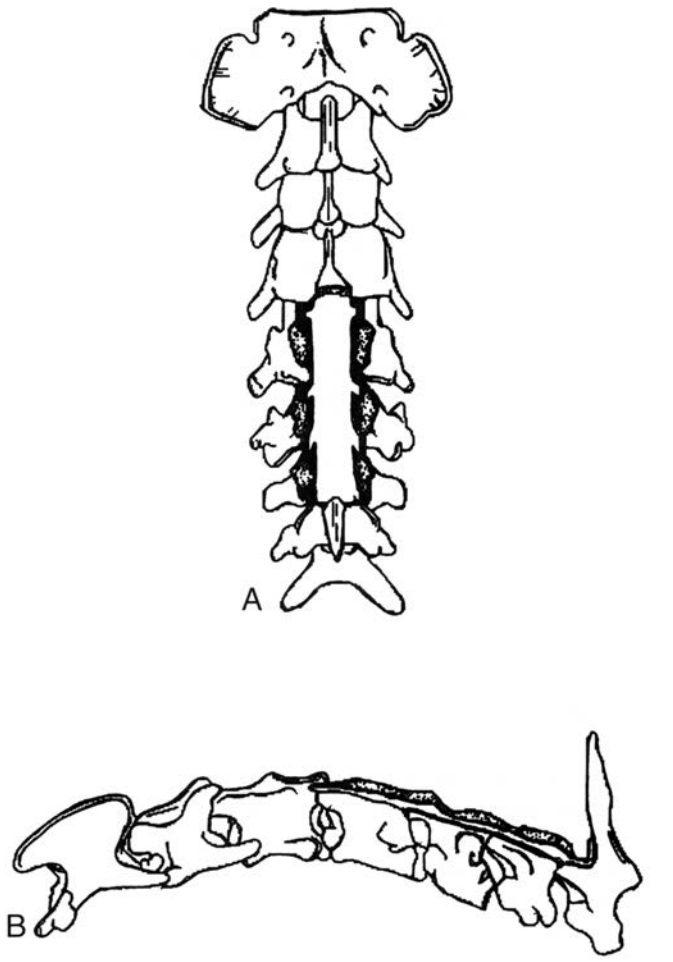

Figure 47-20. A. and **B.** The dorsal laminae have been removed from C4 through C7 to provide direct decompression of the caudal cervical spinal cord.

prevent the formation of a fibrous laminectomy membrane with subsequent stricture and spinal cord compression. Paraspinal muscles and fascia are approximated and the remaining closure is routine. A cervical bandage or brace is generally required.

Post-operative Management of CCSM Patients

Analgesics may be necessary for 24 to 48 hours postoperatively. Corticosteroids are not indicated in the postoperative period and may be contraindicated. Non-steroidal antiinflammatories and oral opiods can be used for post-operative pain management. A cervical bandage of rolled cotton and stretch gauze can be placed postoperatively to prevent excessive head and neck movements. This bandage can remain in place for 3 weeks. If warranted and tolerated, a neck brace constructed of fiberglass cast material or a heat moldable splint material, incorporating the cervical and cranial aspect of the thoracic spine may limit movement, thereby promoting fusion. Handles built into the brace may allow for better assistance when rising and walking. A thoracic harness should be used instead of a neck collar. Post-operative management of CCSM patients is generally divided into ambulatory or non-ambulatory convalescence. Patients with an ambulatory status post-operatively are generally managed in the following manner: cage confinement, brief exercise 2 to 3 times a day for 2 to 3 weeks, and home on restricted exercise and/or passive range of motion exercises. Non-ambulatory patients are managed in the following manner: elevated padded cage rack or waterbed, passive range of motion exercises and turned every 2 to 4 hours, bladder expressions 4 to 5 times a day, serial neurologic evaluations and frequent hydrotherapy (swimming with support) until return to an ambulatory status is achieved. Care most be taken especially in the giant breeds to monitor for and prevent aspiration pneumonia secondary to recumbancy and poor lower esophageal sphincter tone after anesthesia. Patients who are recumbent should be held up in sternal recumbancy when offered food and water to prevent the occurrence of aspiration. Crate or pen confinement is recommended for 6 to 8 weeks with gradual return to normal activity to follow.

Neurologic recovery is generally very rapid, but exceptions do occur. Neck pain usually subsides within 24 to-48 hours. Tetraparetic patients should begin to show improvement within days, as well. Any neurologic improvement within 3 weeks of surgery is encouraging. The neurologic status 6 weeks postoperatively is a good indication of ultimate neurologic recovery, however patients may show improvement in function up to 6 months postoperatively.[4,5] Serial neurologic exams and compliant owners are essential in the follow-up of these patients. Iatrogenic spinal cord trauma, post-operaative compressive hemorrhage, irreversible demyelination and myelomalacia or agenesis of the affected spinal cord limits the success of surgical techniques used to treat CCSM.

Surgical Treatment of Atlantoaxial Instability

Kurt Schulz

This topic is written based on the available literature through 2010 and does not cover the most current literature on this topic.

Two categories of surgical techniques have been described. Both dorsal and ventral approaches aim to stabilize the atlantoaxial joint in the normal position; however, only ventral approaches allow for complete fusion of the involved cervical vertebrae and permit excision of the dens if necessary.

Ventral Approach

Atlantoaxial instability can be resolved permanently by fusing the two vertebrae in anatomic alignment, a procedure that is easier from a ventral approach. This approach also allows access to the dens if removal is indicated because of fracture or severe dorsal displacement. With the dog in dorsal recumbency, the head and neck should be extended and supported by padding under the cervical area (Figure 47-21A). The surgical approach is made through a ventral midline incision extending from the larynx to the manubrium, followed by separation of the paired sternothyroid muscles. The trachea, esophagus, and carotid sheath are bluntly dissected to allow lateralization. The paired hypaxial muscles ventral to the atlas and axis then are separated carefully on the midline and are lateralized with self-retaining retractors.

The joint capsule of the atlantoaxial articulation should be identified and opened with a No. 11 Bard-Parker blade (Figure 47-21B). In chronic cases, the joint capsule may be thickened and may contain increased volumes of joint fluid. The joint may be reduced to normal position by retraction with small, pointed reduction forceps on the caudal body of the axis. If the dens is fractured or ununited, it should be removed through an incision through the membrane between the two articulations. The ligaments attached to the apex of the odontoid process are exposed through a ventral opening in the fascia covering the foramen magnum. The dens may be removed after careful severance of these apical and alar ligaments. Removal of the dens should not be necessary if it is united to the body of C2 and, if accurate, stable realignment can be accomplished.

Arthrodesis of CI and C2 is optimized by removal of the articular cartilage from the joint spaces and placement of a cancellous bone graft obtained from the proximal humerus. Access to the joints may be increased by gentle caudal retraction of C2 with reduction forceps, and the cartilage may be removed with rongeurs or an air drill. Because of the architecture and location of the joints, it is unrealistic to expect removal of all the articular cartilage; removal of the ventral 75% from all four articular surfaces is probably adequate. The bone graft is packed into the joint spaces after adequate removal of cartilage and lavage of the surgical site.

Ventral stabilization of the atlantoaxial joint may be achieved using pins alone, pins and polymethylmethacrylate, lag screws, or bone plates. A power drill is necessary for accurate placement of pins and screws. If pins alone are to be used, two small Steinmann pins or large Kirschner wires are driven from the center of the axis across the atlantoaxial joint and are seated in the atlas just medial to the alar notch (Figure 47-21C and D).[1] The point of each pin must be kept as ventral as possible to avoid penetrating the dorsal surface of the thin wings of the atlas. The length of the pins is premeasured from the point of entry into the axis to the palpable medial aspect of the alar notches on the atlas. When both pins are seated, they are cut off close to the body of the axis. The protruding ends are crimped and bent to prevent cranial migration of the pins into the occipital condyles.

The addition of polymethylmethacrylate to the stabilization technique may increase the odds of successful arthrodesis by enhancing stability and may reduce the risk of pin migration (KS Schultz, Waldron DR, unpublished data). Pins are first placed into the atlas (Figure 47-22A). This placement is facilitated by gentle dorsiflexion of the atlantoaxial joint that allows visualization of the spinal canal. Kirschner wires or small threaded pins are directed perpendicular to the long axis of the spine from ventral to dorsal into each of the pedicles of the atlas. The atlantoaxial joint is then reduced, and pins are placed across the joints as described for pin stabilization alone. One or two pins are then placed into the caudal body of the axis (Figure 47-22B). All pins are cut short and are bent, leaving enough pin length to engage a small mass of polymethylmethacrylate (Figure 47-23). Antibiotic powder should be added to the cement, and cool saline flush should be applied during polymerization of the cement to dissipate heat.

The surgical approach and preparation of the atlantoaxial joints are identical for stabilization with lag screws.[2] In small dogs,

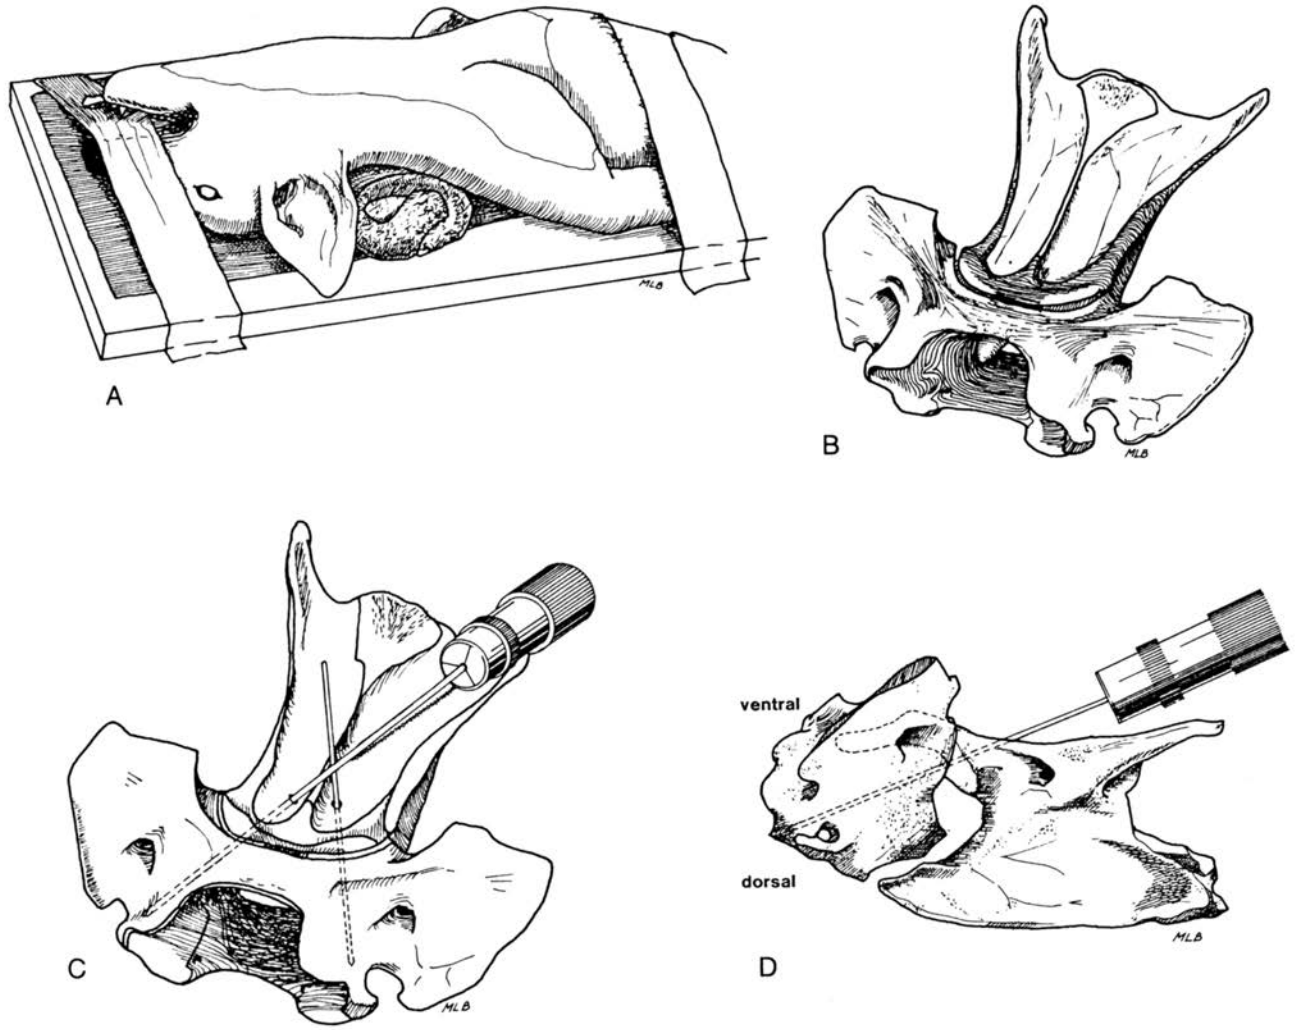

Figure 47-21. A. Positioning of the patient for a ventral approach to the atlantoaxial joint. **B.** The ventral aspect of the atlantoaxial joint seen from a craniolateral view. **C.** Pin placement through the atlantoaxial joints from the ventral body of the axis. Accurate seating of the pins into the medial side of the alar notch is essential. **D.** A lateral view of the stabilization pin placement from the ventral body of the axis, through the atlantoaxial joint, and into the heavy bone surrounding the neural canal.

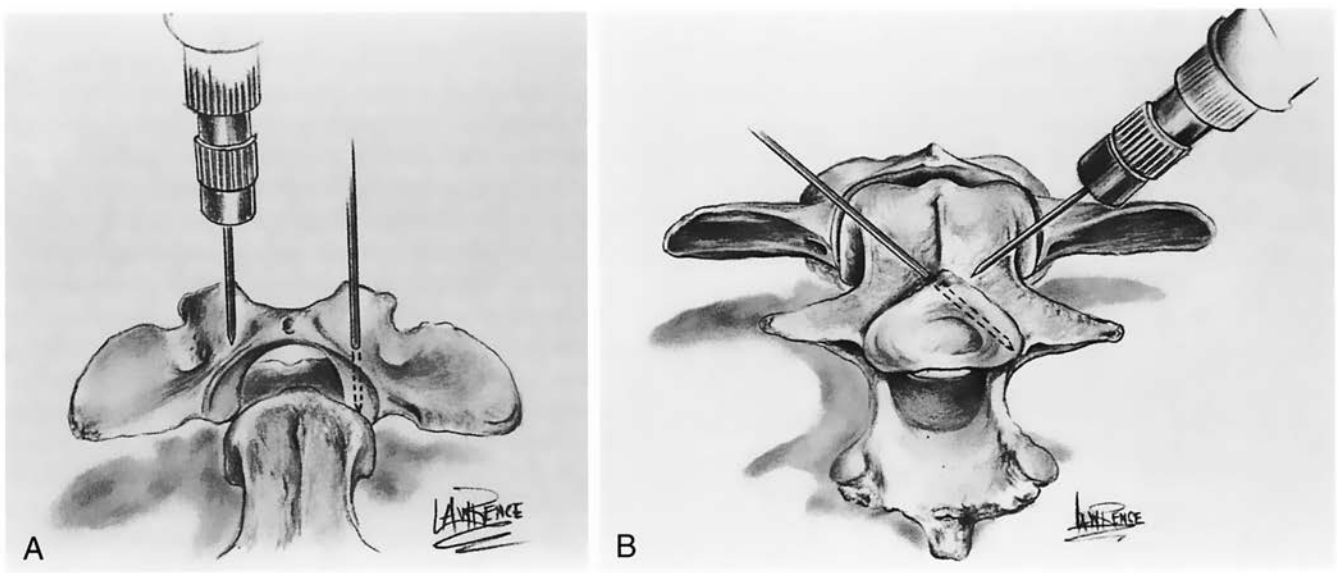

Figure 47-22. A. Pin placement into the lateral masses of CI. **B.** Pin placement into the caudal body of C2.

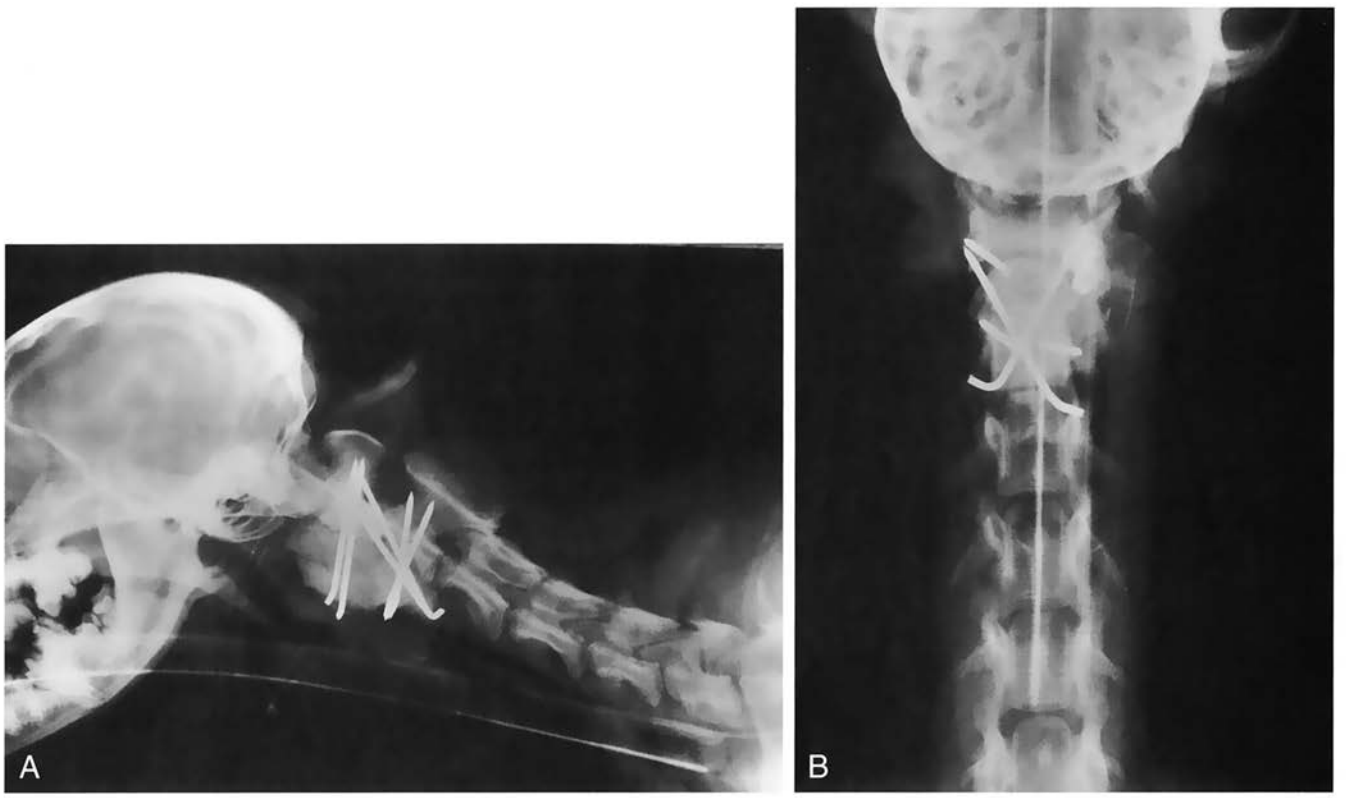

Figure 47-23. Lateral and ventrodorsal radiographs showing stabilization of the atlantoaxial joint with ventral pins and polymethylmethacrylate.

1.5-mm cortical screws are placed across each of the joints in a lag fashion. This technique may be facilitated by use of a cannulated drill and screw system. In either case, placement of the screws is in a direction similar to that of the transarticular pins. Ventral application of bone plates has also been described; however, the size of most patients may limit the practical application of this technique.[3]

Postoperative radiographs should be obtained after stabilization with any of the ventral techniques to demonstrate reduction of the atlantoaxial joint and accurate placement of implants. Neck braces should be maintained if possible for several weeks, and initial cage rest is strictly enforced. Radiographs may be obtained 8 weeks postoperatively to evaluate maintenance of reduction and progression of arthrodesis.

Complications of ventral stabilization techniques include implant migration and loosening.[4] The result may be subsequent instability and recurrence of neurologic signs. Placement of pins or screws within the vertebral canal may also worsen the neurologic signs. Tracheal necrosis has been reported with the ventral approach; therefore, gentle dissection and attention to preservation of the delicate blood supply of the region are indicated. As with any surgical implantation of polymethylmethacrylate, concern exists for thermal injury and infection.

Dorsal Approach

The dorsal arch of the atlas is secured to the dorsal spine of the axis with heavy suture material, orthopedic wire, or grafts of the nuchal ligament. Descriptions of these techniques are available in the third edition of this text. Although ventral techniques are more difficult, we recommend them because of their lower failure rate.[4] Complications of dorsal techniques include instability resulting from breakage of the suture, wire, or graft and fracture of the axis or atlas. Wire stabilization may fail because of cycling, and the addition of polymethylmethacrylate to the wire technique has been recommended to alleviate this complication. Fracture of the axis may be due either to inappropriate placement of the holes or to the remaining motion of the joint, which places excessive forces on the stabilization technique.

Medical management including cervical splinting has been successful in selective cases; however, surgical therapy is recommended for patients demonstrating significant neurologic signs that have no other contraindications for anesthesia or surgery.[5] Ventral techniques are technically challenging, but because of the higher failure rates of dorsal techniques, the routine use of dorsal procedures should be avoided.[4]

Surgical Treatment of Fractures of the Cervical Spine

Karen L. Kline and Kenneth A. Bruecker

General Considerations

When considering treatment options for a patient with a spinal fracture, luxation or subluxation, several factors should be considered; 1) results of the neurologic examination, 2) is the fracture pathologic or traumatic, and 3) is the fracture stable or unstable.

The neurologic examination is critical in determining prognosis. If the patient has lost all sensory and motor function caudal to the lesion, the prognosis is unfavorable and treatment is generally supportive. Surgery in this situation may be indicated for prognostic purposes only (ie. exploratory laminectomy). If deep pain perception is still present, the prognosis is guarded to favorable (depending on the degree of neurologic dysfunction and the timing of the event or injury) and surgical decompression and stabilization is performed with curative intent.

Patients with pathologic fractures have an underlying localized or generalized disorder. Examples of this would include a solitary plasma cell tumor, multiple myeloma or other classifications of paraneoplastic or infectious disorders. The cause of the underlying disorder must be determined and therapy instituted prior to or concurrent with spinal fracture/luxation repair.

Physical examination findings and radiographic assessment may be helpful in determining the inherent stability of the fracture/luxation.[1] In small animal patients, traumatic disruption of the spinal column can be divided into dorsal compartment injuries, ventral compartment injuries, or combined compartment injuries. Combined compartment injuries are more devastating and more common than injuries isolated to one compartment. The majority of spinal injuries are flexional injuries, but occasionally hyperextension or direct compression injuries may occur. Rotation is a common concurrent force associated with these injuries.

Fractures may be classified as stable or unstable by the radiographic appearance and by the force causing the injury. Forces resulting in damage to the dorsal compartment generally result in an unstable injury. Examples include laminar or pedicle fracture, dorsal spinous process fracture, articular process fracture, and supraspinous/interspinous ligament rupture.[2]

If surgery is deemed necessary, it is important to select a technique that will not further destabilize the spine. Herniated disk material or osseous fragments within the spinal canal may be anticipated in flexion or bursting type injuries. Concussive and contusive forces can cause spinal cord swelling even without evidence of an extradural mass. Extradural hematoma formation can be quite extensive and can be delineated on MRI or CT scan imaging. Infolding of the ligamentum flavum during hyperextension injuries may also result in spinal cord injury.

Generally, stable fractures in patients with good voluntary motor movements to the limbs are successfully managed by conservative means, including the use of analgesics, non-steroidal anti-inflammatory agents, body splints, and strict cage confinement.[3,4] Serial neurologic examinations are performed (twice daily) to determine the response to treatment.

Surgical management is indicated 1) if the fracture/luxation is considered unstable, 2) if the patient presents nonambulatory paraparetic or tetraparetic with no voluntary motor movements, or 3) if with conservative therapy, the patient remains unacceptably static or deteriorates neurologically.

Several factors must be considered when selecting a stabilizing technique: 1) location of the fracture/luxation (cervical, thoracic, lumbar, sacral), 2) presence of a compressive lesion within the spinal canal (ie. osseous fragment, disk material, hematoma), 3) size of the patient, 4) age of the patient, 5) equipment available, 6) experience of the surgeon, and 7) physical and emotional capability of the owner to provide postoperative nursing care.

Surgical Techniques

The two objectives of any surgical technique used to repair spinal fracture/luxation are decompression and stabilization. Many techniques have been successfully used to stabilize spinal fracture/luxation in small animals. In the following discussion, techniques commonly used to repair fractures and luxations of the spine will be described as they are indicated in various regions of the vertebral column. These chapters will be divided into surgical treatment of cervical spinal fractures, luxations and subluxations and surgical management of thoracolumbar, lumbar and lumbosacral fractures, luxations and subluxations. The above discussion regarding prognosis and patient selection in cases of spinal trauma applies to both categories of injury and disease.

Fractures of the Cervical Spine

Cervical spinal fractures are uncommon.[4,5,6] Most fractures of the cervical spine involve C1 (axis), particularly the dens and/or body.[6] In fact, the most frequent anatomic location of cervical fracture/luxation is the cranial cervical region with 80% occurring at C1-2. Because the cervical region has the largest ratio of vertebral canal to spinal cord diameter, conservative management consisting of external support and cage rest in unstable and/or displaced fractures may carry a more favorable prognosis than elsewhere in the spine.[7] Mortality rates can be as high as 35 to 40% with surgery.[7] Severe intraoperative hemorrhage may also occur with C2 fractures and reduction can be challenging.[5,7,8] External splints, though cumbersome, may be made from various materials. Surgery is best reserved for those animals that 1) are tetraplegic or have poor ventilatory function 2) show neurologic deterioration despite proper confinement or external fixation, and 3) remain painful beyond the initial 48 to 72 hour period following injury.[5]

Fractures of the dorsal spine of the axis should be approached dorsally and stabilized with orthopedic wire to reestablish the continuity of displaced fragments. A decompressive hemilaminectomy can be performed if fragments of bone are present in the

spinal canal, or if a displaced body fracture cannot be reduced. Atlantoaxial subluxation can be repaired from a dorsal approach utilizing either a double or single wiring or suturing technique.[7]

C1-C2 body fractures/luxations, traumatic cervical disk extrusions, and atlantoaxial subluxation can be approached ventrally. Ventral cross-pin techniques may be used for stabilization of atlantoaxial subluxation[10] (Figure 47-24).

Fractures and luxations rarely occur from C3 to C7 however, a predisposition to luxations at C5-C6 may exist.[6,11] Fracture/luxations of C3-C7 may be approached dorsally or ventrally. Dorsal techniques include articular facet wiring or screwing, dorsal spinous process plating and multiple Steinmann pins and polymethyl methacrylate (described in detail under Fractures of the T-L and Lumbar Spine). Ventral techniques include pins and polymethyl methacrylate and ventral body plating (plastic [footnote a] or metal [footnote b]). One advantage to the ventral approach is that a ventral slot can be performed if disk fragments have extruded into the spinal canal.

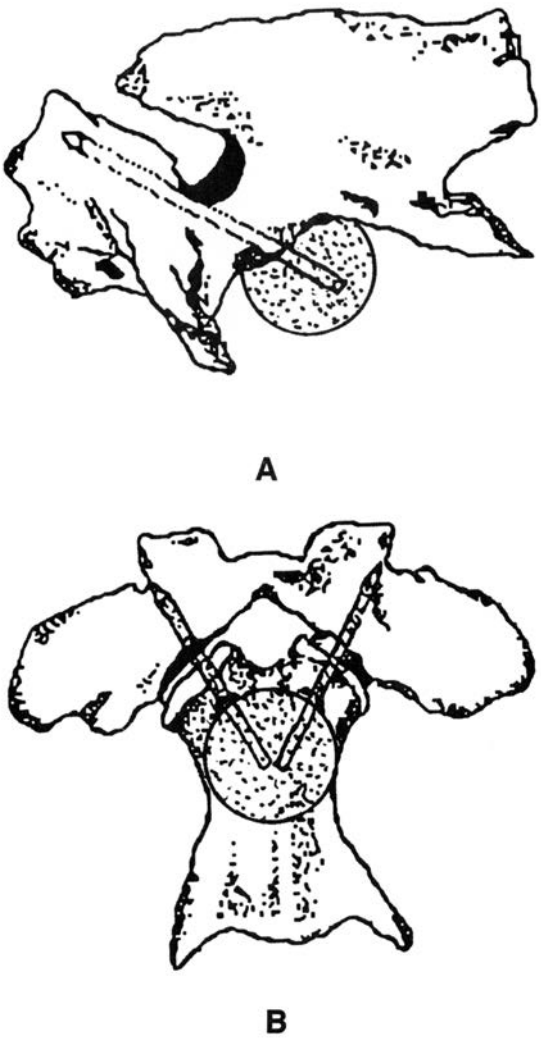

Figure 47-24. A. and **B.** Pin placement for arthrodesis of atlantoaxial joints in treating atlantoaxial subluxation by the ventral approach. The exposed portions of the pins (depicted within the dotted circle) can be notched and covered with methyl methacrylate to prevent pin migration. (From Sorjonen DC and Shires PK. Atlantoaxial instability: A ventral surgical technique for decompression, fixation, and fusion. Vet Surgery 1981;10:22-29.)

The use of pins (or screws)and polymethyl methacrylate should be considered for cervical spinal fractures involving the vertebral bodies of C2-C7. The ventral aspect of the involved vertebrae is exposed.[12] Once the fracture is reduced, a minimum of two trocar tip pins should be placed in the cranial fragment and a minimum of two pins should be placed in the caudal fragment. Alternatively, the fractured vertebral body can be bridged by insertion of pins into the vertebrae cranial and caudal to the fracture. It is important to engage two cortices with each pin. The pins are inserted on the ventral midline of the vertebral body and directed 30 to 35 degrees dorsolateral to avoid entering the spinal canal. In addition, the pins can be angled cranially and caudally to enhance stability of the implant. The pins are cut leaving 1 to 1.5 cm exposed. The exposed pins can be notched with pin cutters and covered with sterile polymethyl methacrylate[13] (Figure 47-25). Preferentially, specific purpose acrylic pins with threaded trocar tips and knurled shaft allows good bone anchor and foothold for the PMMA. The heat of polymerization is dissipated with 5 to 10 minutes of cool saline irrigation. A neck brace may be used for 4 to 6 weeks postoperatively. The limiting factor of this technique is the purchasing ability of the pins in small fragments. Screws can also be used as described above.[14,15,16] The main disadvantage of the above described techniques can be failure if used to span more than one intervertebral space especially in cases where the vertebral body is shattered or collapsed. In these cases, at least 3 implants should be placed on either side of the fracture and Steinman pins used to reinforce the cement. In some reports[2,11] if dorsal stability is required (ie especially after facet luxation), screws can be placed transarticularly.[5] Reduction of cervical fracture/luxations can be facilitated by gently distracting the affected vertebral bodies. Fenestration of the adjacent intervertebral disks or slots drilled into the vertebral bodies cranial and caudal to the fracture/luxation can be created to accommodate a vertebral distractor. A Gelpi retractor, modified by blunting the tips, is a useful vertebral distractor.

Stabilization with ventral locking plates and screws has become another method of repair and will be of interest in the future once the technique is perfected and the price of the spinal plates becomes less cost prohibitive.

After cervical spinal stabilization, complications can include Horners syndrome (which can be permanent or transient) and respiratory depression and/or distress secondary to diaphragmatic paresis or paralysis. This occurs in the aftermath of hemorrhage into or contusion to the phrenic nerve nuclei located at the C4-6 cervical spinal cord segments.

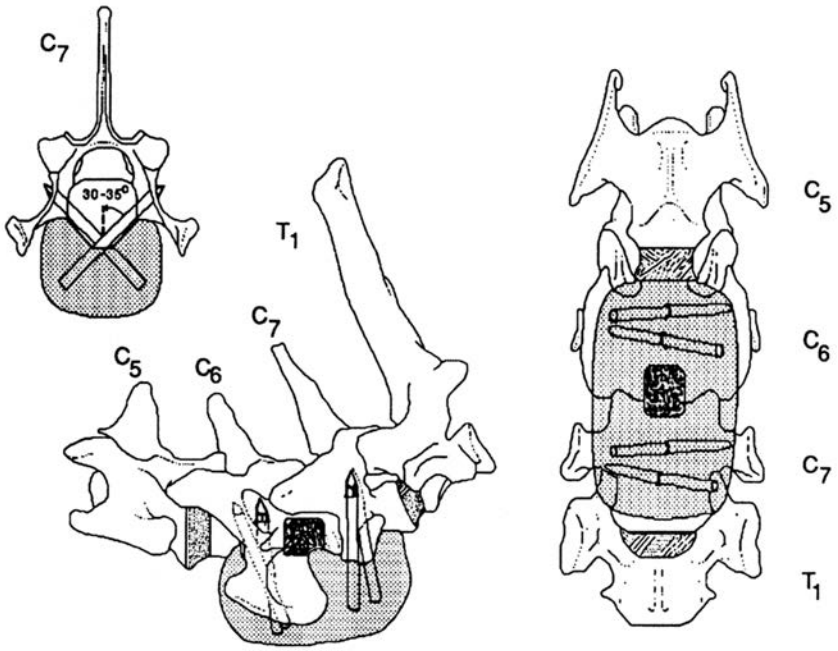

Figure 47-25. Stabilization with ventrally placed Steinmann pins and methyl methacrylate of cervical fractures/luxation. Ventral slot can be performed to remove herniated disk material. (From Blass CE, Waldron DR, van Ee RT. Cervical stabilization in three dogs using steinmann pins and methyl methacrylate. J Am Anim Hosp Assoc 1988;24:61-68.)

Chapter 48

Thoracolumbar and Sacral Spine

Intervertebral Disc Fenestration

James E. Creed and Daniel J. Yturraspe

Indications

Fenestration of thoracolumbar intervertebral discs is appropriate for dogs of breeds predisposed to disc herniation (such as the dachshund and Pekingese), with clinical signs ranging from lumbar pain to paresis, that are otherwise in good health and are less than 8 years of age. One study indicated that only 5% of dogs with thoracolumbar disc herniations were more than 8 years of age.[1] Whether older dogs are less likely to have recurrent problems is unknown, but in such dogs a conservative approach seems advisable initially.

Fenestration should be considered when signs of disc herniation are first evident; the operation is definitely recommended if signs progress in severity or on the first recurrence. Dogs presented with caudal motor paralysis should undergo spinal cord decompression, because disc fenestration alone is not appropriate treatment for paralysis. If the dog still perceives pain in the rear toes, fenestration should also be accomplished. Fenestration can be performed within a variable period after disc herniation; we prefer to operate within the first 2 to 3 days. The patient can then recuperate from surgery while hospitalized to treat signs produced by that herniation.

Preoperative Preparations

Corticosteroids and antibiotics are administered preoperatively. Anesthesia is induced with a short-acting anesthetic agent and maintained by endotracheal administration of an acceptable volatile agent. Intravenous fluids are administered during surgery and postoperatively. An area of the back extending from the vertebral border of each scapula to the crest of each ilium is clipped and prepared for surgery. The dog is positioned in ventral recumbency on an insulating pad to conserve body heat. It is most convenient for surgeons to operate from the side of the patient opposite that of their dominant hand. Radiographs and a skeleton should be available for reference.

Surgical Technique

A dorsolateral approach[2] is used to gain access to eight intervertebral discs between T10 and L5. Discs between T9-10 and L5-6 can also be fenestrated if they are calcified or partially herniated. These discs are not routinely fenestrated because of their low incidence of herniation. They are also technically more difficult to fenestrate because of anatomic differences. Not only is the L5-6 disc more difficult to fenestrate, but also considerable risk of creating a femoral nerve deficit exists if the adjacent ventral nerve branch is damaged.

A skin incision is made from one to two spinous processes rostral to the anticlinal vertebra (T11) to one vertebra rostral to the ilium. This incision may be made directly on the dorsal midline or 1 to 2 cm lateral to the midline on the side from which discs are to be fenestrated. The cutaneous trunci muscle, subcutaneous fat, and superficial fascia are incised in the same plane and are reflected sufficiently to expose lumbodorsal fascia 1 to 2 cm lateral to the dorsal midline (Figure 48-1A). Lumbodorsal fascia and aponeurosis of the longissimus thoracis et lumborum muscle

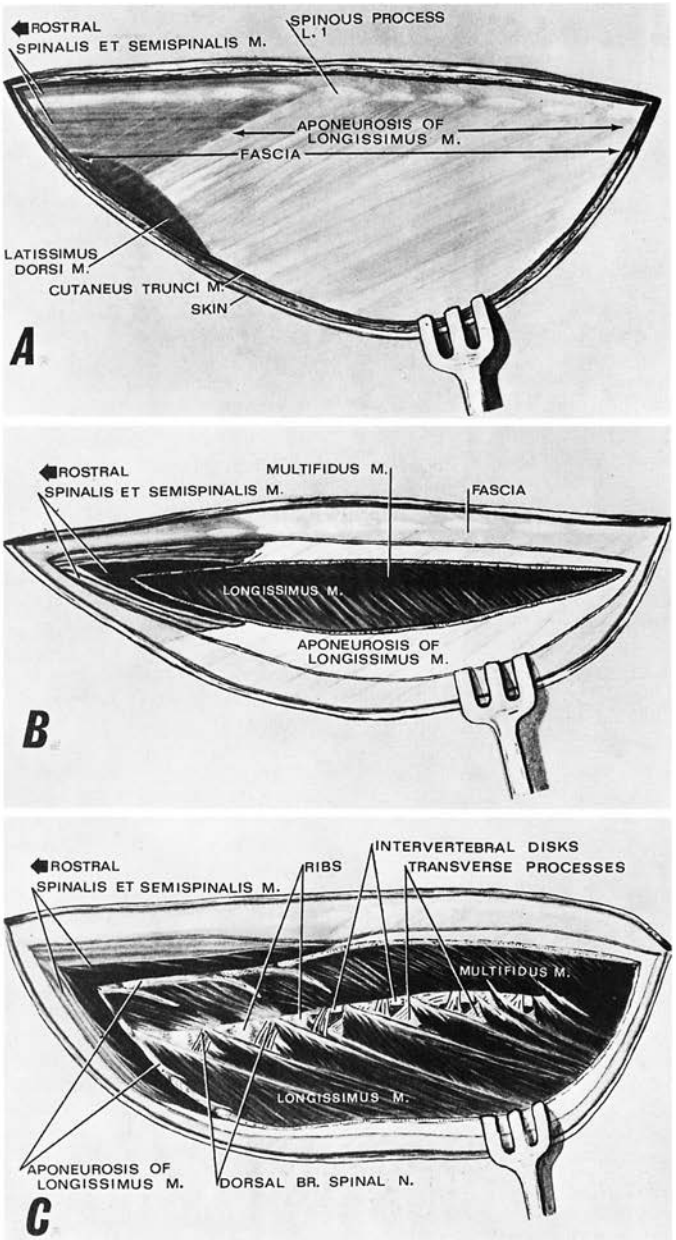

Figure 48-1. Surgical anatomy of the dorso-lateral approach to the thoracolumbar discs of the dog. **A.** The skin, subcutaneous fascia, fat, and cutaneous trunci muscle have been incised and reflected laterally on the left side of the dog. **B.** The deep external fascia of the trunk, the aponeurosis of the longissimus thoracis muscle, and the caudal edge of the spinalis et semispinalis muscles have been incised to expose the underlying multifidus and longissimus muscles. **C.** The multifidus muscle is separated from the longissimus thoracis muscle by blunt dissection to expose the thoracolumbar spine for intervertebral disc fenestration.

are incised along an imaginary line from a point 5 mm lateral to the spinous process of T9 to a point 1 to 2 cm lateral to the comparable process of L6 (Figure 48-1B). In the rostral portion of the surgical field, the caudal border of the spinalis and semispinalis thoracis muscles, interposed between the lumbodorsal fascia and aponeurosis of the longissimus thoracis muscle, is also incised (Figures 48-1B and 48-2).

Access to intervertebral discs is gained by opening the intermuscular septum between multifidus lumborum and thoracis muscles medially and longissimus dorsi and sacrococcygeus dorsalis lateralis muscles laterally (Figures 48-1C, 48-2 and 48-3). This septum is the first one lateral to the dorsal spinous processes; it is easiest to locate in the midlumbar region, where fat is interposed superficially between muscles. Muscles are easily divided by blunt dissection in the lumbar region; however, the septum is less distinct over the ribs. All blunt dissection is done with a curved semisharp Adson, or comparable, periosteal elevator in each hand. As tubercles of the last four ribs are exposed, care should be taken not to disturb small nerves and vessels coursing craniolaterally immediately dorsolateral to each tubercle. Separating muscles is carried to the base of the lumbar transverse processes.

The novice should completely separate muscles to this level taking care to avoid dorsal branches of spinal nerves (See figure 48-1C). This provides good visualization of intervertebral discs and adjacent structures. Experienced surgeons can "tunnel" down to each lumbar transverse process, thereby avoiding considerable tedious dissection and trauma. The short transverse process of L1 lies adjacent to the last rib, assuming the thirteenth rib is present, and is used as an anatomic reference point. All other lumbar transverse processes can be "tunneled" down to by referring to the lateral radiograph and estimating the distance between each process. If judgment is correct, the veterinary surgeon will never see dorsal branches of each rostral spinal nerve or its allied vessels. As the operation proceeds caudally from T13 to L1, succeeding transverse processes are progressively deeper.

As the surgeon exposes lumbar transverse processes (L1-5), the lumbar discs are exposed. The lateral anulus of intervertebral discs lies immediately rostral to the base of each transverse process (Figure 48-4). In the caudal thoracic area, discs are rostromedial to the head of each rib. The T10-11 disc is difficult to expose because it is 1 to 2 cm ventromedial to and is partially covered by the rib tubercle. Each disc can be visualized by elevating tissue off the lateral anulus with a periosteal elevator. Use of a small self-retaining retractor (Gelpi or Weitlaner) or hand-held retractors enhances visualization. Care should be taken not to invade intervertebral foramina, which lie immediately dorsal to each disc

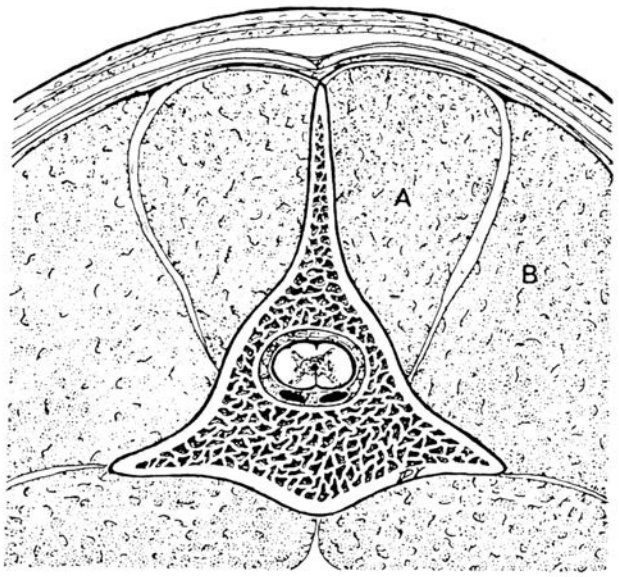

Figure 48-3. Cross section through L4. *A.* Multifidus lumborum muscle. *B.* Longissimus lumborum muscle.

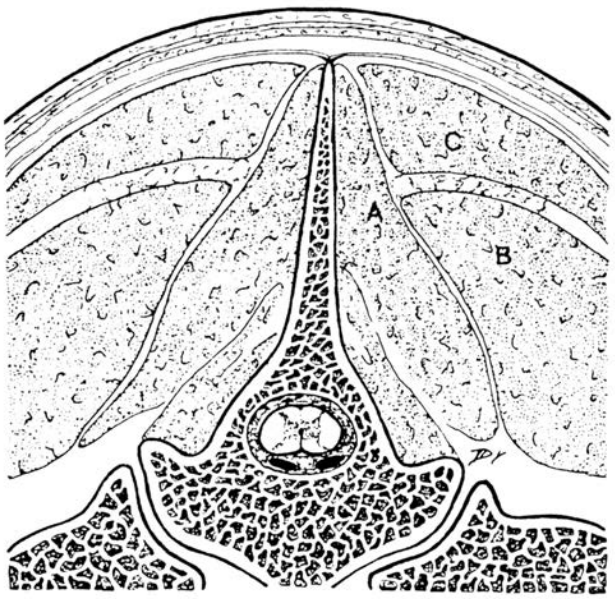

Figure 48-2. Cross section through T12. *A.* Multifidus thoracis muscle. *B.* Longissimus thoracis muscle. *C.* Spinalis et semispinalis muscles.

and contain spinal nerves and allied vessels. The inexperienced surgeon may overcompensate while attempting to avoid intervertebral foramina and work too far ventrally, where one risks injuring ventral branches of spinal nerves. Ventral branches of spinal nerves pass adjacent to the ventrolateral aspect of each disc (See figure 48-4).

In the lumbar area, ventral branches of the spinal nerves are located under the intertransverse fascia and are not visible in the surgical field unless an attempt is made to expose them. To ensure that a ventral branch is not traumatized, the tip of a curved mosquito hemostat can be introduced into the intertransverse fascia adjacent to the ventrolateral border of the anulus and the jaws can be spread gently. This exposes the ventral nerve branch occasionally, and creates a landmark for the surgeon to avoid. If the L5-6 disc is fenestrated, the ventral branch of the fifth lumbar nerve should be identified and avoided to ensure it is not damaged.

A disc's lateral anulus is visualized best for fenestration if adjacent muscle is retracted rostrodorsally with a curved, semisharp periosteal elevator. This instrument also protects dorsal branches of spinal nerves and associated vessels. A pointed scalpel blade is used either to incise or to remove an elliptical section of the anulus fibrosus. The anulus should not be cut where it cannot be visualized. Fenestration is accomplished with a modified dental-claw tartar scraper or the eye portion of a large suture needle held in a needle holder. Modifications to dental tartar scrapers include grinding off the sharp tip and sides of the claw. The nucleus pulposus is removed using a circular motion. The tip of the hook or needle-eye is directed upward, with care taken not to break through the dorsal anulus. A partially herniated disc must he fenestrated cautiously, to avoid forcing additional nucleus pulposus into the spinal canal (Figure 48-5). The surgeon must remove as much disc material as possible.

Figure 48-5. The correct position of a modified dental claw tartar scraper to fenestrate a disc, in this case a partially herniated disc.

Fenestrating T10-11 disc requires special care to avoid creating pneumothorax; pleura, directly ventral to this disc, rises and falls with respiratory movement. If existence of pneumothorax is in question, irrigating the area with saline solution and expanding the lungs by compressing the ventilation bag should provide an answer; air bubbles will appear in the surgical field if significant pneumothorax exists.

Minimal hemorrhage associated with exposure and fenestration of thoracolumbar discs can usually be controlled by topical pressure on bleeding tissue with a periosteal elevator. Rarely, hemostatic forceps or electrocautery is required to control bleeding.

Every disc fenestrated should be identified to ensure no discs are missed between T10 and L5. If clinical signs merit decompression of the spinal cord, decompression should be performed first, followed by disc fenestration. Fenestration is more compatible with hemilaminectomy than with dorsal decompression. Hemilaminectomy and fenestration can be performed from the same side; although the multifidus muscle is badly traumatized, no adverse clinical signs have been observed. Lateralization of signs often dictates performing a decompressive surgical procedure and fenestration on opposite sides of the spinal column.

Debridement of tissue is not necessary when the "tunnel" technique is used to expose lumbar discs. Performing a hemilaminectomy on the same side, or division of the multifidus and longissimus dorsi muscles down to the level of transverse processes for improved exposure, may necessitate some debridement. Aponeurosis of the longissimus and spinalis et semispinalis muscles in the caudal thoracic area and overlying thoracolumbar fascia are approximated with one suture line of absorbable suture material. Subcutaneous tissues are apposed with similar material, catching underlying fascia occasionally to obliterate dead space. The skin incision is closed with any dermal suture. A light-pressure bandage may he applied around the trunk of the dog and left in place for 4 to 7 days.

Postoperative Care and Prognosis

Corticosteroid and analgesic agents should be administered for 1 to 3 days postoperatively because most dogs experience some discomfort. Thereafter, treatment depends on clinical signs. Because corticosteroids are used in association with this operation, skin sutures should be left for at least 3 weeks to avoid incisional dehiscence. Dogs routinely go home 48 to 72 hours after surgery, or as soon as voluntary urination is evident. In addition to preventing subsequent attacks of disc prolapse, fenestration eliminates the need for prolonged confinement of dogs with functional ambulatory ability. Physical therapy can be initiated within a day or so of surgery in patients with caudal paralysis.

Paresis, if present, remains unchanged in most animals immediately postoperatively. Because clinical signs occasionally are more severe immediately after the procedure, the client must be forewarned of this possibility. Deterioration in neurologic status can be associated with the operation. If pathologic changes in the spinal cord, which may or may not be known,

are progressive at the time of surgery, disc fenestration itself will not be responsible for a worsened neurologic state. Such a condition may result from spontaneous herniation of additional nucleus pulposus while the dog is anesthetized for radiographs or surgery. Overzealous fenestration of a partially herniated disc may also force additional material into the spinal canal. Trauma to the spinal cord from the fenestration hook is an unlikely cause of increase in neurologic deficit. The client should be advised that some dogs suddenly deteriorate neurologically without radiographs or operation.

The most likely potential surgical complications are 1) failure to fenestrate a disc, 2) creating a pneumothorax, 3) injury to spinal nerves, 4) damage to the spinal cord, and 5) cutting spinal arteries.

In most dogs, evidence of some degree of spinal nerve injury exists for at least a few days postoperatively. Dogs may have slight scoliosis, with deviation to the operated side, and sag (paralysis) of abdominal muscles ipsilateral to the operated side may be noticeable. If the ventral branch of the fifth lumbar (L5-6) has been damaged, the dog will have at least a temporary femoral nerve deficit. Severity of these signs is directly correlated with the expertise of the veterinary surgeon.

We are aggressive in promoting thoracolumbar disc fenestration because it is impossible to predict severity of a recurrent disc attack. Herniation of a cervical disc has not been observed to cause permanent caudal paralysis or death from diffuse myelomalacia; in the thoracolumbar region, however, such a sequela is not unusual. Fenestration, properly performed, should minimize chances of subsequent disc episodes, and the dog's locomotion should not be compromised.

The dorsolateral approach is preferred for fenestrating thoracolumbar discs because it 1) permits decompression by hemilaminectomy when this procedure is also indicated, 2) results in minimal trauma, and 3) provides easy access to nine discs. Thoracolumbar intervertebral disc fenestration is more difficult than cervical disc fenestration, and the potential for severe and possibly permanent neurologic injury can not be overemphasized. Success with this procedure requires a thorough understanding of anatomy and basic surgical principles. Consequently, the novice should perform this surgical procedure on a cadaver before attempting it on a clinical patient.

Prophylactic Thoracolumbar Disc Fenestration

M. Joseph Bojrab and Gheorghe M. Constantinescu

Surgical fenestration of the intervertebral space provides a means of prophylaxis in disc disease. If protrusion exists, surgical removal of the nucleus remaining in the intervertebral area will eliminate the pressure causing the protrusion. When all other discs that are potential problems (T9-10 to L5-6) are fenestrated at the same time, complete prophylaxis against future disc protrusions is achieved. The material already extruded into the canal cannot be removed by disc fenestration alone; however, fenestration of other degenerated discs is recommended, so vigorous physical therapy, such as hydrotherapy and cart walking, can be prescribed without fear of causing another protrusion or even extrusion.

The ventral fenestration technique described here facilitates access to all potentially offending discs with a minimum of surgical trauma. Ten discs are fenestrated (T9-10 to L5-6). The thoracic discs are exposed through a left tenth intercostal thoracic approach, and the lumbar discs are exposed through a paracostal abdominal incision (Figure 48-6).

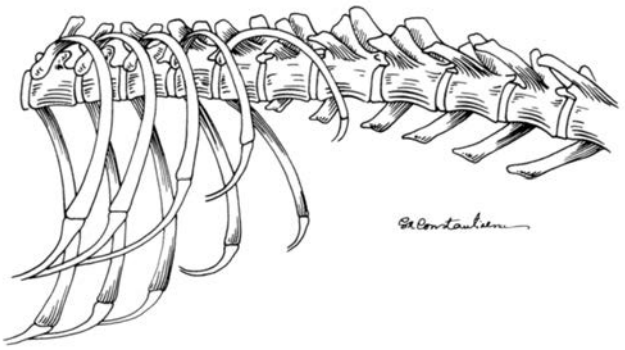

Figure 48-6. Diagrammatic representation of the ventral vertebral column from the left lateral view. Note the relation of the vertebral costal foveae and the rib heads to the various disc spaces.

Surgical Technique

The patient is medicated preoperatively with corticosteroids (dexamethasone 1 mg/lb) and antibiotics. The patient is placed in right lateral recumbency, and the left lateral side is clipped and prepared aseptically. The skin incision is made over the thirteenth rib from the dorsal to the ventral midline. The subcutaneous tissue is dissected, the incision is slid caudally, and a paracostal incision is made into the abdomen. The left kidney is located and is reflected ventrally with the peritoneum. Frazier laminectomy retractors are positioned (Figure 48-7), and the abdominal viscera are packed off with a laparotomy pad. This retroperitoneal abdominal exposure affords access to the LI-2 through L5-6 intervertebral spaces. The iliopsoas (psoas minor) muscle is hooked with a muscle retractor and is retracted away from the ventral midline (Figure 48-8). The ventral crests can be palpated.

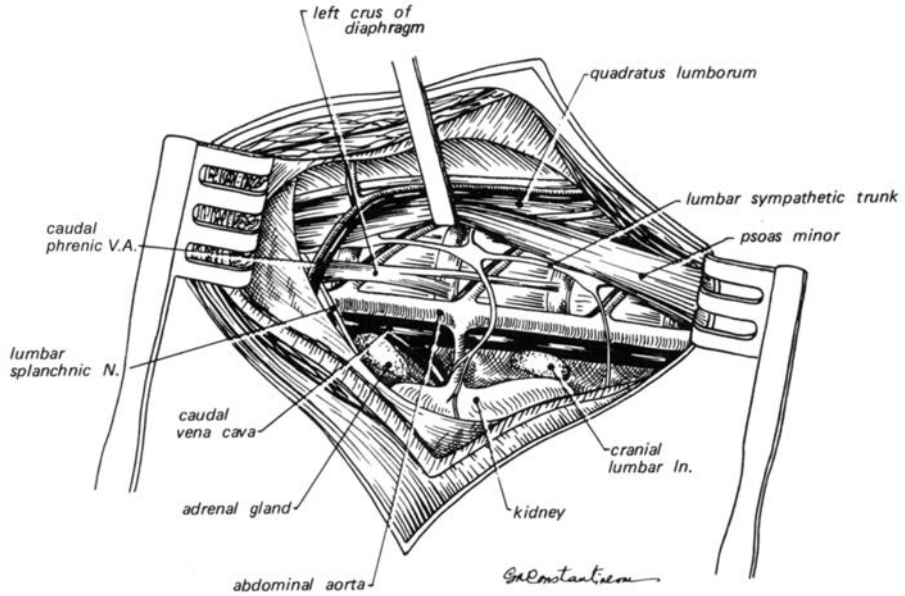

Figure 48-7. Paracostal incision by retroperitoneal exposure for lumbar disc fenestration.

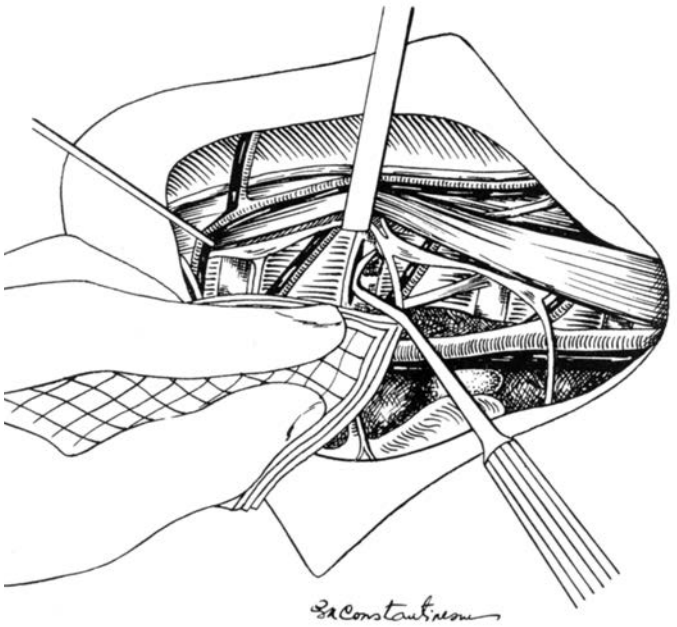

Figure 48-8. The sublumbar muscles and sympathetic trunk have been elevated, and the crus of the diaphragm and the aorta have been depressed during a lumbar disc procedure.

The transverse processes are identified and are numbered for orientation. Medial to the first transverse process is the T13-L1 intervertebral space. This space is not easily exposed from the abdominal approach and thus is fenestrated from the thorax. The remaining intervertebral spaces (LI-2 to L5-6) are fenestrated by first cutting the ventral longitudinal ligament and annular fibers of the ligament of the rib head with a scalpel. The nucleus pulposus is removed with a Miltex scaler B tartar scraper. An inward, upward, and outward motion is used to clear the intervertebral space of as much nucleus as possible. Once this maneuver has been completed, the retractors are removed, and the muscle layers are individually sutured with 2-0 synthetic absorbable suture material.

The skin incision is slid in the cranial direction, and an incision is made into the thorax between the tenth and eleventh ribs. Frazier laminectomy retractors are placed (Figure 48-9), and ventilation is instituted. The T9-10 through T13-L1 intervertebral spaces are located and are dissected free of pleura; the sympathetic trunk and intercostal vessels are carefully avoided. When the dissection is complete, the discs are fenestrated in the same manner as already described (Figure 48-10). The thorax, latissimus dorsi muscle, and skin are closed in a routine manner.

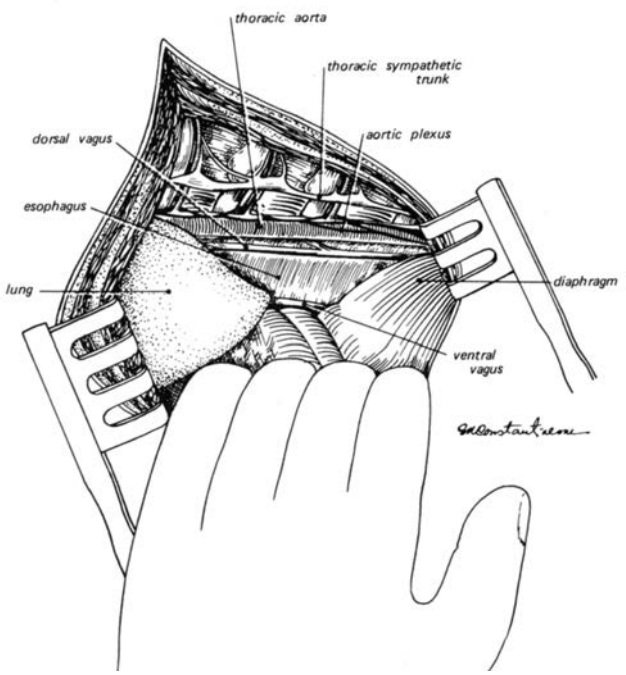

Figure 48-9. Exposure for thoracic disc fenestration.

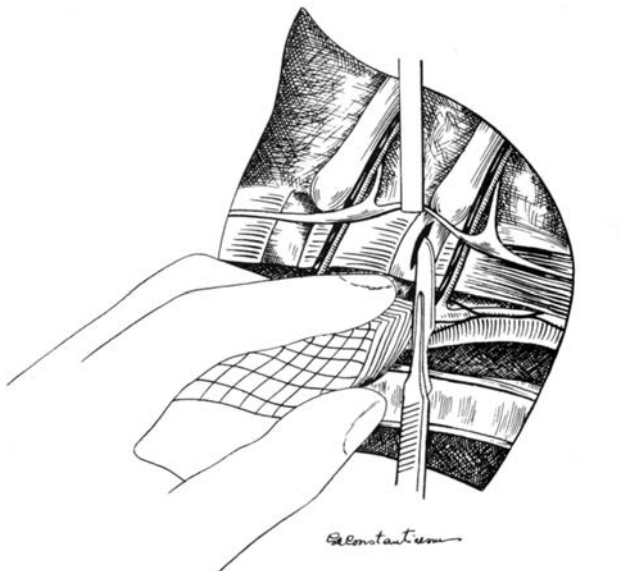

Figure 48-10. The aorta is protected and depressed with a gauze sponge, and the thoracic disc is incised with a scalpel.

Postoperative Care

The animal is monitored closely during the anesthetic recovery period. Antibiotics are given, the bladder is kept evacuated, and intensive physical therapy is instituted. Physical therapy includes hydrotherapy and cart walking.

Hemilaminectomy of the Cranial Thoracic Region

James F. Biggart, III

Indications

The most common indication for surgery of the thoracic spinal cord is the removal of extradural masses usually diagnosed by myelography, CT and MRI. Disc herniations in the thoracic spine are rare, and many surgeons ignore the few disc lesions seen there. The intercapital ligaments occupying the floor of the canal between T2-10 help to protect the spinal cord from disc herniation. Neoplasia in the thoracic spine is relatively more common than in other areas of the spine because of the lack of thoracic disc herniation. Therefore, exploration of the thoracic cord is likely to yield a tumor more often than in other areas of the spine.

Thoracic spinal fractures are rare because of the stabilizing influence of the ribs and long dorsal spines that help to prevent rotational deformities as well as flexion extension injuries. The mobile spine anterior and posterior to the thorax suffers more traumatic lesions.

The degenerative changes seen in the cervical and lumbar spine are not so common in the thoracic spine. Disc degeneration occurs as frequently as elsewhere in the spine, but disc herniations into the canal are rare. Redundancy of the ligamentum flavum is rare. Acquired bony stenosis is not often seen. Facet degenerative changes, synovitis, and synovial proliferation seldom cause cord stenosis or cord pressure. Bony stenosis, such as seen in the cervical region of caudal cervical spondylopathies of large dog breeds, has not been reported. Because many of these degenerative changes occur in more mobile segments of the spine, the more rigid thoracic spine is believed to be spared these changes.

Positioning of the Patient

The patient is placed in ventral recumbency. Elevation of the sternum (but not the elbows) by pillows, sandbags, or padding raises the spine in relation to the scapula. Pulling the forelegs forward usually loosens the adduction of the scapula to the spine, thereby allowing lateralization of the scapula. However, positioning the forelimbs posterior or crossing them under the sternum may aid in spinal visualization, so experimentation with foreleg positioning may be helpful.

Surgical Approach and Anatomy

A midline incision is made through the skin, subcutaneous fat, and fascia to the midline over the dorsal thoracic spinous processes. Just off the midline, the approach continues ventral alongside the dorsal spines to the dorsal lamina, which forms the base of the dorsal spines. The cutaneous trunci, trapezium, and cleidocephalicus are the first muscles encountered and are incised along their attachment to the dorsal spine processes on the midline. The latissimus dorsi and rhomboideus muscles are likewise incised, allowing lateralization of the scapula by self-retaining rib, Gelpi, or Weitlaner retractors. The cranial serratus dorsalis insertions are incised, as are the insertions of the thoracic spinalis and semispinalis muscles on the dorsal spines. The spinalis thoracis muscles are elevated by periosteal elevators to expose the lateral dorsal spines. The longissimus muscles are lateralized with retraction and do not require incision. The thoracic multifidus muscles are elevated with periosteal elevators or are incised at their origins. The supraspinatus ligament and interspinales muscles are left intact. The longi and breves rotatores muscles are incised at their origins exposing the dorsal lamina (Figure 48-11). The levator costae muscle can be spared unless rib head exposure is needed.

Once the lamina is exposed, a high-speed drill is needed to remove the dorsal lateral lamina. For right-handed surgeons, a left-sided hemilaminectomy is preferred (Figure 48-12). The

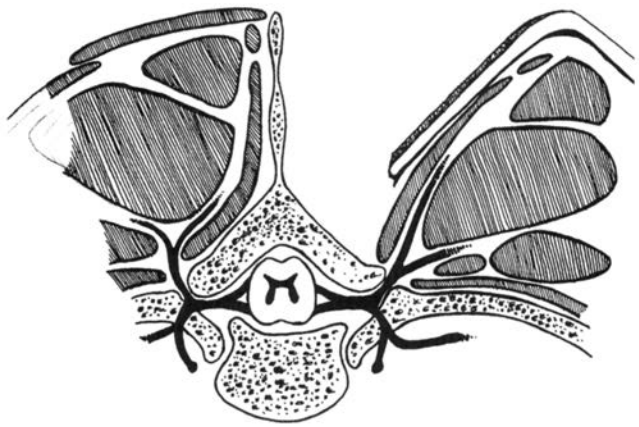

Figure 48-11. Exposure of the dorsolateral lamina.

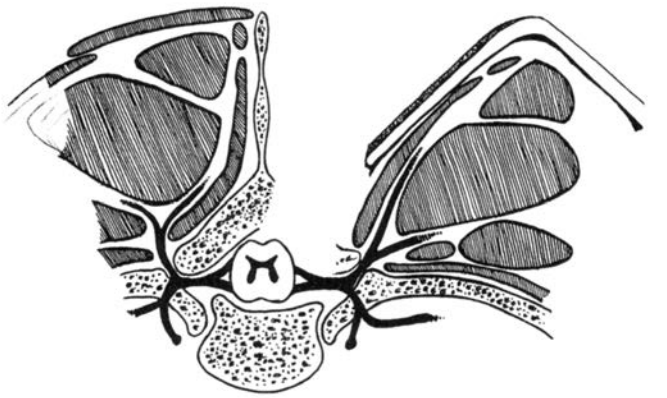

Figure 48-12. Hemilaminectomy exposing the spinal cord.

dorsal spine can be undercut to the off side of the spinal canal. The ventral 1 to 2 cm of the dorsal spine can be removed, allowing wide lateral exposure to the off side (Figure 48-13). The resultant floating dorsal spine, suspended by interspinous muscles and supraspinous ligament, produces no noticeable effect. Likewise, the rib head, neck, and tubercle can be removed as needed for lateral cord exposure on the near side. The resultant floating rib seldom causes problems because it is supported by adjacent ribs through the intercostal muscles. As the surgeon moves forward in the thoracic spine, the ribs articulate higher in the interdiscal space and may necessitate rib head, neck, and tubercle resection. Resection of the proximal rib head, neck, and tubercle allows adequate spinal cord visualization. Care must be taken to avoid dissection below the rib that could allow penetration into the chest cavity, thereby creating a pneumothorax.

The length of the dorsal spines in some breeds may create a deep surgical field. Proper instrumentation and lighting allow careful cord evaluation. The arteries encountered are the dorsal branches of the intercostal arteries. The spinal branches supply the spinal cord through the foramen just above the rib neck. These vessels can be avoided by staying close to the midline along the dorsal spines. The veins encountered parallel the arteries and join the azygos posterior to the heart and the costocervical-vertebral trunk anterior to the heart.

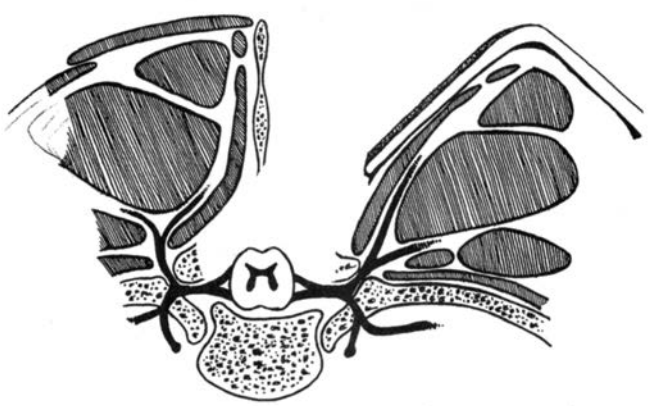

Figure 48-13. Dorsal laminectomy necessitating removal of the dorsal spine.

Wound closure is similar to that of lumbar or cervical hemilaminectomy. A free fat graft harvested from the subcutaneous tissue is placed into the hemilaminectomy defect. Careful cord hemostasis lessens the hemorrhage under the fat graft that increases scar invasion of the graft. The more graft that undergoes revascularization, the less restrictive scar forms above the cord.[1-3] The trapezius, rhomboideus, serratus dorsalis, and cranialis muscles should be reattached to preserve scapular function. The rest of the epaxial muscles reattach to the spine without direct suturing.

Postoperative care is similar to that after other spine approaches. Lameness is common for a few days until the scapular sling muscles lose their tenderness.

Benefits

Inclusion of this approach to the thoracic spine with well-known approaches to the neck and lumbar spine allows the surgeon to explore any lesion in the spinal canal from the foramen magnum to the coccygeal vertebrae. Most extradural lesions can be removed from the spinal canal, especially if undercutting the dorsal lamina or removal of the base of the dorsal spine is used to gain access to the far side of the spinal cord.

Limitations

Long, wide laminectomies over many disc spaces entail removal of the bases of many dorsal spines. The need for stabilization of these spines to prevent their ventral collapse into the laminectomy site adds additional hardware, expertise, and complexity to an already challenging approach. In addition, visualization, especially under the spinal cord, is sometimes poor.

The scapula prevents a lateral view of the cord in the cranial thoracic spine. Instruments have to be placed from a dorsal aspect. This necessitates using right-angled instruments that are not used in cervical and lumbar spine operations. Removal of the rib head and neck, especially over many disc spaces, adds complexity.

A surgical headlamp and 2x loop magnification are helpful in visualizing the spine especially in deep surgical fields. Bipolar cautery and fine tip suction are essential in providing hemostasis. The added visual acuity gained by hemostasis is more beneficial than the more obvious benefit of preventing blood loss and shock.

Because of the stabilizing influence of the adjacent dorsal spines and ribs, the destabilizing effects of wide deep laminectomy over the thoracic spine are less than those of the cervical or lumbar spine. Wider exposure of the spinal cord is possible, allowing a greater amount of adjacent tissue excision for biopsy or tumor removal. However, the close proximity to the aorta, azygos vein, and chest cavity makes exposure ventral to the cord or rib head hazardous. Damage to the nerve roots exiting the foramen cause some loss of forelimb function as well as loss of intercostal function affecting respiration.

Variations: First and Second Thoracic Cord Exposure

The first and second thoracic vertebral cord can be approached as a posterior extension of a seventh cervical dorsal laminectomy.[4,5] The thoracic dorsal spines can be exposed anteriorly without disturbing the ligamentum nuchae or supraspinous muscles, which are retracted laterally. The drill is angled from anterior to posterior, with the right-handed surgeon positioned on the right side of the patient that has been placed in sternal recumbency. Removal of the lamina between the base of the dorsal spine and first rib head exposes the spinal cord and canal over one side. Care must be used to leave enough of the base of the first dorsal spine to maintain the strength necessary to support the head and neck through its attachment of the nuchal ligament. This limits the exposure of the first thoracic spinal cord. If complete removal of the base of the first dorsal thoracic spine is needed, then enough of the base of the spine should be removed to prevent downward pressure of the spine stump on the exposed cord. Support of the head by the nuchal ligament, which attaches to the first three dorsal spines, pushes the remaining spine ventrally when its lower base is removed.

Approaching the anterior thoracic cord in this way avoids the disruption of the musculature along the dorsal spine and attachments to the scapula. The scapula influences the approach to the thoracic spine only anterior to T6 or T7. Posterior to these areas, the approach is similar to that of the lumbar spine.

Hemilaminectomy of the Caudal Thoracic and Lumbar Spine

Karl H. Kraus and John M. Weh

Hemilaminectomy of the Caudal Thoracic and Lumbar Spine

Hemilaminectomy of the caudal thoracic and lumbar spine is used to gain access to the vertebral canal for the removal of offending masses, often impinging on or involving the spinal cord. These masses include intra and extradural tumors, granulomas, bone fragments resulting from vertebral fracture, and (by far most common) intervertebral disk extrusions and protrusions. The term "hemilaminectomy" may be a misnomer, since the lamina of the vertebrae is the boney structure which is dorsal to the vertebral canal, dorsal to the articular facets. The pedicle, or root, is the boney structure lateral to the vertebral canal between the vertebral body and articular facets. It is the pedicle, more than the lamina that is removed during what is commonly referred to as a hemilaminectomy. Some authors do refer to removal of sections of the pedicle as pediculotomy, however the term hemilaminectomy is used to describe the common surgical procedure for removal of part of the vertebral arch on a single side of the spinous process to gain access to the vertebral canal.

The timing of surgical intervention and the urgency of spinal cord decompression has been explored in several clinical studies. Though there is some disagreement in interpretation of the clinical studies, and hospitals have different capabilities for after hours imaging and surgery, a general consensus regarding the triage of patients with spinal cord compression is available. In cases of thoracolumbar spinal cord compression resulting from presumed intervertebral disk extrusions or protrusions the recommendations are as follows:

1. No deep pain less than 12 hours. Emergency operation should be recommended. The prognosis is 50% for ambulating. At present, there are no clinical studies that demonstrate efficacy of any glucocorticosteroid including methylprednisolone sodium succinate, therefore the administration of these medications in not indicated.
2. No deep pain over 24 hours. Operate when practical. "Practical" is defined as in the morning if presented at night, as soon as possible if presented during the day, but do not wait until the next day. There is no reported correlation between duration of paralysis prior to surgery, and clinical outcome.
3. Acute, less than 12 hours with no motor function but deep pain is present. Offer emergency operation contingent on personnel, progression of neurologic signs and how long to morning (e.g. is it 3:00am? Then wait.) These cases may loose deep pain as the pathophysiology is not static. Prognosis is therefore guarded but not poor.
4. Deep pain present, no motor function, over 24 hours. Operate when practical. Prognosis is good with 96% of dogs becoming ambulatory. It will take an average of two weeks for these dogs to walk.
5. Non-ambulatory, purposeful motor movement. If admitted in evening, then operate in am. Perform serial neurologic exams to assure patient's neurologic status does not worsen. Some facilities will delay day admitted cases if the neurologic examination is static and noninvasive imaging (CT,MR) is available in the morning, therefore avoiding a myelogram. Prognosis is good for ambulating. It will take an average of one week for these dogs to walk.
6. Ambulatory paretic. Operate the next day. Of course sooner if patient is stable and facilities and personnel are available. Prognosis is excellent for ambulating. Cage rest can be considered if cost is a factor, but owners should be warned about worsening of neurologic status including paralysis.

A majority of disk extrusions occur near the thoracolumbar junction; rostral to the lumbar intumescence of the spinal cord

and caudal to the thoracic intumescence. Therefore the neurologic signs are normal sensation, proprioception and motor function to the thoracic limbs and loss of proprioception, motor function, and pain sensation (in that order) to the pelvic limbs. The common neurologic localization and clinical diagnosis is a T-3 to L-3 (third thoracic to third lumbar spinal cord segment) myelopathy. Disinhibition from compromise of the upper motor neurons to the femoral and sciatic nerves results in hyper-reflexia or upper motor neuron signs to the patellar and cranial tibial reflexes. The progression of signs from loss of proprioception, to loss of motor function, to loss of superficial then deep pain, is most often a function of compression on the descending and ascending spinal cord axons. The larger axons, such as those that carry proprioceptive information, are affected first. Deep pain sensation, or spinal thalamic pathways are not discrete in domestic animals as they are in humans. Instead they are diffuse, multisynaptic and bilateral within the spinal cord. Loss of deep pain perception reflects a functional transection of the spinal cord. Though a functional transection does not necessarily mean an irreversible condition, the loss of deep pain sensation is a negative prognostic indicator. The alpha motor neurons to the femoral nerve are located above the interbertebral disk between the third and fourth lumbar vertebrae. The alpha motor neurons to the sciatic nerve are located roughly above the fourth and fifth lumbar vertebra. For this reason compressions of the spinal cord in these locations can result in lower motor neuron signs to the segmental reflexes in these areas. Offending masses can impinge on vertebral nerve roots and can result in pain and hyperesthesia due to the radiculopathy. Hyperesthesia in descrete areas as assessed by the paniculus reflex can give a more precise indication of the location of an offending mass.

Because the neurologic examination often does not give an exact localization of the area of compression or side of the mass if it is lateralized, imaging should be performed to define the pathology of the mass (tumor or disk, size) and location (vertebral segment, left, right, midline). Myelography with conventional radiographs has classically been used to localize the lesion. Though sufficient in most cases, a discrete lesion my not be apparent if there is considerable spinal cord swelling. In addition it may be difficult to differentiate disk extrusions from other pathologies. Computed tomography (CT) can be used since many disks are partially calcified. The soft tissue resolution of newer CT scanners is very good and can image most masses. Spiral CT scanners are very fast and can noninvasively localize a lesion in less than 10 minutes in most cases. Magnetic resonance imaging (MRI) scanners provide the best resolution of both soft and boney tissues and are becoming the standard of care for neurologic imaging in veterinary medicine.

Once a lesion is localized with either modality, identifying the proper location for a surgical approach to perform hemilaminectomy can be troubling for inexperienced surgeons. Several strategies can be employed. First, the surgeon should count the number of lumbar vertebrae. This is obvious with myelograms and most CT scans, but a scout image must be taken with MR scans. Though in most cases there are seven lumbar vertebrae, in some patients there are transitional vertebrae. Vestigial ribs may arise from the first lumbar vertebra, or the most caudal rib may be present on one side only. Since ribs are not always imaged with MR, a dorsal plane scout film (dorsal plane localizer) from the sacrum to the twelfth thoracic vertebra will demonstrate rib anatomy. Hemi-vertebra may be present at the lumbosacral junction. These anatomic variations must be noted and kept in mind. With MR, a scout film (sagittal localizer) will image the celiac and cranial mesenteric vessels along with the lumbar vertebrae. The vessels arise below the thirteenth thoracic or first lumbar vertebrae. These vessels serve as land marks for more focal MR images.

Palpation of the spinous processes can usually give the proper location in the lumbar area. The spinous process of the seventh lumbar vertebra may be palpated between the cranial aspects of the wings of the ilium. The spinous processes are usually palpable and the surgeon can count cranially to find the proper surgical site. In some cases where lumbar fat is very thick, the surgeon may need to make an approximate surgical approach through the skin and lumbar fat, then palpate the spinous processes surgically. In the thoracolumbar area, the ribs serve as landmarks for localization. Again, confirm the anatomy of the patient, as transitional vertebrae and small vestigial ribs can confuse localization. After an initial surgical approach through the skin and fat is made, a small incision in the lumbar fascia lateral to the longissimus and iliocostalis muscles is made by the thirteenth rib just large enough to accommodate one's index finger. The thirteenth rib can be palpated. This rib attaches to the cranial aspect of the thirteenth thoracic vertebra. The spinous process of the thirteen thoracic vertebra is also often the first that can be distinctly palpated as those of the ninth to twelfth tend to be very close to each other. Once the thirteenth thoracic spinous process can be identified with certainty, the location for laminectomy can be accurately determined. Matching the shape of the spinous processes seen during a surgical approach with pre-operative imaging is also helpful.

Some surgeons use other techniques to localize the proper location for the hemilaminectomy. Specifically a hypodermic needle (such as 22 ga.) can be pressed into a spinous process prior to surgery, then a lateral radiograph taken to define which spinous process the needle is in. The hub of the needle is then cut off leaving the shaft of the needle beneath the skin. The needle is then found during the surgical approach, defining the proper surgical location. It is not uncommon, however, for a surgeon to loose the needle and spend some time finding it during the surgical approach. Another similar technique is to use Methylene blue. Instead of leaving the shaft of the needle under the skin, a needle is pressed into a spinous process then a lateral radiograph is taken. A small amount of sterile methylene blue 1% (0.1 ml) is injected into the area of the spinous process then the needle removed. The area of staining is found during the surgical approach defining the proper location. However, the staining may not be as discrete as desired, especially in the lower thoracic area, and therefore the surgeon may not be absolutely certain about anatomic localization.

It is a standard of care in surgery on humans to take an intra-operative radiograph during the surgical approach to confirm localization. Many veterinary surgical hospitals have equipment

for intraoperative radiographs such as C-Arms and fluoroscopy. Intraoperative radiographs are probably the best technique to assure and document surgical localization, and should be used when available.

Deciding on Approach

A hemilaminectomy is often chosen over a dorsal laminectomy for several reasons. It is a rapid operation that gives good exposure to the dorsal, lateral and ventral spinal canal on one side. Though a dorsal laminectomy gives exposure to both sides of the vertebral canal, this approach does not allow direct exposure of the ventral floor of the vertebral canal and the intervertebral disk. In the lower lumbar area essential nerve roots are in the area of a hemilaminectomy and can be avoided with a dorsal laminectomy. However, if carefully performed, a hemilaminectomy can be utilized throughout the thoracic and lumbar spine.

Surgical Prep and Positioning

A hemilaminectomy is performed by a dorsal approach close to the midline. The hair should be clipped in the area of the lesion, extending about 5 cm laterally on each side. A more liberal clip should be performed both cranially and caudally to assure that the surgeon has enough flexibility to extend the incision if needed. The skin of the dorsum of dogs and cats is quite movable allowing some flexibility if the skin incision does not exactly match the approach to the vertebrae. The patient is placed on the operating table in ventral recumbency. It is very important to make sure the patient's spine is straight and placed straight on the table, and also that the patient is not leaning to the left or right. Errors can be easily made during the hemilaminectomy when the orientation of the patient makes anatomic perspective confusing. Patient postitioners such as vacuum bags are very useful to stabilize the patient and keep them steady during the operation. Rolled towels and orthopedic tape are also helpful.

Goals of Surgical Decompression

A hemilaminectomy is simply the approach made by the surgeon to decompress the spinal cord. The overall goal should be to remove the offending mass without manipulation of critical neurologic structures. With this in mind, the principles of proper surgical decompression are as follows:

1. The approach should be made aseptically and atraumatically.
2. The hemilaminectomy should be performed so that the offending mass can be removed without manipulation of the dural sac.
3. The offending mass must be removed completely without residual compression.
4. Hemorrhage must be minimal as postoperative hematoma can act as a compressive mass.

These principles of decompression dictate the instrumentation needed and the surgical techniques employed to properly perform the surgical procedure.

Instrumentation

A surgical pack with basic high quality instruments is needed. In addition, several other instruments are very helpful. Visualization of the surgical field is very important. Proper surgical lights should have at least 5,000, and preferably closer to 10,000 Foot Candles at 36 inches. Two light heads are important to prevent shadowing. Many surgeons use a head light which is very helpful, especially if the surgical lighting is questionable. Surgical loupes are also important for magnification (Figure 48-14). Custom built loupes for inter-pupillary distance, frame size, corrective lenses, and working arm distance (focal distance) should be used so that the surgeon is not distracted by improper fit. Usually 2.5x magnification is sufficient. Higher amounts of magnification give a smaller field of view.

Hemostasis is essential to prevent blood loss, provide better visualization, and prevent postoperative hematoma which can act as a compressive mass (Figure 48-15). A high quality electrocoagulation unit should be available. Usually about 35 watts of power are used for both cutting and coagulation. Bipolar cautery should be available as this tends to localize current and prevent inadvertent stimulation of nervous structures and heat damage. With bipolar cautery the power is reduced to 15 Watts. Bone wax is very helpful in stopping hemorrhage from cancellous bone. Other hemostatic agents such as absorbable gelatin sponge and oxidized cellulose are useful in stopping hemorrhage and encouraging coagulation.

Elevating and retracting the axial muscles are performed with periosteal elevators and retractors (Figure 48-16). Besides either ASIF or Keyes periosteal elevators, Freer elevators are very helpful for fine elevation. Gelpi retractors are used by many veterinary surgeons and several sizes should be available.

Historically different instruments have been successfully used to perform the laminectomy including trephines and ronguers. However, a principle of surgical decompression is to remove the offending mass without manipulation of the dural sac and other eloquent neurologic structures. It is difficult, if not impossible

Figure 48-14. A head light and prescription 2.5X loops provide a surgeon with illumination and magnification which is very helpful in neurosurgery.

Figure 48-15. Different techniques and agents are used to establish hemostasis. Shown here from left to right are cellulose, collagen, bone wax, bipolar, and monopolar cautery.

Figure 48-16. Retraction of the axial musculature is frequently performed with Gelpi retractors. Having several sizes is helpful. Elevation of muscle from the vertebrae can be performed with several different types of periosteal elevators.

to chip away the lamina or pedicle of a vertebra with a rongeur without placing one tip of the rongeur into the vertebral canal and therefore pressing on the dural sac. Currently, most surgeons will use a high speed drill with a variety of burrs to remove bone. Air (nitrogen) powered drills are most useful as they stay cool and are durable (Figure 48-17).

Suction is essential for removal of the bone swarf (particles of bone material produced during drilling), blood and saline. Small Frazier suction tips are best. The area can be lavaged using a 10 cc syringe with a needle or canulla (Figure 48-18).

Removal of the offending mass requires a variety of different instruments depending on the specific situation. These include dental instruments, pituitary curettes, wire loops, nerve root retractors, probes, biopsy forceps, etc. (Figure 48-19). Different surgeons have their own preferences regarding which instruments work best. A very versatile and inexpensive instrument is small gauge wire (24 or 26 ga,) which can be fashioned into many different shapes and held with a mosquito hemostat or small needle holder.

Figure 48-17. Making an aperture in the vertebrae is principally performed with a high speed drill (left) and various sizes and shapes of Burs. Rongeurs such as Kerrison, Ruskin, or Lempert (right) may also be used, or used in conjunction with a high drill.

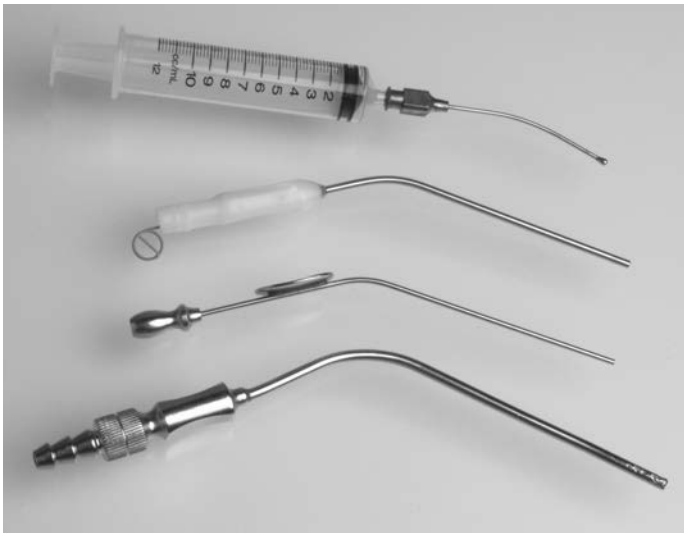

Figure 48-18. Precise lavage can be performed with a syringe and cannula (top). Different small sizes of Frazier suction tips provide suction and visualization of the surgical field.

Figure 48-19. Once the hemilaminectomy has been performed, disk material or other masses can be removed with a variety of different instruments depending on the situation or surgeon's preference. These include probes, nerve root retractors, curettes, dental instruments, or orthopedic wire.

Technique

A skin incision about four vertebra in length is made, and the approach advanced to the lumbar fascia. Many surgeons will towel or drape the incision for added sterility. An incision through the lumbar fascia using a scalpel or electroscalpel is made on the dorsal midline between the spinous processes and just to the side of the hemilaminectomy around the spinous processes in a scalloped like shape. Then a periosteal elevator is used to elevate each (usually four) spinous process. In the lumbar area, the elevation is carried to the transverse processes. In the thoracic vertebra the elevation is carried to the costal fovea or articulation with the rib. A scissor is then used to cut the interspinous ligament, lengthwise between the spinous processes, allowing the transversospinalis muscles to be retracted laterally. Gelpi retractors are commonly used with one tip deep in the musclulature and the other in the interspinous ligament over the area of the laminectomy. At this point, many surgeons will remove the tendinous attachments of the lumbar musculature from the articular facets of the vertebrae. This will provide further retraction of the axial musculature, however it will also result in a small arterial hemorrhage which must be controlled. The hemilaminectomy can be performed without this dissection and as the facet is removed with a bur, the muscles will retract laterally and carry the small arteriole laterally as well.

Though some surgeons still use rongeurs to perform laminectomies, the use of a high speed burr allows better exposure with less manipulation of the dural sac. Burring must be performed carefully, but a few simple techniques make this technically simple. The most common mistake in burring is to try to breach the vertebral canal as quickly as possible with a large burr. This results in a limited exposure to the vertebral canal (Figure 48-20). This small hemilaminectomy with sharp bone edges is not helpful as it provides limited exposure, and can make decompression without spinal cord manipulation difficult. In addition, extending a small approach with rougeurs requires one tip of the rongeur to be placed inside the vertebral canal which can result in manipulation of the dural sac. The preferred approach utilizes smaller burr size for more precise bone removal. The compressive lesion can be relieved from the spinal cord without manipulation of the spinal cord. The burring is begun in two separate locations, at the level of the accessory process (dorsolaterally) in the center of the vertebral pedicle on either side of the offending disk space, until cancellous bone is exposed. The key to careful and efficient burring is to locate the layer of cancellous bone (red in appearance) between the outer cortex of the vertebra and inner cortex (white in appearance), beyond which lies the vertebral canal and spinal cord. Burring is continued until the inner cortical bone is exposed, but stopped before the vertebral canal is entered. The bur is directed ventrally and burring continues ventrally removing the lateral cortical wall of the vertebral pedicle. The burr is not directed toward the vertebral canal, but safely in the direction of bone to be removed (Figure 48-21). A sharp, properly sized burr will progress through cancellous bone quickly and safely. The dorsal extent of the hemilaminectomy of the two vertebrae is connected longitudinally across the articular facets (Figure 48-22). Since the facets are cortical bone, it is much more difficult to gauge the appropriate burr depth. That is why burring is begun at the center of a vertebra where outer cortex (white), cancellous bone (red), and inner cortex (white) can be more easily discerned. The surgeon can then extend the bone aperture at the correct depth across the articular facets.

Ventrally, bone is removed to the level of the ventral aspect of the vertebral canal. The bur is then directed from either direction toward the vertebral foramen. Removing bone from either side of the ventral aspect of the vertebral foramen is the

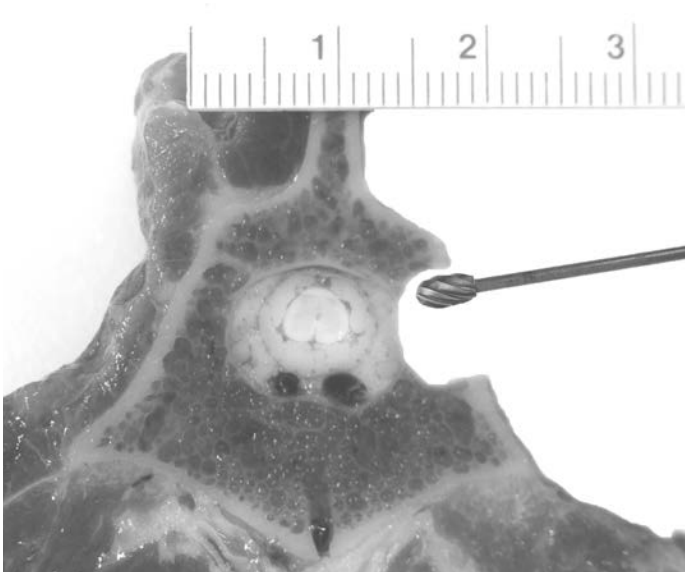

Figure 48-20. An approach with a larger burr that enters the vertebral canal directly will result in a small aperture, limiting exposure and the surgeon's ability to remove an offending mass without manipulation of the spinal cord.

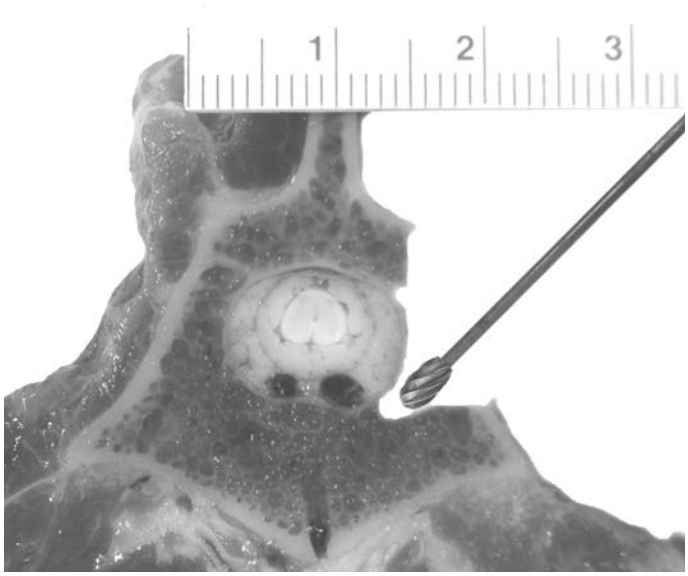

Figure 48-21. Burring is started at the level of the dorsal aspect of the vertebral canal, in the center of a vertebra. The bur will progress through the outer cortical bone (white in appearance), then through cancellous bone (red), then to inner cortical bone (white again). The outer cortical bone and cancellous bone is removed progressing ventrally.

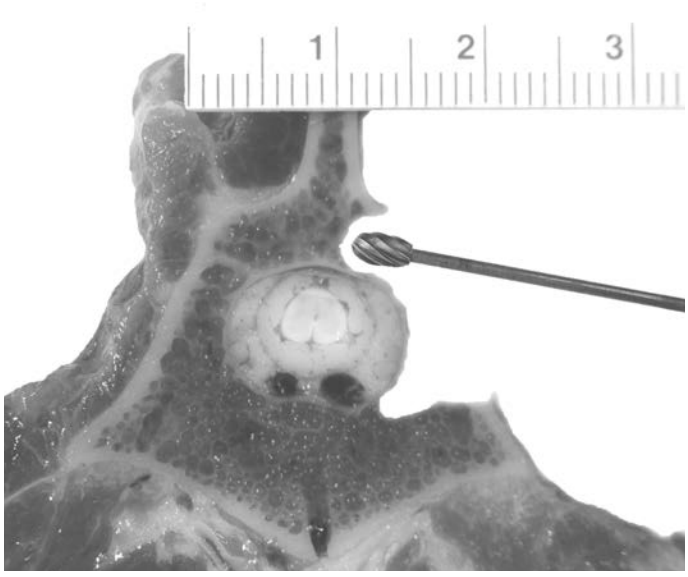

Figure 48-22. The hemilaminectomy can extend dorsally. The handle of the high speed drill is directed such that the surgeon is always pushing toward bone, not the vertebral canal, to prevent accidentally entering the vertebral canal.

most difficult aspect of this operation and should be performed most carefully as the arterial and venous supply to the vertebral canal, and nerves or nerve roots can be damaged. However, carefully preformed, the end result is an oval to almost rectangular aperture with dorsal and ventral extents at the levels of the vertebral canal. At this point a smaller bur is chosen to enter the vertebral canal. The smaller bur is then used to remove bone around the perimeter of the hemilaminectomy. The bur should not be directed straight toward the vertebral canal, but rather toward the perimeter of the bone window to prevent inadvertent penetration of the vertebral canal (Figure 48-23). Usually the side of the bur us used to remove bone from the vertebral canal and the bur can be subtly felt to "give way" when the inner cortical bone is removed. If skillfully and carefully performed, the inner cortical bone can be removed without breaching the inner periosteum of the vertebral canal. If the inner periosteum is kept in tact, the vertebral canal can be entered dorsally with a dental or other instrument. This periosteum can be retracted ventrally, exposing the vertebral canal and spinal cord and in addition avoiding and even occluding the ventral vertebral sinuses.

Once the laminectomy is complete, the offending mass can be seen and removed. It is important to relieve the mass without manipulation of the spinal cord. Rounded instruments are used rather than sharp to avoid lacerating the venous sinuses. The spinal cord should be completely decompressed. Hemorrhage should be controlled with collagen sponge or other techniques.

If there is a significant amount of disk material adhered to the dura mater, or in cases of Hanson Type II, it may be impossible to remove the disk material without manipulation of the spinal cord. In these cases the laminectomy is extended under the spinal canal leaving the dorsal annulus of the disk intact. A small bur removes disk and bone until a small cavity exists (Figure 48-24). This can extend well over 50% of the distance to the opposite side. The dorsal annulus and disk material can then be pushed down into this cavity thereby relieving spinal cord compression without manipulation of the spinal cord.

Closure

There is some controversy regarding placement of fat or other materials over the laminectomy site. Laminectomy membranes and resultant pain are not as frequent in veterinary medicine as in humans. If a hemilaminectomy is performed as described, the

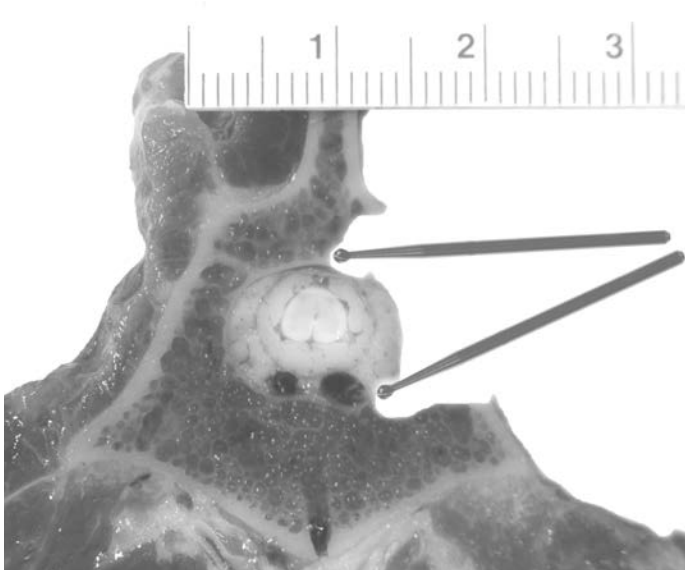

Figure 48-23. A smaller bur is used to enter the vertebral canal. The bur, again, is held so that the surgeon is not pushing toward the vertebral canal. The side of the bur is used to enter the vertebral canal, preferably without breaching the inner periosteum.

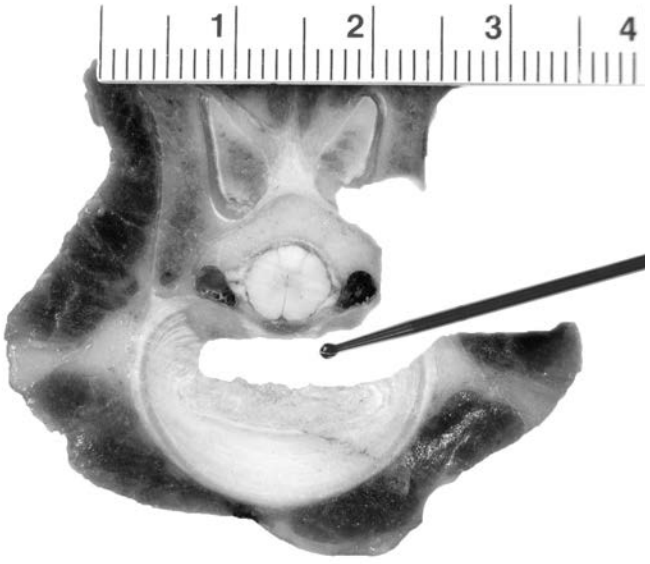

Figure 48-24. In some situations, such as adherent disk material or Hanson type II disks, the mass cannot be removed without manipulation of the dura, which must be avoided. In these cases the disk and vertebral end plates beneath the dorsal annulus are removed. The disk can then be pulled into the cavity that is formed, thereby decompressing the spinal cord.

resulting scar and fibrous tissue do not result in compression of the spinal cord or nerve roots. A small amount of fat placed in the laminectomy aperture will prevent some scar tissue from forming. Fat grafts are frequently used in veterinary surgery. However, the surgeon should use a small amount of fat as too much can result in spinal cord compression when the hypaxial musculature swells post operatively. The deep lumbar fascia is closed with a monofilament absorbable suture material in a simple continuous pattern. The subcutaneous tissues and skin are closed routinely.

Post operative Care

Steroids and antibiotics are not used post operatively. If the spinal cord is decompressed, there is no rational for continued administration. Complications associated with steroid use in neurosurgical patients are severe and well reported. Incisional infections are very rare. The main consideration for postoperative care is micturition. If the patient recovers with purposeful motor movement, they can usually urinate on their own. However, if the patient does not have purposeful motor movement, the bladder must be cared for until motor function returns, or the bladder converted into an automatic bladder that the owner can care for at home. An indwelling urinary catheter can be used for several days, but will often result in a urinary tract infection. In many cases the bladder can be expressed several times a day without catheterization. The bladder must never be allowed to overfill, because this results in stretching of the detrusor muscle and an atonic bladder. In male dogs it may be necessary to administer medications that relax the urethral spincters. The internal urethral spincter can be relaxed with phenoxybenzamine and the external urethral sphincter with Diazepam.

Those patients requiring several weeks to recover will require physical therapy. The goal of physical therapy is to frequently move the limbs in physiologic walking motions. Resolution of spinal cord swelling and remyelination of damaged axons will result in complete return of neurologic function if axons are intact. However, more severe spinal cord damage with axonal loss and gliosis will require establishment of new synaptic connections and central plastic reorganization. Physiologic motion enhances the speed and degree of these processes. Swimming is excellent if tolerated, and should be begun as soon after the sutures are moved as possible. The patient's limbs should be moved in walking motions for at least fifteen minutes three times a day. The patient should be encouraged to stand, support weight, and walk as much as possible.

Modified Dorsal Laminectomy

Eric J. Trotter

Introduction

A variety of surgical procedures have been described for decompression of the spinal cord in the thoracolumbar region of dogs. The procedures differ in the amount of bone removed, and thus, are referred to as hemilaminectomy, mini-hemilaminectomy, pediculotomy, pediculectomy, dorsal laminectomy, modified dorsal laminectomy, and laminectomy modifications, including laminotomies and laminoplasties. Each technique has its own indications, inherent advantages and disadvantages, and most, if performed properly, satisfy the two basic tenets of spinal cord surgery, *i.e.*, spinal cord decompression and mass removal. There is no one best technique for all patients.

Hemilaminectomy, mini-hemilaminectomy, and pediculectomy are particularly well-suited to the removal of extruded or protruded intervertebral disc material from the vertebral canal without fear of laminectomy membrane formation. Bone removal and resultant exposure of the vertebral canal and spinal cord are minimal in comparison to dorsal decompressive techniques. Vertebral column stability is less compromised with these procedures, even with concurrent prophylactic intervertebral disc fenestration than with dorsal laminectomy techniques which require bilateral exposure and partial facetectomies.

Objective comparison of the many decompressive techniques, at least in intervertebral disc disease, has been clouded by the many variables associated with spontaneous extrusion or protrusion of intervertebral discs in the thoracolumbar region. Personal preference and the individual surgeon's training have all too frequently determined the type of decompressive procedure utilized. Previously, severely-limited imaging modalities, *i.e.*, flat films and myelography, also made rational, logical selection of the most appropriate technique for the individual patient difficult, if not impossible. With the increased availability of CT and MRI, selection of the most appropriate decompressive technique based on the precise location of the extradural mass became far more objective, and allowed for minimally invasive surgical techniques. For these reasons, although performed for many years with excellent results at this hospital, dorsal or modified dorsal laminectomy are only infrequently performed for uncomplicated thoracolumbar intervertebral disc extrusion or protrusion in chondrodystrophoid or non-chondrodystrophoid dogs. However, in many cases, *i.e.*, vertebral column fractures, luxations, congenital vertebral malformations, synovial cysts, arachnoid cysts, vertebral or spinal cord neoplasms, or syrinxes, and in some cases with intervertebral disc disease, laminectomy will be the procedure of choice to allow for expansive spinal cord exposure, decompression, and mass removal when these other techniques would prove to be inadequate.

Surgical Technique for Modified Dorsal Laminectomy

Following confirmation of the neuroanatomic lesion by either myelography, CT, or MRI, the anesthetized patient is placed in sternal recumbency, without pressure on the abdomen, and prepared for aseptic surgery of the thoracolumbar spine. Prophylactic antibiotics (cefazolin, 22 mg/kg IV at time of surgery, then 22 mg/kg PO BID, G.C. Hanford Manufacturing Co., Syracuse, NY 13201) are administered intravenously at the time of surgical intervention, and may be continued in the early postoperative period. Corticosteroids (methylprednisolone sodium succinate, 30 mg/kg IV, Solu-Medrol, Pharmacia & Upjohn, Kalamazoo, MI 49001) may be administered at the time of surgery in patients who have not already been treated with steroids. Gastric protectants (Pepcid, Famotidine, 0.5-1mg/kg QD or BID, Bedford Laboratories, Bedford, OH 44146; and sucralfate, medium and large dogs 1 gm TID, toy dogs (< 7 kg) 0.5 gm TID, Major Pharmaceuticals, Livonia, MI 48150) are administered preoperatively when possible, and continued postoperatively.

The skin incision, centered over the area of involvement, is made slightly lateral to the dorsal midline. Length of this incision is determined by the specific pathology in the individual patient. Moistened laparotomy tapes or surgical paper towels are clipped to the reflected subcutaneous tissue and/or superficial fascia on each side of the incision to cover any exposed skin. The thoracolumbar fascia is incised bilaterally immediately lateral to the spinous processes. Periosteal elevators are utilized to lever or reflect the epaxial muscles bilaterally to a level just ventral to that of the accessory processes (Figure 48-25). Utilization of self-retaining retractors (Gelpis or Beckmans) allows for relatively atraumatic dissection under tension, which is most easily performed from caudal to cranial. Maceration of the epaxial musculature contributes to delayed wound healing, postoperative pain, and laminectomy membrane formation. Small branches of either the paired lumbar or intercostal arteries are cauterized by means of bipolar cautery as they are exposed both cranially and caudally to the cranial articular processes of each adjacent vertebra. Care must be exercised during both periosteal elevation and the cauterization of small bleeders around the articular processes to avoid exacerbation of spinal cord ischemia by interruption of the, at best, tenuous spinal cord blood supply through the varying intervertebral foramen (dorsal and ventral radicular branches).[1-3]

For laminectomy at the thoracolumbar junction, the 13th rib and first lumbar transverse process are readily identifiable landmarks to confirm the appropriate site for laminectomy. The 13th rib arcs dorsocaudally and is located far more superficially than the cranioventrally directed first lumbar transverse process. Particularly in obese patients, some surgeons prefer to place a sterile hypodermic needle into one of the dorsal spines during preoperative films to confirm anatomic location, especially in the mid lumbar spine, since localization by palpation of the dorsal spine of the seventh lumbar vertebra may be difficult. The spinous processes of the vertebrae cranial and caudal to the disc space (in a two level laminectomy) are removed by means of bone rongeurs (Figure 48-26). This is preferable to the utilization of a bone cutter which can result in excessive torque being applied to the vertebral column of small breed dogs.

By means of a high-speed air drill with a new 4 mm egg-shaped bur with notched flutes, the remainder of the dorsal spine is removed. Meticulous hemostasis, and irrigation with sterile saline or lactated Ringer's solution and fluid removal by suction maintains a clear field, removes the bone dust produced by the air drill, and dissipates the minimal amount of heat produced by a new bur. Old dull burs should not be used for this technique because they generate significant heat by sanding rather than cutting away the bone of the laminae. In cases of thoracolumbar disc disease, the laminectomy defect is centered over the area of involvement and most often extends cranially and caudally almost to the adjacent interarcuate ligament unless significant spinal cord compression and edema necessitate extension of the defect until normal amounts of epidural fat are visualized surrounding the spinal cord in the epidural space. Length of the defect in other cases is determined by the specific pathology encountered. Width of the defect is determined by the joint spaces between the cranial and caudal articular processes at the involved interspaces (Figure 48-26, arrow). Complete facetectomy at multiple locations has been shown experimentally to result in some vertebral column instability, although this has not been problematic in clinical cases other than vertebral

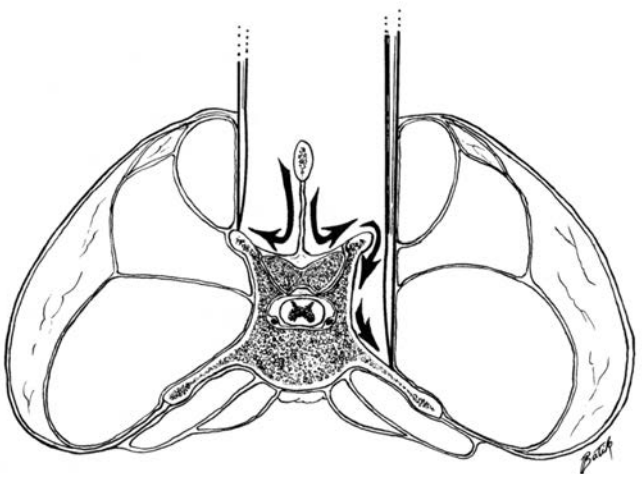

Figure 48-25. Periosteal elevation of the epaxial musculature for dorsal laminectomy. Arrows indicate the direction of force applied to the elevator for atraumatic periosteal elevation.

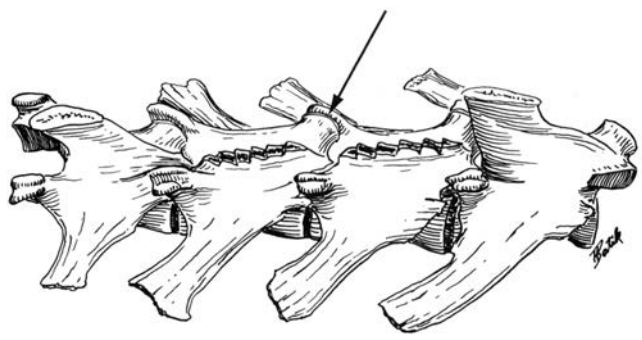

Figure 48-26. The arrow indicates the joint space between the cranial and caudal articular processes, which is used as a guideline for the lateral extent of the laminectomy.

column fractures/luxations in which this induced instability is compensated for by the vertebral column instrumentation which had been planned.

The bone structure and color are reliable indices of the depth of drilling: (1) outer cortical bone is dense and white; (2) middle cancellous bone is spongy and reddish-brown; (3) the inner cortical bone is dense, white, and very thin. Only cortical bone is present at the attachments of the interarcuate ligament. Once the limits of the laminectomy defect have been defined, drilling continues to completely remove the outer layer of cortical bone and then the middle layer of spongy cancellous bone (Figure 48-27). Hemorrhage from the cancellous bone is easily controlled with bone wax.

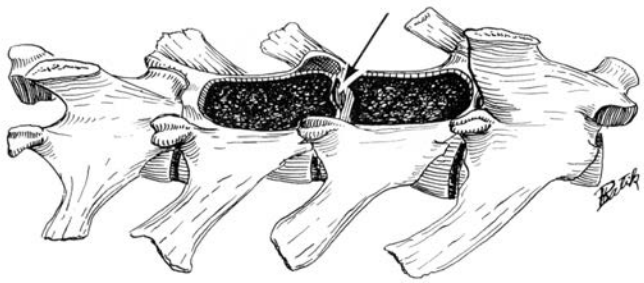

Figure 48-27. The outer cortical bone and most of the middle layer of cancellous bone, including that of the caudal articular processes, have been removed. The arrow indicates the dense cortical bone at the intervertebral space and the interarcuate ligament.

The surgeon must remember that he or she is removing the top of a horizontally-oriented cylinder while maintaining bone at the pedicles at a level dorsal to the dorsal tangent of the spinal cord. The inner layers of the laminar-pedicle junctions are excavated bilaterally to provide complete exposure of the epidural space (Figure 48-28). When the thin layer of inner cortical bone begins to sag under the pressure of the drill, a 2.3 or 1.6 mm round carbide-tip bur is substituted for the large bur

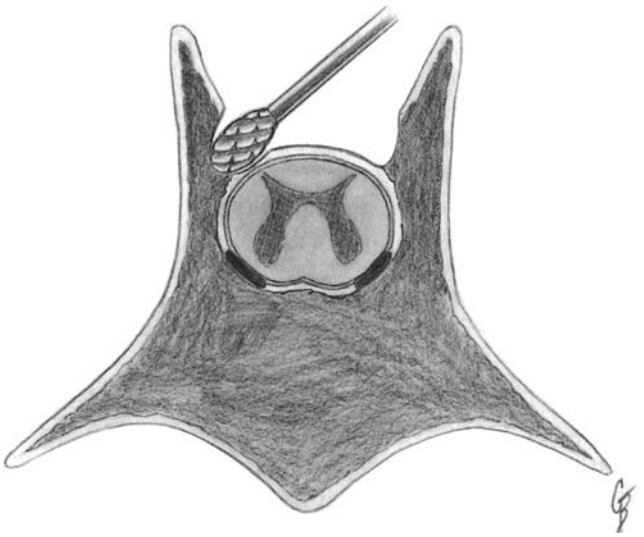

Figure 48-28. After excision of the middle layer of cancellous bone, excavation of the pedicles is begun with a 4-mm-diameter bur.

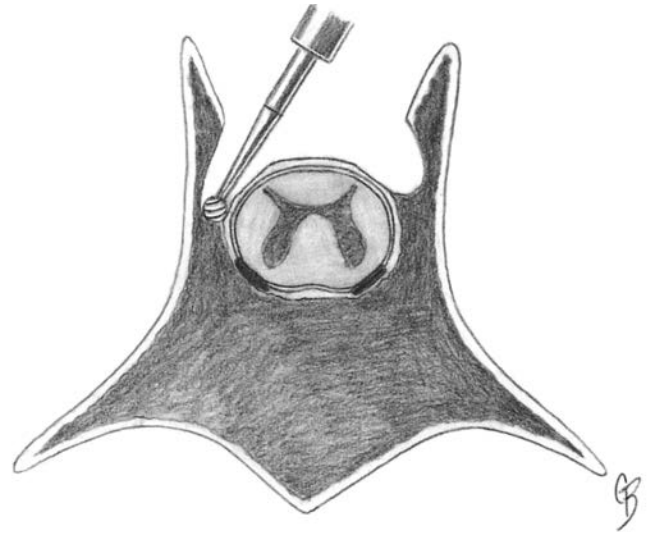

Figure 48-29. Further excavation of the middle layer of cancellous bone of the lateral laminae is performed with on of the small round burs.

(Figure 48-29). A thin plate of inner cortical bone remains in all areas of the defect to protect the spinal cord during the majority of the drilling, or "brushing away" of the bone. This thin plate of inner cortical bone is isolated by drilling around the periphery of the laminectomy defect with a small drill with approximately a 45 degree angle away from the spinal cord (Figure 48-30). The angled drilling into the pedicles avoids drilling directly over the spinal cord and results in smooth, deeply undercut edges of the laminectomy with excellent exposure of the full width of the vertebral canal. Some additional undercutting is necessary to remove portions of the cranial articular processes of the more caudal of the two vertebrae which are located somewhat in the frontal plane, deep to the caudal articular processes of the more cranial of the two vertebrae. Complete excision of the caudal articular processes and undercutting in this region results in impressive exposure of the full width of the spinal cord for resection of intra- or extramedullary mass lesions and sufficient access to the vertebral canal for the removal of extradural mass lesions, even those located ventral to the spinal cord. Excavation of the pedicles, *i.e.*, removal of the inner cortical and middle layers of cancellous bone of the pedicles, while preserving the outer layer of cortical bone of the pedicles, dramatically increases exposure without predisposing to the phenomenon of constrictive fibrosis (Figure 48-31).[4-7] Removal of extruded intervertebral disc material, even if located bilaterally or ventral to the spinal cord is uncomplicated, in spite of the minimal epidural space of chondrodystrophoid dogs with relative vertebral

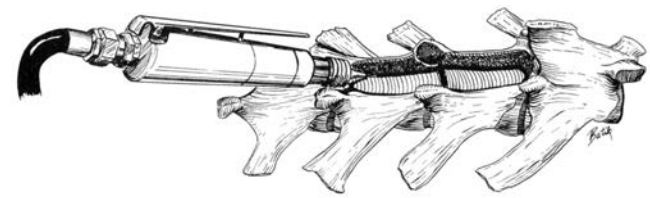

Figure 48-30. Angled drilling into the cancellous bone around the periphery of the thin plate of inner cortical bone avoids drilling directly over the spinal cord and results in smooth, deeply undercut edges. This technique increases both exposure and decompression and facilitates removal of extradural mass lesions.

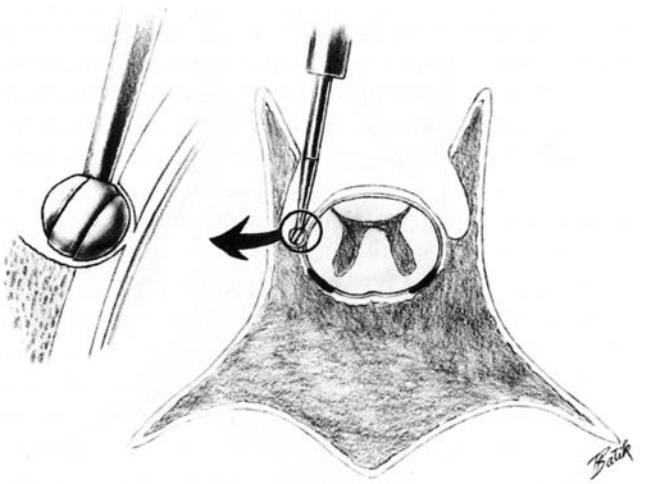

Figure 48-31. The inner cortical bone shelf is cut around the periphery with the smallest bur.

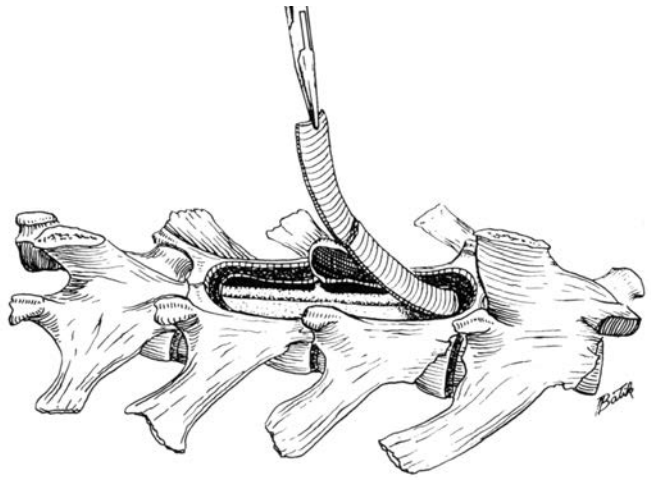

Figure 48-32. The thin shelf of inner cortical bone is grasped with a hemostat and is removed as a unit.

canal stenosis. Minimal spinal cord manipulation is necessary. The spinal cord may be gently retracted by means of a small suture placed in a relatively avascular area of the dura mater. Rhizotomy in appropriate locations releases the dural tube for additional retraction or "rolling". Fine-tipped suction and various ophthalmic and dental instruments have proven useful for the removal of mass lesions from the vertebral canal. Bleeding from the internal vertebral venous plexus is controlled by means of bipolar cautery, macerated muscle, or absorbable gelatin sponge (Gelfoam, Upjohn Co., Kalamazoo, MI 49008). It is imperative that the bone of the remaining pedicles on both sides of the defect be maintained at a level dorsal to the dorsal tangent of the spinal cord to prevent the occurrence of secondary spinal cord flattening during healing of the laminectomy defect (laminectomy membrane formation, epidural scar, laminectomy scar, postlaminectomy stenosis, or constrictive fibrosis). For the same reason, a hemilaminectomy, with complete excision of the facets, or articular processes, should never be converted to a dorsal laminectomy, nor should facet or laminar fragments be indiscriminately removed in vertebral column fractures unless appropriate (and as yet somewhat unproven) measures are taken to prevent secondary spinal cord compression due to formation of the laminectomy membrane. When the thin remaining layer of inner cortical bone has been completely isolated (See Figure 48-32), it is grasped with a hemostat and "peeled off", or removed as a complete boney shelf with the periosteum lining the vertebral canal. Because laminectomy scar formation and secondary spinal cord compression increase with an increase in not only defect width, but length, the length of the defect should be limited to only what is necessary to decompress the involved segments of spinal cord or resect the offending mass lesion.

Durotomy may be performed for the removal of intradural mass lesions or may be utilized to establish a more definitive prognosis in paraplegic, analgesic cases in which acute focal, segmental spinal cord necrosis, malacia, thrombosis, blanching, or chronic loss of cord substance with glial scarring is suspect. Dorsal midline myelotomy is only performed in paraplegic, analgesic patients in which the prognosis is in question. Continued leakage of cerebrospinal fluid has not been a problem with durotomies. A mild, transient neurologic deficit has been demonstrated in normal dogs following durotomy. The dura mater appears to heal rapidly by neomembrane formation.[5]

Durotomy is performed with either Potts-Smith 60 degree angled cardiovascular scissors or a bent disposable 20 to 25 gauge needle. The dura mater is usually incised on the dorsal midline for the full length of the laminectomy defect. Incision of the inelastic, and often opaque (loss of the normal translucent appearance) dural sheath and frequently the underlying pia mater may result in greater intramedullary decompression of the spinal cord and associated vasculature. Neither hypothermic or normothermic perfusion are utilized routinely.

Torn or devitalized epaxial musculature is excised prior to closure. This also appears to limit the infolding or collapse of the epaxial musculature into the laminectomy defect, a factor in the formation of laminectomy membrane. A section of absorbable gelatin sponge, creased on the midline to resemble a tent, and shaped to conform as closely as possible to the margins of the laminectomy defect is carefully placed in direct apposition with the remaining pedicles (marginal fitting). With this particular technique in the thoracolumbar region of dogs, the healing pattern following implantation of absorbable gelatin sponge is predictable and relatively innocuous.[5] Other implants such as absorbable gelatin film (Gelfilm, Upjohn Co., Kalamazoo, MI 49008), muscle, and free or pedicle fat grafts have met with variable and unsatisfactory or even disastrous results. Although highly successful in other locations, subcutaneous fat grafts in this location, with this laminectomy technique actually increase spinal cord compression postoperatively.[7,8] Cosmetically unacceptable scars, structural defects, or vertebral column instability have not been problems with this technique.

Postoperative Care

Postoperative analgesia, predominantly with opioids, is usually indicated for the first 12 to 24 hours. Corticosteroid therapy is no longer continued in the postoperative period due to the limited benefits confirmed by experimental studies and the possibility of gastrointestinal complications. Nonsteroidal anti-inflammatories are rarely used since most patients have been treated with corti-

costeroids either pre- or intraoperatively. Their concurrent or sequential use would increase the risks of catastrophic gastrointestinal bleeding or perforation. Postoperative therapy includes manual expression of the urinary bladder or urinary tract catheterization, tail walking, whirlpool hydrotherapy, exercise carts, and general supportive care. Patients are discharged from the hospital as soon as conscious control of micturition is regained. Early return to familiar surroundings seems to promote enthusiasm on the part of the patient and owner, more rapid return of urinary continence, and an early return to full function.

Surgical Treatment of Cauda Equina Syndrome

Guy B. Tarvin and Timothy M. Lenehan

Introduction

A definitive preoperative diagnosis of cauda equina syndrome can be difficult to make. Not all practitioners have access to magnetic resonance imaging, the best modality for defining problems in the lumbosacral region. Access to computed tomography (CT) is equally limited, and often myelography or epidurography is required in concert with a CT scan to demonstrate soft tissue lesions such as nerve root entrapment. Epidurography alone is difficult both to perform and to interpret if conducted only on occasion. Electrodiagnostic testing and electromyography require special equipment and expertise to perform and to evaluate, and not all dogs with cauda equina syndrome have electrophysiologically demonstrable signs of lower motor neuron disease. Myelography is incapable of defining many pathologic processes involving the nerve roots of the cauda equina in the lumbosacral area of the dog. Stressed radiographs (hyperextension-flexion) of the spine demonstrate hypermobility, but they are not necessarily diagnostic of neurologic involvement even when used in conjunction with myelography. In fact, many animals affected by cauda equina syndrome have normal spinal radiographs. Hence, a veterinarian must use clinical acumen along with one or more of these diagnostic modalities to establish a diagnosis of cauda equine syndrome before recommending surgical intervention. In many cases only an exploratory laminectomy can provide both a diagnosis of and cure for cauda equina syndrome. The purpose of the surgery is to decompress the conus medullaris or those nerve roots of the cauda equina that are causing clinical symptoms. The surgeon should be vigilant to remove only as much bone as needed to accomplish this task, especially when dealing with cauda equina syndrome secondary to lumbosacral instability. The removal of portions of discs or facets progressively destabilizes the spine and may predispose the patient to adverse postoperative sequelae.

Surgical Procedure

The animal is placed in ventral recumbancy with the stifles and hips flexed and the hocks extended. If extensive foraminal exploration is anticipated, then placement of the patient's hind legs in the forward extended position combined with padding

placed under the belly in the lumbosacral region will accentuate lumbosacral kyphosis to more widely open the foramina at the lumbosacral junction.

A dorsal midline approach to the lumbosacral spine is performed. Several large Gelpi or hinged Weitlaner retractors facilitate muscle retraction (Figure 48-33). Suction is essential for good visualization, and most typically a No. 10 or 12 Frazier suction tip is adequate. Electrocautery, surgical sponge (Gelfoam), bone wax and small pieces of epaxial muscle placed on small bleeders are essential for adequate hemostasis in large breed dogs.

A modified dorsal laminectomy is performed over the affected interspaces (generally L7 to S1-2), initially leaving the caudal pedicles of L7 intact. If the compression is due to either midline disc bulging or hypertrophy of the interarcuate ligament, then this surgical approach alone should result in decompression. If the surgeon is unsure of complete decompression, then extradural fat and fibrous connective tissue are removed from the spinal canal as needed to facilitate visualization of the various nerve roots and ganglia of the cauda equina. A nerve hook helps to isolate and trace individual nerves as they enter their respective foramina to exit the spinal canal. Unilateral or bilateral pediculectomy is performed as needed to gain further exposure and decompression of the involved nerves. In some cases, foraminotomy without pediculectomy is possible and preferred. Tethered nerve roots are freed from any fibrous connective tissue constraints. In the case of a Hansen type I disc rupture, the ruptured nuclear material is removed (generally by suction). If a Hansen type II disc rupture is present, the location of the bulging annulus in relation to a compressed nerve determines the surgical procedure. Disc material that is entrapping a nerve root is either cut away or, alternatively, is left alone and the nerve decompressed by facetectomy, pediculectomy, or foraminotomy.

Once decompression has been achieved and hemostasis is complete, an autologous free fat graft is harvested from the subcutaneous region and placed over the laminectomy site to minimize cicatrix formation. Muscle, fascia and subcutaneous layers are closed, respectively, with synthetic absorbable suture material. Inaccurate closure of the muscle results in a palpable midline defect, whereas inattention to subcutaneous closure results in seroma formation. The application of a compression bandage is optimal, yet difficult to apply and maintain, given the location of the operative site, especially in male dogs.

Postoperative Care

Postoperative recommendations include strict confinement to house and leash walking activity only for 8 weeks' time, before a return to moderate function. This confinement allows time for the musculature to adhere to the lamina and for the spine to adjust to the added instability imposed by the surgical procedure.

In most cases, a modified dorsal laminectomy is sufficient to gain good visualization of the problem and to effect decompression. Removal of the dorsal spinous processes and dorsal laminectomy minimally destabilize the lumbosacral motion unit in four point flexion/extension tests in vitro. Hence, one may expect resolution of nerve root symptoms without significant subsequent clinical deterioration if successful mechanical decompression has been achieved (and if mechanical compression alone was the source of the pain). Osteoarthritic symptoms may be expected to persist however (i.e. morning and exercise induced stiffness with occasional episodes of low back pain lasting several days). The addition of discectomy, foraminotomy or facetectomy further destabilizes the spine. Clinically significant sequelae such as facet fracture, lumbosacral subluxation, cicatrix formation and ongoing clinical symptomatology can result. It is therefore important to use a minimalistic approach in one's decompression technique.

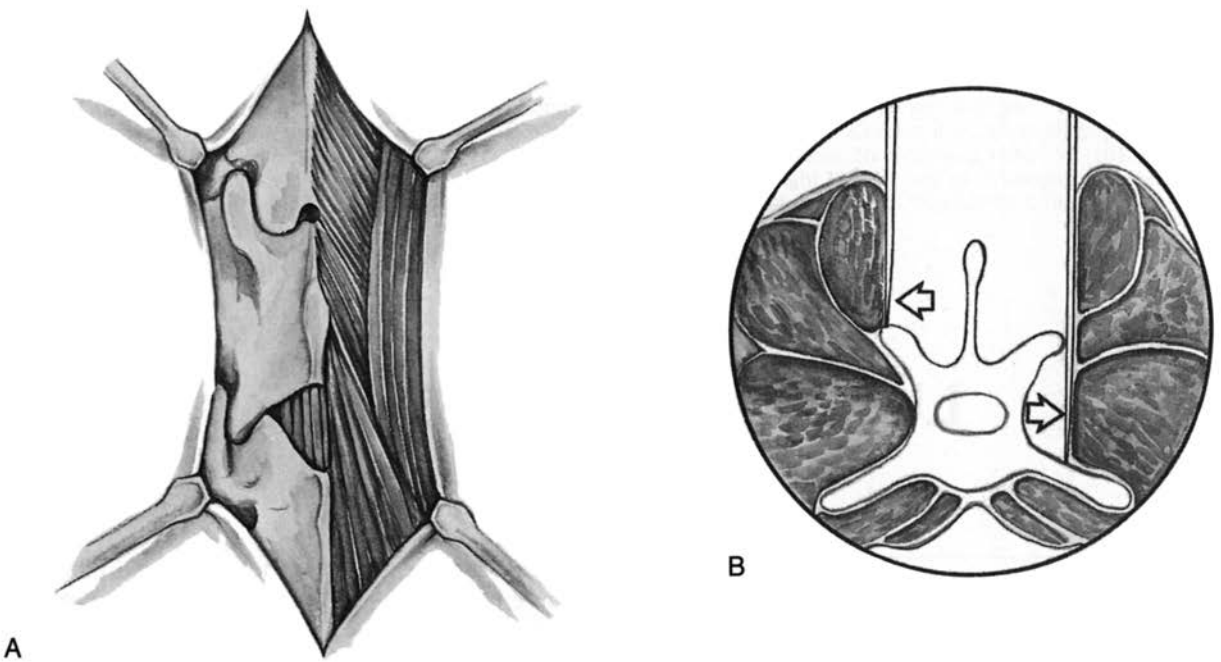

Figure 48-33. Muscle elevation for dorsal laminectomy.

Decompressive laminectomy in a hypermobile lumbosacral segment should be undertaken with caution, particularly if discospondylitis is suspected. In such instances, laminectomy only further destabilizes an already unstable situation and may have orthopedic and neurological sequelae, if the infection is not brought under control quickly.

The literature would indicate that on average 85% of the animals operated on demonstrate initial improvement. However, subsequent deterioration occurs in up to 1/3 of patients resulting in an overall longterm success rate of around 55%. Approximately 25% of cases are improved by surgery but not symptom free, and there is on average a 25% failure rate. Persistent postoperative clinical symptoms most probably relate to ongoing lumbosacral instability, attendant discogenic pain, epidural scarring, arachnoiditis, facet arthritis or fracture, insufficient decompression at the operative site, alternate segment disease, iatrogenic conus or nerve root trauma, infection, etc. Preoperative conditions predisposing to surgical failure seem to include advanced age, chronicity of symptoms, concurrent hind limb problems, and urinary or fecal incontinence. Favorable preoperative conditions include young age and mild clinical symptoms.

If there is a recurrence of symptoms in the early postoperative phase, a second exploratory surgery is justified in selected cases.

Bony or soft tissue disease at any of the L5-6 to S1-2-3 vertebral interspaces potentially can result in clinical signs of cauda equina syndrome (sciatic or sacral nerve root involvement) (Figure 48-34). The clinician must attempt to localize the lesion to a specific area of the spinal cord or nerve roots preoperatively. A "routine" dorsal laminectomy at the L7-S1 interspace may miss the underlying disorder entirely, if the signs of the cauda equina syndrome are, for example, due to an intramedullary tumor affecting the L6 segment of the spinal cord.

Surgical Treatment of Fractures, Luxations and Subluxations of the Thoracolumbar and Sacral Spine

Karen L. Kline and Kenneth A. Bruecker

Introduction

The thoracolumbar and lumbar spine are relatively common locations for spinal fractures, luxations and subluxations in the dog and cat. As previously mentioned, it appears that the higher incidence of fracture/luxations at certain sites along the vertebral canal may not correlate to differences in muscular or ligamentous attachments, but rather to areas of the vertebral column with a static/kinetic relationship (ie. thoracolumbar and lumbosacral junction).[1,2,3,4] As mentioned also in the previous chapter on cervical spine injury, the history, physical and neurologic examinations are crucial to the determination of prognosis and surgical outcome.

Technique Selection

There are numerous techniques that have been developed to stabilize thoracolumbar and lumbar spinal fractures, luxations and subluxations in dogs and cats.[5-19] As mentioned previously, the technique chosen is dictated by the location of the fracture, size, age, and disposition of the patient, equipment available and experience of the surgeon.

Surgical Techniques

Dorsal spinous process plating requires exposure of the dorsal spinous processes and articular facets.[5] The supraspinous and interspinous ligaments should be preserved if possible. A minimum of three spinous processes on each side of the fracture/luxation should be exposed. Metal or plastic plates are available for dorsal spinous process plating. When using plastic plates, a plate is used on each side of the exposed dorsal spinous processes (2 plates total)[6,8] (Figure 48-35). The roughened side of the plate is placed against the dorsal spinous processes. The plates are attached with appropriate size nuts and bolts placed between the dorsal spinous processes. It is important to keep the plates as close to the base of the dorsal spinous processes as possible. Grooves can be created in the lamina at the base of the spine using a high speed bone burr or rongeurs to help keep the plates low on the spine. This will allow maximal purchase of the spinal plates to the dorsal spinous processes. Metal plates are used in a similar fashion however the nuts and bolts are placed through the dorsal spinous processes (Figure 48-36).

The advantage of dorsal spinous process plating is preservation of the inherent stability provided by the articular facets, supraspinous and interspinous ligament. The major limiting factors of dorsal spinous process plating are the age and size of the patient. The dorsal spinous processes must be large enough and the bone compact enough to support the stresses that are encountered by an unstable spine. This technique is commonly used in combination with other stabilization techniques (ie. pins and polymethyl methacrylate, vertebral body plating). The most common postoperative complications are fracture of the spinous processes and plate slippage.

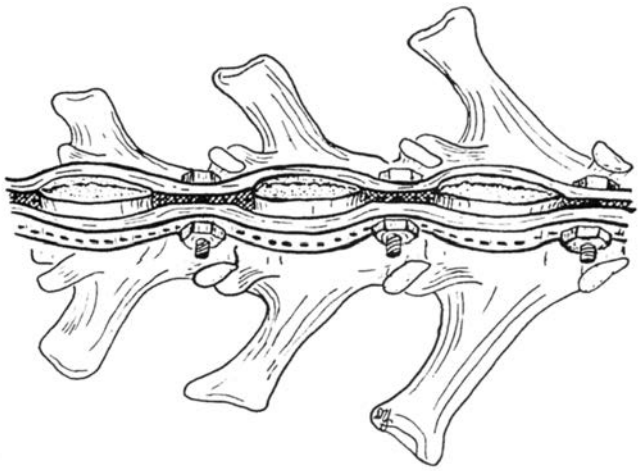

Figure 48-35. Dorsal spinal plating using plastic plates. (From Lumb WV and Brasmer TH. Improved spinal plates and hypothermia as adjuncts to spinal surgery. J Am Vet Med Assoc 1970;157:338-342.)

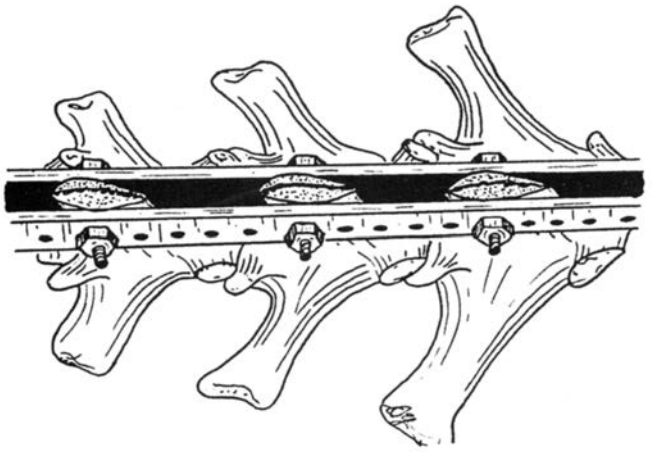

Figure 48-36. Dorsal spinal plating using metal plates. (From Lumb WV and Brasmer TH. Improved spinal plates and hypothermia as adjuncts to spinal surgery. J Am Vet Med Assoc 1970;157: 338-342.)

Spinal stapling also requires exposure of the dorsal spinous processes and facet joints. An intramedullary pin is placed through a dorsal spinous process, bent 90 degrees, laid along the lamina between the base of the spinous processes and articular processes, and secured to the base of the dorsal spinous processes with orthopedic wire (Figure 48-37). Added security can be accomplished by wiring the pin around the base of the transverse processes in the lumbar spine or around the rib heads in the thoracic spine (Figure 48-38) or by incorporating multiple pins and wires in a modified segmental spinal instrumentation technique (Figure 48-39).[9] At least two interspaces on each side of the fracture/luxation should be included in the repair.

Vertebral body plating (dorsal body plating) requires dorsolateral exposure of the articular facet, vertebral body and transverse process of the lumbar vertebrae or the articular facet, vertebral body and rib head of the thoracic vertebrae[10] (Figure 48-40). Care should be taken to protect the spinal nerve roots encountered cranial and caudal to the fracture/luxation. The spinal nerve and vessels at the involved space must be severed. The proper length and size plate is selected and placed on the dorsolateral aspect of the vertebral bodies. There should be at least four cortices engaged cranial and caudal to the involved fracture/luxation. Use of locking plates and screws may permit monocortical screw placement. If a luxation, subluxation or fracture close to the interspace exists, stabilization of the two adjacent vertebrae is adequate, however if a mid body fracture exists, three vertebral bodies should be spanned. The holes are drilled and screws are placed in a ventral and medial direction, being careful to avoid entering the spinal canal dorsally or the abdominal cavity ventrally. Placement of the plate on the thoracic vertebrae is more difficult due to the presence of rib heads. The rib heads must be removed and the transverse process contoured so the plate lies flat against the vertebral body. It is recommended that an anatomic specimen be available for visualization during placement of plates and screws. The need for rhizotomy precludes the use of vertebral body plating caudal to the fourth lumbar vertebra.[10,a,b]

Figure 48-38. Added stability can be achieved to the spinal stapling if rib heads and/or transverse processes are incorporated into the repair (From Helphrey M and Seim HB. Spinal trauma in Bojrab MJ (ed): Current Techniques in Small Animal Surgery. 3rd edition, Lea and Febiger, Philadelphia, 1990.)

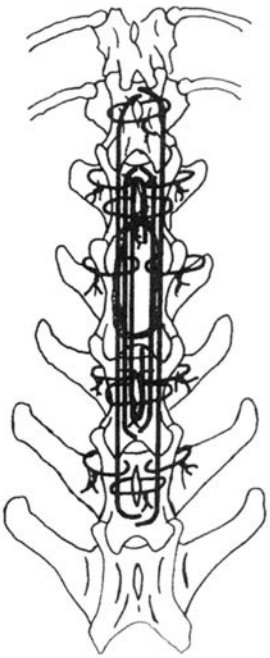

Figure 48-39. Modified segmental spinal instrumentation using multiple Steinmann pins and orthopedic wire. (From McNaulty JF, Lenehan TM, Maletz LM. Modified segmental spinal instrumentation in repair of spinal fractures and luxations in dogs. Vet Surgery 1986;15:143-149.)

Stabilization techniques utilizing pins (or screws) and polymethyl methacrylate require exposure of the dorsal spinous processes, articular facets and transverse processes bilaterally.[11,12] A minimum of two appropriate sized endthreaded, knurled acrylic pins are placed into the vertebral bodies on each side of the fracture/luxation. In the thoracic vertebrae, the pins are inserted into the pedicle and driven into the vertebral bodies, using the tubercle of the ribs and the base of the accessory processes as landmarks. In the lumbar vertebrae, pins are inserted directly into the vertebral bodies using the accessory processes and transverse processes as landmarks. Because pin placement is critical and landmarks vary considerably, depending on the level of the spine, a skeleton should be available for reference. The pins are directed cranioventral and from lateral to medial in the vertebral body cranial to the fracture/luxation, and caudoventral and from lateral to medial in the vertebral body caudal to the fracture/luxation. The Steinmann pins are power driven so they exit 2 to 3 mm from the ventral aspect of the vertebral body and are cut leaving 1.5 to 2 cm exposed dorsally. The polymethyl methacrylate forms around the knurled shaft of the pin and helps prevent pin migration. The surgical field is lavaged and dried in preparation for application of polymethyl methacrylate. If a laminectomy is not performed, polymethyl methacrylate is simply applied as a spherical mass, incorporating the Acrylic pins as well as the articular facets and adjacent dorsal spinous processes (Figure 48-41A and B). If a laminectomy is performed, the exposed spinal cord is covered with an autogenous fat graft and the polymethyl methacrylate is molded into the shape of a doughnut (Figure 48-42). Care is taken not to allow the polymethyl methacrylate to contact the spinal cord. The polymethyl methacrylate is lavaged with cool saline to dissipate the heat of polymerization. Portions of the epaxial muscles adjacent to the polymethyl methacrylate may

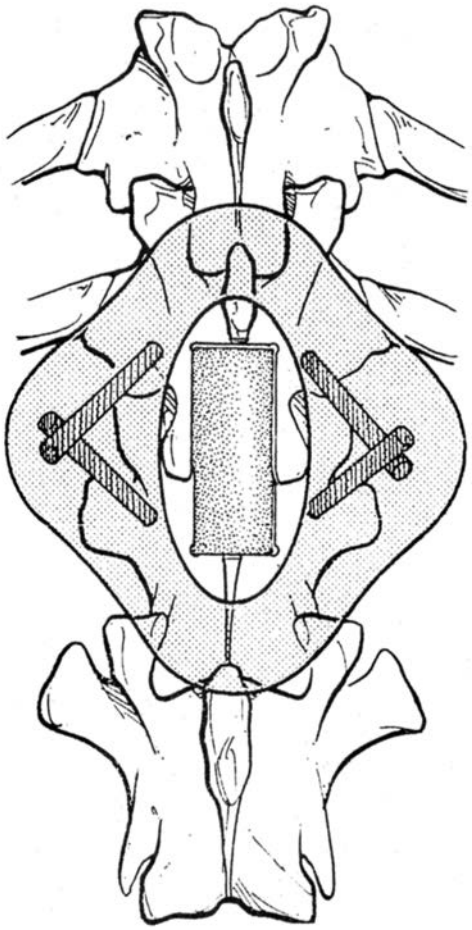

Figure 48-42. Dorsal placement of Steinmann pins and polymethyl methacrylate to stabilize lumbar fracture/luxations following laminectomy. Note that the polymethyl methacrylate is not placed over the laminectomy site (From Blass CE and Seim HB. Spinal fixation in dogs using steinmann pins and methyl methacrylate. Vet Surgery, 1984;13:203-210.)

have to be excised to facilitate closure. Rarely, relief incisions in the lumbodorsal fascia lateral to the polymethyl methacrylate are necessary to allow closure of the primary incision.[11,12]

The major disadvantage of this technique is the exposure necessary for pin placement, however, in a series of dogs treated with this technique, there were no failures associated with stress fatigue.[11] The technique is relatively straightforward, requires minimal special equipment, though a thorough knowledge of anatomy and constant reference to an appropriate anatomic specimen are recommended.

In some instances (generally T-L fractures or luxations in large breed dogs with hyperactive personalities), a combination of the above described techniques should be considered. Combinations such as pins and polymethyl methacrylate with dorsal spinous process plating, cross pins with dorsal spinous process plating, or body plating with dorsal spinous process plating have proven successful.[a]

[a]Lubra¨ plate, Lubra Co, 1905 Mohawk, Fort Collins, CO 80521

Fractures of L6, L7 and S1

Fractures and luxations of the caudal lumbar and sacral vertebrae are relatively common due to the static-kinetic relationship of the sacral and lumbar segments, respectively. Neurologic signs occurring secondary to trauma of the cauda equina, result in varying degrees of femoral, sciatic, and sacral nerve dysfunction. Because the spinal cord ends cranial to L7, patients with 60 to 70% displacement of the spinal canal may still have a favorable prognosis.[1]

Due to the increased shearing forces present in the lumbosacral region, caudal lumbar and lumbosacral fracture/luxations are difficult to stabilize. Techniques used to successfully treat L7-S1 fracture/luxations include transilial pinning, transilial pinning with plastic plate support, pins and polymethyl methacrylate, transilial pinning with external skeletal fixation, and spinal stapling.[6,9,13,14,15,16,17]

Surgical Techniques

In cases of L7-S1 luxations or subluxations, manipulation of L7-S1 during reduction involves grasping towels clamps or bone forceps placed on the wings of the ilium and pulling caudally and slightly dorsal. A non-sterile assistant can place counter traction on the head or front legs and this can help to lever the sacrum against the lamina of L7 while pressing ventrally on L6. Also, a small Hohmann retractor can be used to aid reduction of an L7 fracture or luxation by hooking the jaws of the forceps under the cranial lamina of the sacrum and lower the jaws against the caudal lamina of L7. Transilial pinning requires exposure of the dorsal L7-S1 region.[17] The caudal segment is most often displaced ventrally and cranially. Bone forceps are placed on each ilial wing to help elevate the ilium and sacrum dorsally to align the articular processes of L7 with the cranial articular surface of the sacrum. An appropriate sized trocar tip pin (1/8" or smaller) is driven through the wing of the ilium, across the laminae of L7 and through the opposite wing of the ilium (Figure 48-43). The most common problem associated with this technique is migration of the Steinmann pin. A more stable technique is generally recommended. To help prevent migration of the Steinman pins, bending the ends of each pin at a 90 degree angle can be done, as well as connecting the pins on each side with a double Kirschner clamp (see below) or notching the pins' ends with a pin cutter and incorporating them with bone cement.

The use of plastic dorsal spinous process plates and transilial pins has been reported[6,13] This requires a similar approach and reduction as previously described. Plastic dorsal spinous process plates are placed on each side of the three dorsal spinous processes cranial to the fracture/luxation and secured with nuts and bolts as previously described for plastic dorsal spinous process plating. The plastic plates extend caudad to S2-3. A 3/32" or 1/8" trocar tip pin is driven through one ilial wing, through the plastic plate at the level of L7-S1, and through the opposite ilial wing. A second pin is placed caudal to the first pin. The ends of the pins are bent craniad at a 90° angle and cut to leave 5 mm protruding (Figure 48-44). Postsurgical complications include fracture of the dorsal spinous processes or migration of the transilial pins. Pin migration may be decreased by application of polymethyl methacrylate to notched pins. Transilial pinning and external skeletal fixation with a Kirschner-Ehmer[c] apparatus has been described.[15,16] In this technique the transilial pins are placed percutaneously. In addition, one pin is inserted percutaneously through the vertebral body cranial to the fracture/luxation. Kirschner clamps attach the pins to a connecting bar on each side of the spine (Figure 48-45).

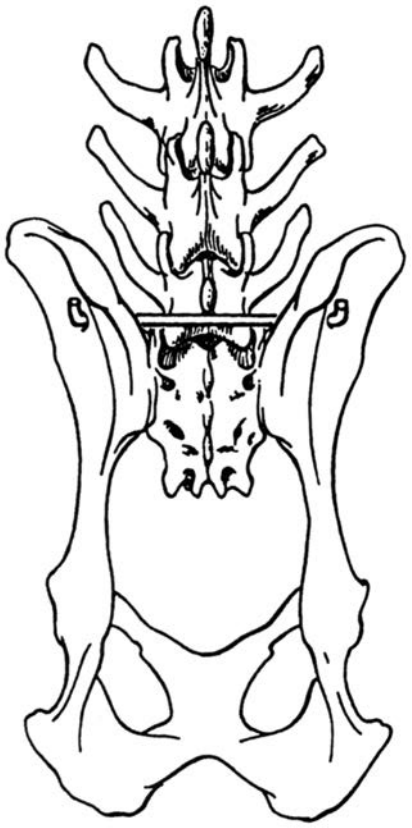

Figure 48-43. Transilial pin used to stabilize a fracture of the body of L7 or lumbosacral luxation. (From Bruecker KA, Seim HB: Spinal Fractures and Luxations in Slatter DH (ed): Textbook of Small Animal Surgery, 2nd ed, WB Saunders Co., Philadelphia 1993)

Pins and polymethyl methacrylate can also be utilized to stabilize lumbosacral fracture/luxations. The approach and reduction is as previously described. Two pins are placed in the vertebral body cranial to the fracture/luxation and two pins are placed in the wings of the ilium. The pins are incorporated with polymethyl methacrylate as previously described. The disadvantage of this technique is the large amount of polymethyl methacrylate needed for adequate stabilization, making closure difficult. Modified segmental spinal instrumentation has been used successfully to stabilize lumbosacral fractures. Pins are prebent 90°, placed through holes drilled in the wings of the ilium, laid alongside the dorsal spinous processes of at least two vertebra cranial to the fracture/luxation, and wired in place to the adjacent articular facets, dorsal spinous processes and lamina (Figure 48-46). Combinations of the above techniques may be utilized in large breed dogs with hyperactive personalities.

Combined Kirschner-Ehmer device and dorsal spinal plate fixation technique for caudal lumbar vertebral fractures in dogs. J Am Vet Med Assoc 1989;195:335-339.)

Sacral and Sacrococcygeal Fractures

Special attention to the S2-S3 dermatomes and evaluation of bowel and bladder function should be considered when performing a neurologic examination on patients with sacral and sacrococcygeal fracture/luxations. Fracture of the sacral wings generally occurs through the sacral foramina, damaging the S1, S2 and S3 nerve roots. Sacroiliac luxation however, rarely effects

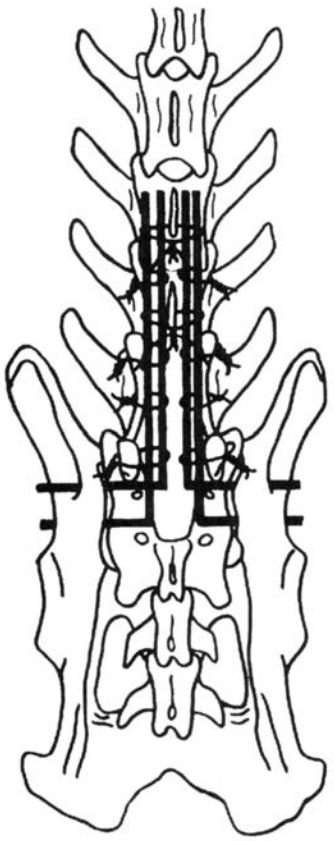

Figure 48-46. The use of modified segmental spinal instrumentation for the repair of lumbosacral and caudal lumbar fracture/luxation. (From McNaulty JF, Lenehan TM, Maletz LM. Modified segmental spinal instrumentation in repair of spinal fractures and luxations in dogs. Vet Surgery 1986;15:143-149.)

the nerve roots. A dorsal approach to the sacroiliac junction can be utilized to expose fractures of the sacral wing. Careful periosteal elevation of the paraspinal musculature allows visualization of the fracture fragments. Once reduced, the fracture can be stabilized with a lag screw inserted through the ilium and sacral fragment and into the sacral body.[18] A parallel trocar tip pin or wire may be inserted to provide rotational stability (Figure 48-47). If the neurologic examination reveals severe nerve root damage (shearing of the S1-S3 nerve roots), laminectomy and exploration of the cauda equina should be considered. Patients sustaining sacral or sacrococcygeal fracture/luxation may present with an anesthetic tail. If the tail remains anesthetic at 2 to 3 weeks post trauma, an amputation may be necessary to eliminate associated fecal matting, urine scalding (cats), and self-mutilation.[14] Traumatic injury of the sacrococcygeal area frequently occurs in cats.[4,19] Avulsion of the nerve roots of the cauda equina is a frequent sequela to injuries causing sacrococcygeal fracture/luxations. The prognosis is good for return of normal urinary function in cats that have anal tone and perineal sensation at the time of initial examination.[19] Cats that are unable to urinate normally within 4 to 6 weeks after the injury are not expected to recover normal urination habits.[19]

Coccygeal fractures

Coccygeal fractures may result in various neurologic deficits to

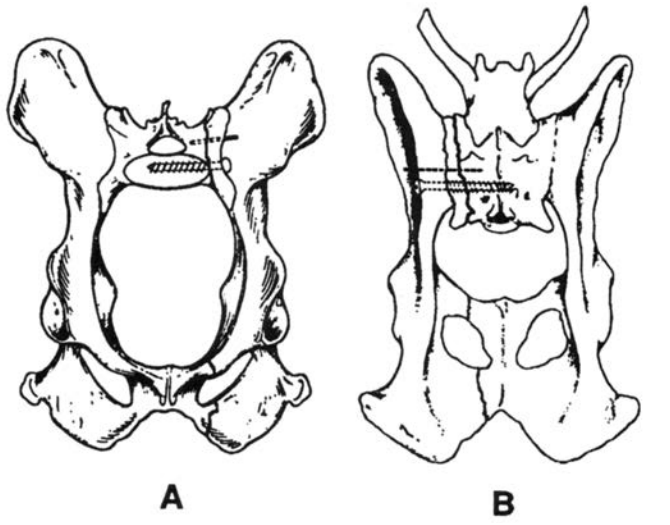

Figure 48-47. Stabilization of sacral fracture using lag screw and Kirschner wire; cranial **A.** and **B.** dorsal views. (From Bruecker KA, Seim HB. Spinal Fractures and Luxations in Slatter DH (ed): Textbook of Small Animal Surgery, 2nd ed., WB Saunders Co., 1993)

the tail. Rarely should they be treated surgically. If anesthesia of the tail persists, amputation may be the only feasible alternative.

New Horizons

One new spinal fixation technique has been described in the literature and involves the use of closed fluoroscopic-assisted spinal arch external skeletal fixation (ESF) for the stabilization of traumatic vertebral column injuries in 5 dogs. In this study, the fixator configuration consisted of pins placed bilaterally in 2 contiguous vertebral bodies cranial and caudal to the fracture. The protruding portion of the pins were incorporated into an external connecting system (IMEX Veterinary Inc., Longview Texas) for spinal stabilization. Results of this study were initially encouraging and this device may prove to be useful in the future.[20,d]

Post-operative Management

Post-operative management of spinal fracture patients is generally divided into ambulatory or non-ambulatory convalescence. Patients with an ambulatory status postoperatively are generally managed in the following manner: cage confinement, brief exercise 2 to 3 times a day for 2 to 3 weeks, serial neurologic and radiographic examinations and home on restricted exercise and/or passive range of motion exercises until radiographic evidence of healing is present. Non-ambulatory patients are managed in the following manner: elevated padded cage rack or waterbed, turned every 2 to 4 hours, bladder expressions 4 to 5 times a day or intermittent sterile catheterization in the male patient 2 to 3 times daily, passive range of motion exercises 3 to 4 times a day, electrical stimulation (if available), serial neurologic and radiographic evaluations and frequent hydrotherapy until return to an ambulatory status is achieved. Complications as described for the recumbent cervical injury patient have been described and apply to these patients as well. The use of back braces or splints is somewhat controversial. If the brace is comfortable, light weight and tolerated by the patient they are helpful. However, most braces are heavy, nonconforming, result in pressure sores and are not well tolerated by the patient.[3] Heavy reliance on a back brace, especially in large breed, hyperactive dogs should be avoided unless surgical intervention is not an option.

Fracture Fixation Techniques and Bone Grafting

Chapter 49

Fixation with Pins and Wires

Application of Cerclage and Hemi-cerclage Wires

Sharon C. Kerwin

Definition and Indications

Cerclage refers to a wire used to encircle a bone. Cerclage wire typically is used to provide interfragmentary compression in a manner similar to that of interfragmentary screws, and is useful in situations where space is limited and screw application would be difficult, or when screws of the correct type or size are not available. Properly applied cerclage wires have been shown not to interfere with the blood supply to bone,[1,2] and may be used in the immature as well as the mature animal.[3,4] Types of cerclage wire application include full cerclage, where the wire completely encircles a complete cylinder of bone, and hemicerclage, where wire is passed through a hole or holes drilled through bone.

For the vast majority of fractures, cerclage wire is used as adjunctive, rather than primary, fixation. The surgeon should keep in mind that while properly applied cerclage wire in selected cases is very effective, errors in application or case selection can be disastrous. Careful attention to detail in fracture repair planning, fixation and post-operative assessment is critical. Cerclage wire is typically applied to long spiral or oblique fractures where the length of the fracture is roughly two and one-half to three times the diameter of the bone (Figure 49-1), and a single cerclage wire is avoided as it acts as a stress concentrator and becomes a fulcrum for motion of the fracture fragments. Cerclage wire may be used both as a temporary reduction device, for example, to hold the fracture in reduction while applying a plate, external skeletal fixator, or interlocking nail, or as a permanent device, often in combination with one of the above or with an intramedullary pin. Although some investigators have commented that cerclage wire may inhibit the surgeon's ability to accurately contour a plate to bone, in practice properly applied cerclage wires are commonly left under plates and mechanical performance in one study showed that cerclage wires used under the plate performed as well as lag screws and were easier to apply.[5]

In certain circumstances, cerclage wire can also be used over a plate,[5,6] although mechanically they may not perform as well as they do under the plate.[7]

An exception to the single cerclage wire rule for long bones may be made if the intent is to prevent a non-displaced fissure fracture from propagating or fracturing further during manipulation of the fracture ends during open reduction (Figure 49-2).

Cerclage wire is made of relatively soft (usually annealed) 316L stainless steel that is available on spools, in coils or as preformed loops. Sizes of cerclage wire typically used in cats and dogs include 22, 20 and 18 gauge. On rare occasions, it may be appropriate to use 24 gauge wire in very tiny patients and 16 gauge wire in very large dogs. A special type of cerclage wire, cable cerclage, uses large diameter braided titanium alloy or stainless steel along with a special clamp system. Cable cerclage is designed for use over total hip replacements or for fixation of trochanteric osteotomies in humans. Successful use of cable cerclage after total hip revision in the dog has been reported.[8]

Wire diameter can exponentially increase load to failure (a 50% increase in diameter may increase load to failure by up to 169%),[9] and the largest diameter wire that the surgeon can apply to the bone without technical difficulty is recommended.[10] The area moments of inertia ($I = \pi r4/4$) of the various common wire sizes are listed in Table 49-1 and give the user an indication of how strength is greatly decreased as the size of the wire decreases, and also why the use of stainless steel suture material (eg, 30 gauge stainless steel wire) in any configuration is strictly contraindicated for fracture repair. Method of wire application and type of knot have been extensively studied in both the human and veterinary literature in order to maximize both initial tightness of the wire and identify configurations that will stand up to cyclic load and maximize load to failure. When reviewing the literature, one should be aware that some studies are designed to evaluate cerclage wire used for spinal or tension band applications rather than for long bone applications, and be cautious when trying to apply results of those studies toward applications which they were not designed to evaluate.

Types of Knots and Types of Twisters

Cerclage wire in veterinary surgery is generally applied either as a twist wire or loop wire (single or double loop). Clinical advantages of twist wires include ease of application with a simple wire twister (Figure 49-3), the ability to tighten and fasten the wire at the same time, and the ability to retighten the wire if it loosens during fracture reduction,[11] as frequently occurs during the placement of multiple cerclage wires. Loop wires have the advantage of better initial tension or tightness when properly applied, and do not have a protruding twisted end that may irritate soft tissues. Loop wires that loosen during fracture reduction must be removed and replaced.

There are many different types of wire tighteners available which have been reported in the literature. They fall into categories of twist tighteners, loop tighteners and there are instruments available that can actually tie a square knot in stainless steel cerclage wire (Table 49-2)

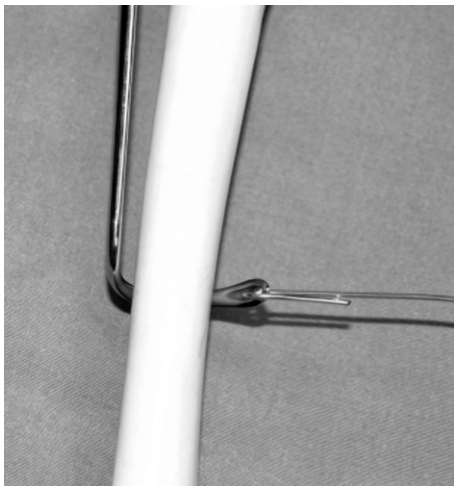

Figure 49-5. Usage of an aneurysm needle as a cerclage wire passer.

Application of Full Cerclage Wire

For fixation of a long bone fracture, cerclage wire should only be used where the fracture can be anatomically reconstructed to complete the original, 360° cylinder of bone. Although wire can keep bone fragments compressed, it cannot keep them apart as a plate and screw construct can. If even a tiny piece of bone is missing, the fracture will collapse as the wire is tightened and a loose wire with loss of reduction will result. In general, cerclage is reserved for two-piece fractures, although occasionally a third piece may be successfully incorporated. It is important to minimize dissection and soft tissue trauma to the musculature attached to the bone while applying cerclage wire. Cerclage wire may be passed around the bone either directly or using an instrument such as a cerclage wire passer (Figure 49-4) or aneurysm needle (Figure 49-5). Soft tissue inadvertently trapped under the wire will undergo necrosis and this will subsequently lead to wire loosening, however, there is no need to attempt to place the wires subperiosteally.[4] Wires are generally placed approximately 1 cm apart and at least 5 mm from the ends of the fracture. Some surgeons recommend that cerclage wires should be placed no nearer that one bone diameter away from the ends of the fracture.

After the cerclage wire has been carefully passed around the diaphysis of the bone and the fracture reduced, it must be tightened while maintaining reduction. For twist wire application, the wire may be twisted by hand for the first one or two twists loosely, leaving about 0.5 to 1 cm between the bone and the twist. A locking wire twister should be used for applying cerclage wire, as use of an ordinary pair of pliers allows loss of tension as the wire is being twisted. Using a locking wire twister, both wire ends should be grasped where they intersect (See Figure 49-3), and the wire pulled firmly up while twisting at the same time to avoid the complication of one wire wrapping around the other, which will drastically weaken the construct. It is of critical importance that the wire be tight. The surgeon should watch as the gap between the wire and the bone disappears, and should periodically check the wire for looseness by pushing firmly on it with a Freer periosteal elevator or other suitable instrument. If the wire is loose, tightening should continue. With practice, the operator will develop a "feel" for the mechanics of stainless steel

cerclage wire, as a rule, it is common to break wires as they are being applied, particularly for the inexperienced surgeon. If the wire breaks between the 2nd and 3rd twist or higher and is tight, it may be left in place, otherwise, it is removed. The wire should be left without cutting or otherwise manipulating the ends until all cerclage wires have been placed, and then checked again for tightness. Care should be taken not to notch or otherwise damage the wire that is going to stay in the animal as even a small notch will greatly decrease the fatigue resistance of the wire.[12] Loose wires should either be retightened or removed and replaced. If the wires were placed for temporary fixation, for example to hold the fracture in reduction while applying a bone plate, they may be removed prior to final tightening of the plate screws.

Twist wires should be cut to preserve at least 2 to 3 twists. It has been shown that wiggling the wire during cutting can substantially decrease the tension in the twist wire.[13,14] Wire ends should not be bent over with twist wires utilized for full cerclage (as opposed to hemicerclage or wire used in pin and tension band fixations).

Loop wires may be applied using either commercially available or hand-made loops. The cerclage wire is placed as described above for twist wires, and the free end passed through the eye of the loop. The loop wire tightener is passed over the free end of the wire, which is passed through the crank of the tightener. The wire is tightened by turning the crank until it can no longer be moved. Tightness of the wire can be checked with a periosteal elevator or other suitable instrument. The wire is then bent over until the free end folds back on itself, maintaining tension on the wire during this step. The crank is then reversed until enough length of wire is exposed so that it can be cut, and the arm is pressed flat to the bone. A double loop wire is made by taking a suitable length of wire, folding it in half, passing it around the bone as described above, and passing the two free ends through the loop. A double loop tightener with two cranks is used to tighten the wire as described above for the single loop wire.[15]

For all types of wire, it is important that they are tightened perpendicular to the long axis of the bone, rather than perpendicular to the fracture line as they will slip down perpendicular to the bone when exposed to weight-bearing forces and become loose. In an area where the bone diameter is changing and wire slippage may occur, the use of a Kirschner wire to prevent slippage as a "skewer pin" may be indicated (Figure 49-6). The K-wire is placed perpendicular to the fracture line, and the cerclage wire is placed around it and tightened so that the ends of the K-wire prevent it from slipping. Skewer pin configurations are not as strong as lag screw fixations, but may be considered for the treatment of short oblique fractures if supported by another device.[16]

Cerclage wires should be placed at least one-half of the diameter of the bone apart. Multiple cerclage wires should always be used unless they are being used to prevent propagation of fissures. In the author's opinion, the operator should also keep in mind that if more than four or five cerclage wires are being placed, that the possibility for excessive stripping of the soft tissues exists and another type of fixation should be considered (See figure 49-6).

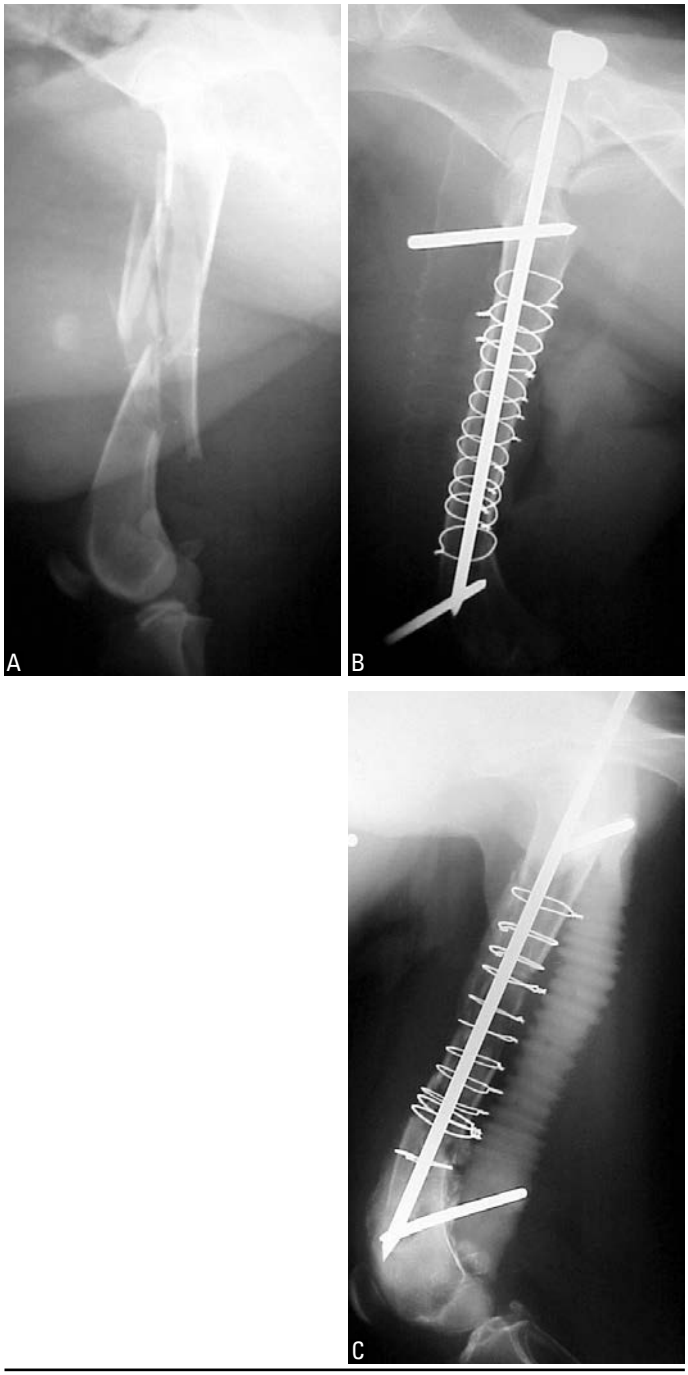

Figure 49-6. A. Comminuted femoral fracture in a 5 year old FS German Shepherd Dog. **B.** Post-operative repair with external fixation and cerclage. **C.** Eight weeks post-operative, osteomyelitis and sequestrum formation likely exacerbated by loss of blood supply due to extensive approach required to apply 12 cerclage wires.

Contraindications

Full cerclage wires are contraindicated in the treatment of transverse, short oblique (with the possible exception of a skewer pin configuration), segmental or multi-fragmented fractures. When evaluating preoperative radiographs of fractures, all of the fragments, even tiny ones, should be counted and if there are more than three, another method of fixation should be considered. Full cerclage are also contraindicated if, for any reason, the full 360 degrees of the shaft cannot be reconstructed, or the shape of the bone is such that wires cannot be applied so that they will sit

perpendicular to the long axis of the bone without slipping. Loose or damaged cerclage wires should always be removed. Finally, the surgeon should balance the risk of damage to the blood supply and potential for a nidus of infection in high-velocity, open or infected fractures and as a general rule, cerclage wire fixation is contraindicated for these types of fractures.

Complications and their Prevention

Properly applied cerclage wires rarely cause problems, however, improperly applied wires are almost always problematic. Loose wires, the most common complication, usually occur either as a result of failure to completely reduce the fracture or because of improper tightening techniques. In the author's experience, cerclage wire failure most frequently occurs when wires are utilized inappropriately on short-oblique or multi-fragmented femur fractures, usually combined with an intramedullary pin in large breed dogs. Loose wires very effectively prevent revascularization of the area around the fracture, and sequestration of dead bone fragments with collapse and rotational instability of the fracture are the end results (Figure 49-7). Prevention of complications depends upon careful case selection and proper application techniques, as described above. A failed pin and cerclage wire fixation can be devastating for the animal and in some cases may be irreparable, even if referred to a specialist with access to all types of orthopedic equipment.

Hemicerclage wire

Hemicerclage wire refers to wire that has been passed through at least one hole drilled through the bone. Although hemicerclage configurations have been reported for the treatment of rotational instability in long bone fractures, in practice they are very weak,[17] reaching only about 3% of the load in Nm of an intact construct and absorbing only 2% of the energy that an intact construct can absorb prior to failure during mechanical testing.[18] Hemicerclage wire applied to long bone fractures may also only be effective if rotational instability occurs in only one direction. Biomechanical testing of a variety of interfragmentary wire designs, either with hemicerclage wire, or combined cerclage wire and K-wire applications showed that a biplanar 90° configuration with wire and cross pin configuration had the highest torsional yield load and safe load,[18] however, this configuration would be difficult to apply clinically and has yet to be tested in vivo.

Hemicerclage is primarily used where applied loads are low, for example in the treatment of mandibular, maxillary and some skull fractures. Considerations for applying these wires include avoiding tooth roots and angling drill holes such that it is easy to grasp the wires and pull them through the bone to allow tightening. Holes drilled for application of hemicerclage wires should be at least 2 implant diameters away from the fracture line to prevent them pulling through or fracturing the fragment as they are carefully tightened. Unlike full cerclage wire, hemicerclage wire is not prone to loosening after being tightened down to the bone and it is acceptable to bend the wire ends over. Overtightening of hemicerclage wire will cause bone failure and pull-out of the wire. Attention should be paid to pulling as much "slack" from the wire prior to tightening, and also to twisting the wire halfway between two points of fixation so the twist does not sit at the level of the drill hole and prevent further tightening.

Figure 49-7. A. Lateral radiograph of a comminuted, closed diaphyseal humeral fracture in an 11 month old German Shepherd Dog. **B.** Lateral post-operative radiograph of repair with intramedullary pins and 4 loop cerclage wires. Note that the distal-most wire is very close to the fracture line. **C.** Rotational instability evident at 8 weeks, distal wire has loosened.

Intramedullary Pins and Kirschner Wires

Sharon C. Kerwin

Definition and Indications

Devices used in the medullary cavity of long bones, such as intramedullary rods or nails, are designed to act as non-compressing splints. A gliding splint allows compression caused by physiologic loading conditions, while a non-gliding splint incorporates features that prevent fragment compaction, for example an interlocking nail. The terms "rod" and "nail", while sometimes interchanged, are not equivalent. A rod is loosely applied, so that contact with endosteal bone is limited. Examples of use of a rod would be a rod suspending a roll of paper towels, allowing free movement between the paper towel tube and the rod, or typical veterinary use of an intramedullary Steinmann pin. In the veterinary literature, the term "pin" is often used interchangeably with "rod". A nail is tightly applied to the endosteal bone to the point of firm wedging, just like a carpenter's nail driven into a board, displacing wood and becoming firmly wedged.[1]

Types of Implants Available

Intramedullary pins (IM pins) used in animals range from ¼ inch diameter (6.3 mm) down to 5/64 inch diameter (2.0 mm). Intramedullary pins in this size range are called Steinmann pins. Smaller pins are usually referred to as Kirschner wires (K-wires), and although they may be used as intramedullary devices in very tiny animals, they are generally used as interfragmentary devices. K-wires are available in .035, 0.045, .054 and .062 inch diameters. Intramedullary pins and K-wires can be obtained as fully threaded, partially threaded or nonthreaded. Although some surgeons use partially (end) threaded pins for intramedullary pins with the intention of increasing rotational stability, in fact those pins do not provide additional rotational stability (Figure 49-8) and are at risk for breakage at the thread-shaft interface or in the weaker threaded portion (Figure 49-9). In addition, fully or partially threaded Steinmann pins and K-wires are more difficult to remove as the bone tends to grow into the threads. For these reasons, the use of threaded pins as intramedullary devices is not recommended.

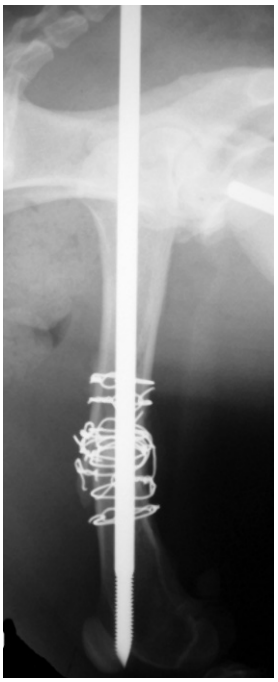

Figure 49-8. Use of a partially threaded intramedullary Steinmann pin and cerclage wires for the treatment of a comminuted femoral fracture in a 5 year old male Labrador retriever. The fracture collapsed within days due to the inability of the pin and wires to sustain rotational forces. In addition, the intramedullary pin has migrated into the joint.

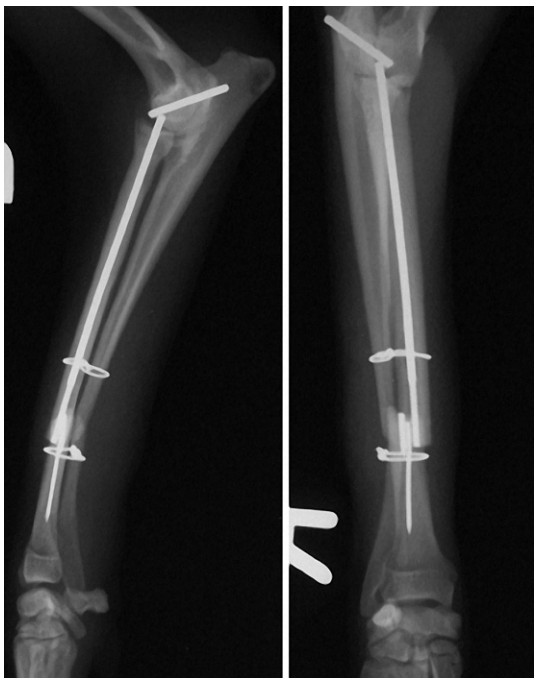

Figure 49-9. Lateral and ventrodorsal view of a radial fracture repair with a threaded Steinmann pin. The pin has broken in the weaker threaded portion at the level of the fracture line. An additional K-wire is present but was unable to control rotational stability. Note also that the Steinmann pin has broken proximally where it was normograded through the articular surface of the radius.

Steinmann pins and Kirschner wires are available in a variety of lengths, usually from 6 to 12 inches long, and may have points on one or both ends. Although most are manufactured from surgical grade 316L stainless steel, pure titanium K-wires are also available. The pins are easily cut, and there is no advantage to the veterinary surgeon in purchasing single pointed pins.[2] Pins may be manufactured with a trocar, chisel, diamond, or bayonet point (Figure 49-10). Trocar points are by far the most commonly used and consist of a three-sided tip with a long bevel and good ability to penetrate cortical bone. Chisel points (also called diamond points) are broad, flat two-sided points with a short bevel and are designed to deflect the pin away from the cortex during drilling rather than engage the opposite cortex. Some pins are available with a trocar point on one end and a chisel point on the other: the starting hole through the cortex can be drilled using the trocar point, and then the pin can be reversed if the surgeon desires for it to deflect off the far cortex. Bayonet points are "single-lipped" or "free cutting" points found on pins designed for transfixation pins for circular external fixators. The ends are such that they can easily penetrate soft tissues and can be tapped through cortical bone with a hammer after being partially drilled through the bone in an attempt to preserve blood supply. These pins also come with "stoppers" in the middle and may be called "olive wires", which may be used to pull a fragment into alignment or allow decreased translation of a bone segment within an external fixator frame (Figure 49-11).

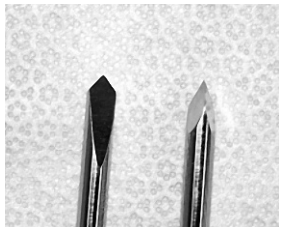

Figure 49-10. Different types of points available on Steinmann pins and Kirschner wires. The pin on the left has a chisel point, while the pin on the right has a trocar point.

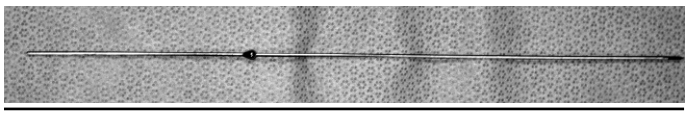

Figure 49-11. Olive or stopper wire. Note the "stopper" placed about 2/3 of the length of the pin away from the cutting tip.

Intramedullary pins excel in resisting bending forces in 360 degrees, can be placed with relatively little in the way of specialized equipment, and often can be placed with a limited approach. Intramedullary pin placement, unless a very large pin is placed or reaming of the medullary cavity is performed, has limited impact on the intramedullary blood supply. Intramedullary pins are relatively easy to remove, in contrast to fixation devices such as lag screws or plates. Intramedullary pins do not prevent rotation or counteract axial forces, and therefore are rarely used alone but combined with other types of fixation, for example cerclage wires, external fixators, plates, and lag screws. From a mechanical standpoint, use of the largest pin possible will result in the stiffest construct and most resistance to bending (Table 49-3). However, use of an excessively large pin has several disadvantages: difficult placement in a curved bone, for example the canine tibia and femur, damage to the intramedullary blood supply, and risk of creating additional fractures if the pin exceeds the diameter of the bone at its' narrowest point, or isthmus. In general, a pin that is approximately 70% of the diameter of the long bone at the isthmus is chosen. If the surgeon anticipates combining the pin with another type of device, such as an external fixator, lag screw or plate, a slightly smaller intramedullary pin is chosen. Use of a pin that is too small may

Table 49-3. Area Moments of Inertia for Steinmann pins and Kirschner Wires[12]

Diameter (inches)	Diameter (mm)	Area Moment of Inertia (mm^4)
1/4	6.3	80
3/16	4.8	24
5/32	4.0	12
9/64	3.5	8
1/8	3.2	5
7/64	2.8	3
3/32	2.4	1.5
5/64	2.0	0.8
0.062 (1/16)	1.6	0.3
0.054	1.4	0.10
0.045	1.2	0.12
0.035	0.9	0.05

result in failure by pin bending or breakage (Figure 49-12). Use of multiple small pins to fill the medullary cavity, also called "stack pinning" to increase resistance to rotational stability, has been shown not to increase rotational stability significantly more than single intramedullary pinning.[3]

In addition to using ancillary devices to control rotational and axial forces on the bone with IM pins, modifications to the pins themselves, including placement of screws through holes across the pin (interlocking nail construct) and modification of the pin itself can be used. A recent example of this in the veterinary literature is the Trilam nail, a stainless steel intramedullary device designed with three "lamellae" extending down its length to counteract rotational forces. The nail is driven with a mallet into the medullary cavity without reaming, such that the three lamellae cut into the inner cortical bone, making it a true nail. Successful use of the Trilam nail in dogs and cats for the treatment of femoral, tibial and humeral fractures has been reported.[4]

K-wires, while they can be used as intramedullary devices, are usually used as interfragmentary devices, often to maintain temporary fracture reduction while the primary fixation (eg a plate) is applied. K-wires by themselves are relatively weak implants (See Table 49-1) and are not generally used alone. In certain fractures, for example physeal fractures in small dogs and cats, cross-pinning with K-wires can be sufficient when fracture healing is expected to be rapid. K-wires are also commonly utilized in combination with cerclage wire for tension-band fixations and to support full cerclage wires in areas of changing bone diameter ("skewer wires").

K-wires have also been modified to improve their anti-rotational characteristics, for example, the Orthofix self-compressing pin recently reported in the treatment of humeral condylar fractures in small breed dogs.[5] These pins are small diameter (1.2 to 2.2 mm threaded segment, 1.5 to 3 mm shaft) pins are designed for use in cancellous bone. As the pin is drilled, the threaded portion cuts a thread into the cancellous bone. When the pin's chamfer (location of the thread-shaft interface where the diameter of the pin increases) contacts the near cortex, further advancement of the implant partially strips the threads cut in the bone in the near fragment, while the threads in the far cortex maintain purchase, leading to interfragmentary compression.

Figure 49-12. Lateral radiograph of a femoral fracture in a dog repaired with an intramedullary pin and cerclage wire. The intramedullary pin diameter is insufficient and has led to failure in bending (rotational instability is also present).

Application Techniques for Intramedullary Pins and Interfragmentary Wires

Intramedullary pins may be inserted either from the fracture site (retrograde insertion) or from either the proximal or distal end of the bone itself (normograde insertion). The local anatomy of the bone often dictates how the pin is driven, for example, retrograde pin insertion in the tibia often results in damage to the articular cartilage or cruciate ligaments. An estimation of appropriate pin size (60 to 75%)[6] may be made from the post-operative radiographs and may be confirmed by observation of the pin as it is gently introduced into the fracture site, even if normograde insertion is planned. If in doubt, a smaller pin should be used initially and replaced with a larger pin if necessary. The pin may be inserted either open or closed. Although closed pinning, based on palpation, can be performed by the experienced surgeon this can become more difficult in larger animals with soft tissue swelling, or in fractures greater than 72 hours old. The increased use of intraoperative imaging (fluoroscopy) can greatly facilitate IM pin placement in a minimally invasive fashion, with less damage to the soft tissues.

Intramedullary pins may be placed either by hand, using a Jacobs' chuck (Figure 49-13), or with a drill. Hand insertion may allow the surgeon to feel whether or not the pin is advancing down the medullary cavity and whether it is up against or about to penetrate cortical bone. When placing pins by hand with a Jacobs' chuck, the smallest amount of pin possible that will allow the pin to advance should be used, in order to prevent "wobble", particularly when smaller pins are used. The chuck should be firmly tightened with the key in at least two separate places to avoid sudden loosening during pin advancement. Although Jacobs' chucks are sold with protective devices that are designed to protect the surgeon's hand from inadvertent pin penetration resulting from sudden pin loosening, in practice many surgeons place the palm of their gloved hand over the end of the pin to gain mechanical advantage. The tip of the pin should firmly engage bone, and the pin rotated back and forth with quarter

Figure 49-13. Jacob's chuck with appropriate length of pin extending from tightened chuck. Note the protective guard that has been threaded into the main body of the chuck.

turns (rather than driven consistently clockwise or counter-clockwise) while avoiding any "wobble" that may enlarge the proximal hole made by the pin and predispose to pin loosening. In larger animals with hard cortical bone, hand placement can be very difficult. In addition, the smaller the pin the more difficult it is to drill by hand and power insertion is mandatory for inter-fragmentary K-wires.

When using a drill to insert an intramedullary pin or K-wire, a cannulated drill should be used to drive the pin to decrease the amount of wobble and the risk of pin bending or breakage during drilling. A high-torque, low speed drill should be used (as opposed to a high speed drill) to decrease heat generation and subsequent bone necrosis. Saline lavage is also important to decrease heating of the bone, particularly with K-wire insertion. When driving an intramedullary pin, whether by hand or with power, it is important to carefully line up the pin with the shaft of the long bone. During open reduction, the surgeon may find it easiest to drive the pin with one hand and stabilize the fracture segment by using a bone-holding forcep gripped with the non-dominant hand. Having an assistant hold a second pin parallel to the shaft of the long bone may be helpful, or in certain cases, placing an "aiming pin" retrograde just a few cm into the medullary cavity so the surgeon can attempt to drive the normograde pin along the axis provided by the aiming pin. When attempting to seat an intramedullary pin into metaphyseal bone, it is important not to accidentally penetrate the articular surface, for example in the distal femur. The surgeon will note an increase in resistance as the pin begins to seat into the metaphysis. In addition, the fracture fragments may begin to distract apart as the pin over-lengthens the bone as it is driven into the metaphysis. In a comminuted fracture, an IM pin may be used to help distract fracture fragments and assist with fracture reduction. As the sharp tip of the pin passes through the first of the two major fracture segments, it may be cut to help prevent penetration of the pin into the joint and will help distract the fracture. The distance that the pin has advanced may be judged by using a second pin of equal length and lining the two pins up after the Jacobs chuck has been removed. After the pin has been seated, the proximal and distal joints should be put through a complete range of motion, as it is easy to inadvertently place a pin into a joint. If available, intraoperative fluoroscopy is useful and much more efficient than closing the surgical approach, traveling to radiology, and returning to the operating room to redirect an implant. Immediately prior to wound closure, the surgeon should carefully palpate the soft tissues surrounding the bone for evidence of overly long or misplaced pins (Figure 49-14), which can be difficult to feel as they unexpectedly exit cortical bone during drilling.

After the pin is judged to be in the correct position, it is cut using specialized pin cutters. Pin cutters are generally designed only to cut pins of a certain range in diameter, and inadvertent use of small pin cutters to cut a large pin may result in permanent damage to an expensive piece of equipment. The surgeon should check the range of diameters listed on the side of the cutter (Figure 49-15). It is helpful to have an autoclavable pin guide (Figure 49-16) in the pack to determine the size of the pin in surgery. The surgeon should also avoid cutting the pin with

Figure 49-14. Radiographs of repair of a distal femoral fracture in a 2 year old cat taken immediately post-operatively. The crosspin is excessively long medially. Note that the intramedullary pin appears to be in the joint on the craniocaudal view but is not based on the lateral view.

Figure 49-15. Pin cutter with indication of maximum pin size that can be cut printed on the side, in this case, up to 2.2 mm or 0.086 inches (up to a 5/64 inch pin).

Figure 49-16. Autoclavable pin ruler that can be used intraoperatively to measure pin size.

bone cutters, which look very similar to pin cutters but will be irreparably damaged if used to cut stainless steel pins or wires. Autoclaved "hardware store" bolt cutters are acceptable but can be bulky and difficult to get into a surgical approach in some cases. Pins accumulate a lot of energy when cut and have the potential to cause serious injury to the surgeon, assistant or circulating technicians if the free end is not firmly grasped or covered with a Huck towel to prevent it from becoming a

projectile. The fracture should be carefully observed during and after pin cutting to make sure that alignment is not disrupted.

Controversy exists over whether to cut pins short or leave them long to facilitate pin removal. Leaving pins long can lead to problems with iatrogenic nerve damage (proximal femur), damage to nearby articular cartilage or patellar tendon (tibia), or soft tissue irritation with subsequent seroma formation or erosion of the tip of the pin through the soft tissues. The alternative to leaving pins long is to cut them short and countersink them, using a countersink and mallet. Many surgeons accomplish this by retracting the pin approximately 1 cm, cutting the pin as short as possible, and then placing the countersink over the top of the pin and tapping it in approximately 1 cm or until it is level with the proximal aspect of the bone (eg, greater trochanter of the femur).

Pin Migration

Steinmann pins and Kirschner wires can loosen and "migrate" out of the bone over time, and in fact have been reported to migrate large distances and penetrate organs including the brain and heart (noted after the use of DeVita pins for reduction of hip luxations),[7] or into a joint, as after pinning of a proximal femoral epiphyseal fracture. Where possible, it is helpful to bend the pin over using either a pin bender designed specifically for bending pins (Figure 49-17) or if such a device is not available, the Jacobs chuck or a metal Freer suction tip can be used to bend K-wires. The surgeon should be cautious when bending larger pins in soft bone or small fragments as the bone could fracture as the pin is being bent, or loss of reduction could occur if stabilization is marginal. Once the pin is bent, it is impossible for it to migrate towards its point, however, it can still migrate in the opposite direction.

Pin Removal

Pins should be removed if they are loose, irritate soft tissues, are in a joint or are infected. Although many surgeons routinely remove intramedullary pins, it has been our experience that stable pins do not need to be removed after the fracture has healed. In humans, there is controversy over whether or not pins should be removed, with one author noting that orthopedic surgeons with implants did not have their own hardware removed, citing a higher refracture rate after implant removal and no documented downside to leaving implants in.[8]

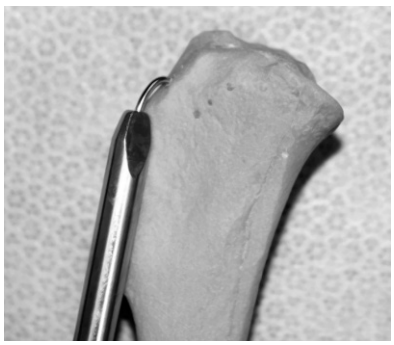

Figure 49-17. Use of a partially cannulated pin bender to bend a K-wire placed in a model of the proximal tibia.

Contraindications

Intramedullary pins alone should never be used for comminuted fractures that will collapse around the pin or fractures that will be rotationally unstable. Pins and cerclage, while effective if properly applied, are useful only for certain types of simple, closed fractures in animals with good healing potential. Although use of an intramedullary pin in an open or infected fracture has been thought to have the potential to spread infection along the medullary cavity, in fact, intramedullary devices can safely be used in infected fractures as long as they are stable.[9]

Complications and their Prevention

Complications associated with intramedullary pinning most frequently include damage to adjacent structures. Bones most amenable to intramedullary pinning include the femur, tibia, humerus and ulna. Pinning of the mandible results in damage to tooth roots and an unstable repair. Pinning of the radius cannot be performed without damaging an articular surface, and bent, broken or migrating pins in the radius are difficult to retrieve. As discussed above, specifics for each bone as to whether the pin should be normograded or retrograded, and how the pin is directed in the medullary cavity, are detailed elsewhere but should be reviewed prior to IM pin fixation.

A common mistake when driving an IM pin is to be slightly off at an angle away from the center of the medullary canal, resulting in the pin penetrating cortical bone prior to crossing the fracture line. If this occurs, the pin must be completely withdrawn and a new entry site drilled, as the pin will tend to fall into the same track that was originally made. If the pin is inadvertently penetrated into a joint, merely withdrawing the pin back into the medullary canal is not sufficient, as once the animal begins to bear weight the pin will migrate into the joint. If possible, the pin may either be withdrawn and replaced with a slightly larger pin, or withdrawn and redriven at a slightly different angle to prevent it from entering the original hole into the adjacent joint.

Post-operative radiographs of the entire bone, in two orthogonal views must always be made post-operatively to confirm pin placement and fracture reduction. Pins that have penetrated a joint should always be removed, as severe damage can occur even within a few days to weeks. If pin migration is noted prior to fracture healing, the fracture is unstable and reinsertion of the implant will not solve the problem. It may lead to infection particularly if a tip of the implant has penetrated the skin. Repeat radiographs should be obtained, and an alternative plan made to address fracture instability with a different form of fixation.

Pulmonary fat embolism is a fairly common complication associated with the introduction of intramedullary devices in humans, and has been reported as a cause of morbidity in dogs during total hip replacement.[10] Although pulmonary fat embolism is not commonly recognized in small animals associated with IM pins, one well-documented case has been reported to cause fatality in a cat,[11] and the surgeon and anesthetist should be aware of the risk and appropriate intra-operative monitoring performed, particularly in animals with pre-existing pulmonary trauma or disease.

Tension Band Wiring

Karl H. Kraus

Introduction

Tension banding is a technique by which tensile forces are converted into compressive forces. This principle can be applied to the repair of fractures in which a fragment is distracted from its original position by the pull of a muscle, tendon, or ligament. The area of fracture opposite the pull under tension is termed the tension side of the fracture. If the tension side of the fracture is fixed with a tension device, the device pulls in a vector which counters the distractive force. If the force of the distractive pull is not in a straight line with the tension device, the force of the distractive pull is redirected to a resulting vectoral force which is a compressive force across a fracture or osteotomy (Figure 49-18).

Indications

Indications for use of tension band wires include repair of fractures or osteotomies of the acromion of the scapula, supraglenoid tubercle, greater tubercle of the humerus, olecranon, greater trochanter of the femur, supracondylar epiphysis of the femur, medial malleolus of the tibia, tuber calcis, tibial tuberosity, and attachments of collateral ligaments. This is a commonly used technique because these are frequent sites of fracture and osteotomies for surgical approaches. A tension band wire can be successfully applied in many situations, if principles of application are followed and proper technique is used.

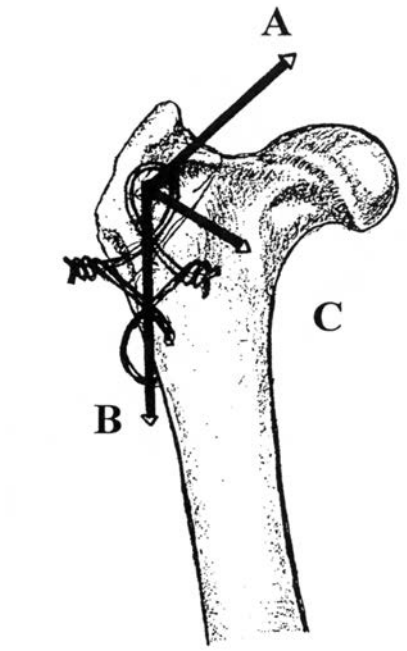

Figure 49-18. The pull of a muscle, tendon or ligament *A.* when countered with the opposing pull of a tension band device *B.* results in a compressive force across the fracture or osteotomy *C.*

Technique

Before a tension band wire is applied, the direction of the distractive forces should be estimated. Because forces can change through the range of motion of a joint, the "average" distractive force should be estimated. The tension band should be applied to the side opposite the distractive forces, the tension side of the fracture or osteotomy.

After the fracture or osteotomy is reduced, two orthopedic pins (Kirschner wires) are inserted from the distracted fragment across the fracture line and into the attaching bone (Figure 49-19A). Two pins are used whenever possible to provide rotational stability. The pins should be applied parallel to the direction of desired compression and so that an orthopedic wire placed over them applies even, undeterred pressure to the tension side of the fracture. These pins should be seated in cortical bone in the opposite cortex to prevent migration.

With a drill or orthopedic pin, a hole is drilled through the cortex to accommodate the tension band wire. The distance of this hole from the fracture line should be such that the figure-of-eight wire does not cross directly over the osteotomy. A section of 0.8 mm, 1.0 mm or 1.2 mm orthopedic wire is looped one-third of the distance from one end. The short end is inserted through the hole in the cortical bone, and the long end with the loop is brought

over the two orthopedic pins in a figure-of-eight pattern, and is twisted to the other loose end (Figure 49-19B). The preplaced loop and twisted ends are tightened alternatively or with the help of an assistant so the wire is evenly tightened (Figure 49-19C). The orthopedic wire should be cut, leaving three to four twists, and bent toward the bone. The Kirschner wires are bent over the tension band wire and are cut to secure it (Figure 49-19D and 49-19E). The ends of the wires are seated against bone. Aftercare of the tension band wire itself is minimal. No more that standard exercise restriction is required.

Complications

Complications are uncommon and are usually the result of improper technique. The six most common technical errors resulting in failure are depicted in Figure 49-20. The first error is having too small a fragment to accommodate an appropriately sized tension band device. Fractures and avulsions can be small, and applying a proper tension band may be difficult. More commonly, however, this error occurs when performing an osteotomy for a surgical exposure, such as an osteotomy of the greater trochanter of the femur or tibial tuberosity. Too small a fragment will break resulting in failure of the tension band. One usually avoidable technical error is the placement of only one pin. Because the vector of the distracting muscle, tendon, or ligament pull may change through a range of motion, there may be a torsional force across the fracture. Two pins prevent rotation. Small avulsion fragments may only accommodate a single pin. However, placing two smaller pins should be used before one larger pin whenever possible. Use of a loop instead of a figure-of-eight wire is an avoidable technical error. A loop tends to center the compression more toward the pin and allows the fracture line on the tension side to distract. Heavy-gauge wire should be used. Although 1.2 mm to 0.8 mm wire may seem difficult to manipulate, smaller wire is rarely appropriate even in

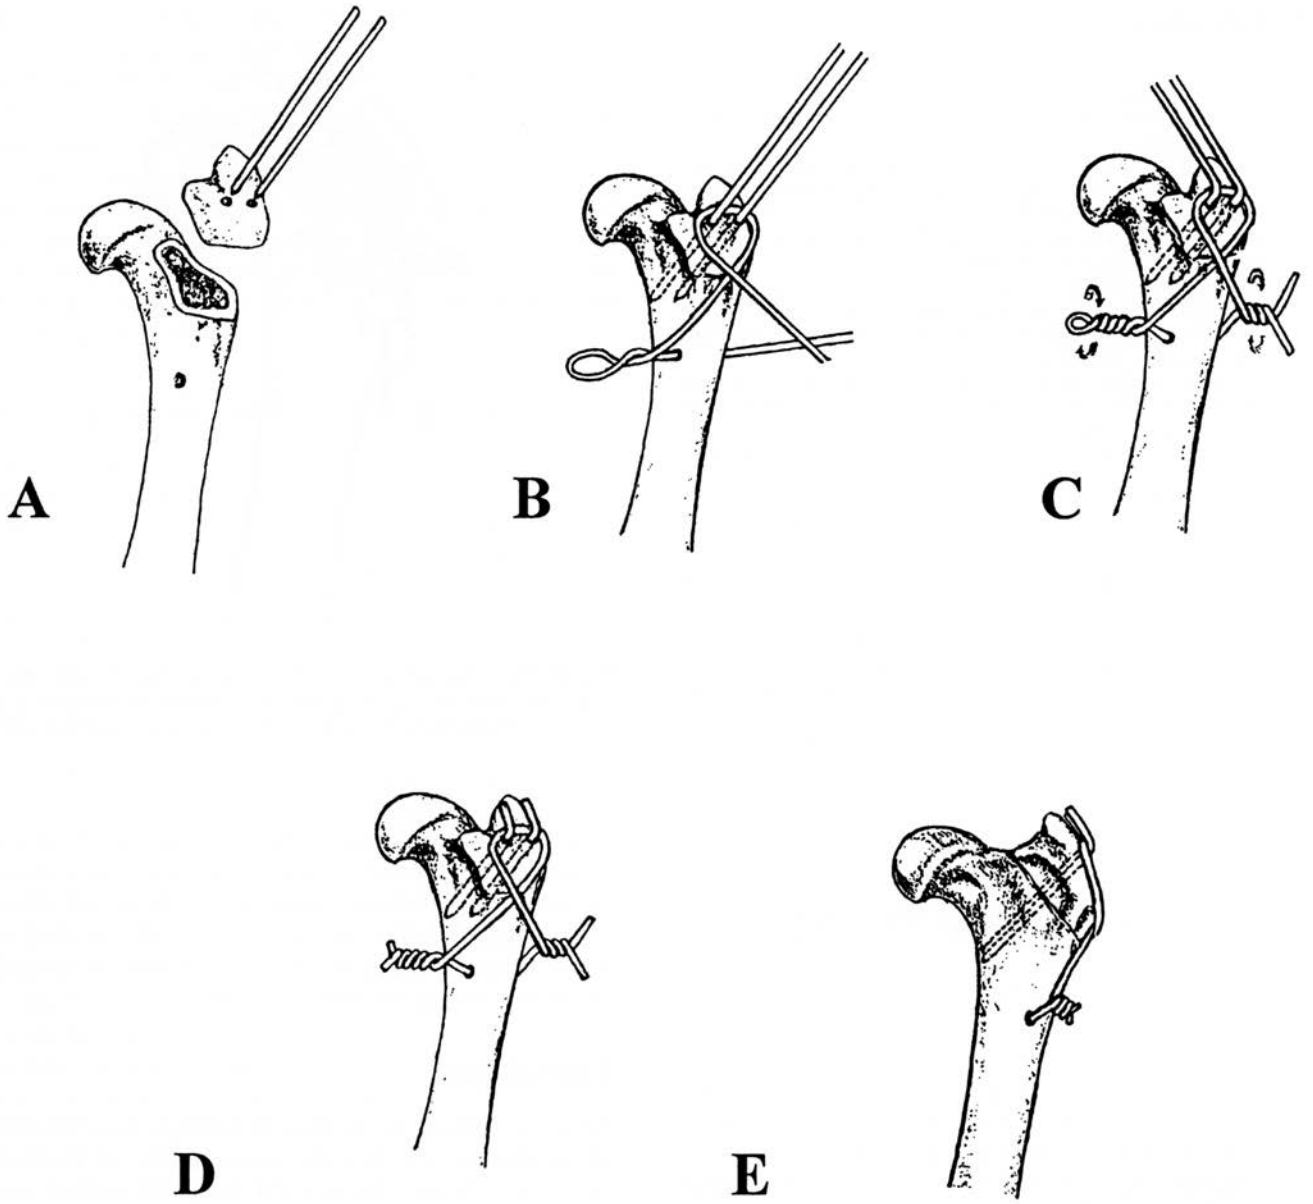

Figure 49-19. Application of a tension band wire. **A.** First the fragment is replaced, and two pins or Kirschner wires are driven perpendicular to the fracture line. **B.** A figure-of-eight wire is placed over the pins and through a hole in the cortex. **C.** The wires are twisted and tightened alternatively. **D.** and **E.** The pins and wires are bent, cut, and seated next to the bone.

small animals. The hole in the bone anchoring the tension band wire should engage enough material to counter the force of the tension device. These forces can be substantial. The pins should be anchored into the opposite cortex. Failure to do so can allow the pin to migrate.

Chapter 50

Interlocking Nailing of Canine and Feline Fractures

Interlocking Nailing of Canine and Feline Fractures

Kenneth A Johnson

This chapter was submitted in 2006 and was based upon the available literature through that year. Other interlocking nail devices have emerged since that time, but are not covered in this chapter.

Introduction

The principles of management of diaphyseal fractures of the femur, tibia and humerus by internal fixation have evolved considerably from the original AO concepts of complete anatomical reduction and rigid stabilization of all the fractured fragments. Nowadays, the concept of biological management of diaphyseal fractures places greater emphasis on less invasive surgical approaches, and preservation of the bone blood supply and the fracture hematoma, especially in cases of comminuted non-reducible fractures. Overall alignment and stabilization of the proximal and distal fragments are obtained without interference with the intermediate comminuted fracture fragments. Interlocking nail fixation is the method of choice for the stabilization of diaphyseal fractures of the femur and tibia in adult humans.[1] In recent years, it has become more widely accepted as a method of treating diaphyseal fractures in small animals as well.[2-8]

Principles of Interlocking Nailing

Interlocking nailing evolved as a modification of intramedullary fixation using Steinmann pins for the stabilization of diaphyseal fractures in small animals. Intramedullary pinning of fractures in animals was first introduced about sixty years ago. While this method often resulted in successful fracture healing, complications due to fracture instability, fracture collapse, pin migration, and sciatic nerve entrapment were not uncommon. Intramedullary pins provide good stability against bending loads during the fracture healing period, provided that the chosen pin is of adequate diameter and stiffness. This is due to the fact that intramedullary pins are located in the neutral axis of loading within the medullary canal, and as such they are more resistant to bending loads than bone plates and other extracortical fixation devices. However, intramedullary pins are quite ineffective at counteracting axial compressive and torsional loads, especially in the case of comminuted fractures. Therefore the basic principle of interlocking nail fixation is that insertion of locking bolts securing the proximal and distal fragments to the nail, counteracts the axial and torsional loads, making the fracture fixation construct much more stable overall.

Types and Sizes of Nails

Several different systems of interlocking nails designed for canine and feline fractures have been developed by surgeons from various countries, world wide.[2-9] In principle, all these interlocking nails function in a similar manner, but they differ somewhat in regard to the instrumentation used for their application. The most widely used interlocking nails in North America (Innovative Animal Products, Rochester, MN) are round in cross section and made from 316L stainless steel that has been cold worked to increase stiffness and fatigue life in vivo. The nails are available in various diameters (4.0, 4.7, 6.0, 8.0 and 10mm) and lengths. An implant of appropriate dimensions (diameter and length) must be selected to match the patient's fractured bone because the nail is not usually cut to length during surgery. One end of the nail has a sharpened trocar point to facilitate insertion into the medullary canal. The other end of the nail is machined with two flanges and an internal thread to allow for precise attachment of the drill-aiming guide during surgery. Typically each nail has two non-threaded transverse holes near to each end, for the insertion of locking bolts. The spacing between these pairs of holes is either 11 mm or 22 mm. The closer hole spacing allows for the insertion of two locking bolts when there is limited metaphyseal bone available. In addition, nails are also available with just one hole proximally or one hole distally for the stabilization of fractures near to the metaphyses, in which case there is less available bone for interlocking (Figure 50-1).

Locking bolts are inserted transversely through the bone and holes in the nail with the aid of a special drilling aiming guide. This instrumentation is described in further detail in the following section about application. The locking bolts have a smooth shaft with four self-tapping threads under the bolt head, to engage the near bone cortex. The shaft of the bolt is almost the same diameter as the nail holes, with just a small under-sized tolerance to prevent jamming during insertion. Prior to the availability of locking bolts, conventional cortical bone screws were used for locking. However, the use of screws for this purpose is no longer recommended, because of their inferior mechanical performance; failure of screws by bending or breakage was occasionally a problem clinically.[10,11] During the course of fracture healing, the locking bolts are mainly loaded by bending or quasi-bending forces. Under these conditions, the stiffness and fatigue life of the locking bolt are determined by its area moment of inertia which is calculated using the formulae of π x radius^4/4. For example, the calculated area moment of inertias for the 2.7 mm diameter locking bolts and cortical screws are 2.61 mm^4 and 0.64 mm^4 respectively.[12] In the case of the cortical screw, this value is much lower because the core diameter of the screw is only 1.9 mm. Under conditions of cyclic bending the fatigue life of the 2.7 bolt is over 140 times greater than that of the 2.7 cortical screw.[13] The diameter of the medullary canal at the level of the locking bolt is also an important factor when considering the mechanical performance of the locking bolt.[14] The bending moment on the bolt is proportional to the unsupported length of the bolt within the medullary canal. Therefore in large breed dogs, the bending load on the locking bolt may be considerable in the metaphyseal region where the bone has a relatively greater diameter. In bones that are ovoid in cross section, it may be possible to reduce the bending load on the locking bolt by orienting it in the direction of the shorter cross-sectional axis of the bone.

Another advantage of using locking bolts instead of cortical screws is that bolts more effectively control torsional instability of the construct. With loading, the threads of cortical screws in the region of contact within the nail hole become deformed and flattened.[15] This effectively reduces the outside diameter of the screw, and allows for greater torsional slack in the construct in comparison to locking bolts.[16,17]

Techniques of Application of Interlocking Nails

Preoperative radiographs of the fractured bone are needed for surgical planning and selection of an appropriately sized nail. The radiographic views need to be true medio-lateral and cranio-caudal projections, with minimal magnification or distortion of bone length. In case of comminuted fractures, radiographs of the contralateral intact bone may be more useful for preoperative planning. The length and diameter of the nail to be inserted can be estimated by overlaying the radiograph with a transparent plastic sheet with the outline of the nail templates printed on it. When using digital radiography, it is necessary to use an internal radiographic marker of known length for calibration of the radiographic magnification, and to import digital templates of the nails for planning.[18]

In case of diaphyseal fractures that are near to the metaphysis, there must be sufficient bone available for seating of the nail and the locking bolt(s), without invading the adjacent joint. Some juxta-articular fractures will not be suitable candidates for interlocking nailing because there is insufficient bone stock for implant fixation. In these cases, alternative means of fixation such as bone plating or hybrid external fixation may provide better stability.

An open surgical approach using appropriate aseptic surgical technique is needed for insertion of the interlocking nail and

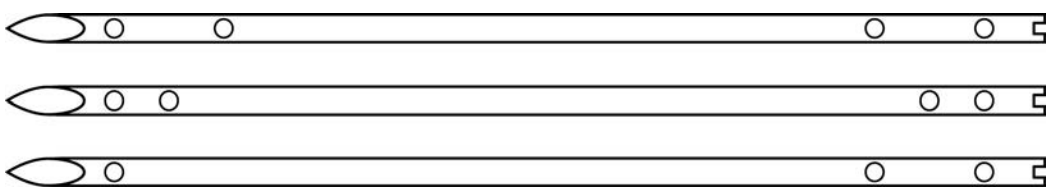

Figure 50-1. Interlocking nails for stabilization of canine and feline fractures have a trocar point for insertion, and one or two holes at each end of the nail for locking.

screws. The extent of the surgical exposure required is influenced by factors such as ease of fracture reduction, the volume of musculature in the region, and how readily the bone can be palpated. Fluoroscopically guided closed nailing of tibial fractures is possible, but closed nailing of femoral fractures in dogs is more challenging. Even if a closed nailing is performed, it will be necessary to make some limited incisions over the proximal and distal ends of the bone for insertion of the nail and locking bolts. Bone holding forceps can be applied to bone through these incisions as well, to allow alignment of the fractured bone. Axial traction is applied to the bone using these bone holding forceps to obtain fracture reduction. For fractures in the metaphyseal region, indirect traction by ligamentotaxis is applied. As far as possible, direct exposure of the fracture hematoma and elevation of the soft tissue attachments of the fractured bone fragments should be minimized.

A small diameter Steinmann pin held in a Jacob's chuck is introduced into the medullary canal to establish axial alignment of the fractured bone. Normograde insertion of the pin is recommended for femoral and tibial fractures. The pin is introduced into the femur through the trochanteric fossa. In the tibia, it is inserted into the proximal end of the bone through a cranio-medial surgical approach, at a point half way between the tibial tuberosity and the medial collateral ligament. In humeral fractures, either retrograde pin insertion from the fracture site or normograde insertion from the greater tubercle is equally appropriate and safe. The opening in the medullary canal can be progressively enlarged by the sequential insertion of Steinmann pins of progressively larger diameter. Alternatively, the medullary cavity can be opened with a reamer. The reamer should only remove cancellous bone from the metaphyseal region. Aggressive reaming of the endosteal cortical bone in the diaphysis should not be performed because cortical bone is much thinner in dogs and cats than in humans. In humans, extensive reaming of the medullary canal is often performed to improve the mechanical performance of an interlocking nail because a large diameter, stiffer nail can be used that is more resistant to fatigue and breakage. However, on the other hand, reaming can cause fracturing of the diaphyseal cortex and damage to the medullary bone blood flow with consequential delayed or nonunion of the fracture.

In preparation for insertion of the nail, an extension piece is attached to the end of the nail (Figure 50-2). The flanges on the end of the nail must interdigitate with those on the extension piece, and the connection is secured by tightening of the threaded, internal spindle with a hexagonal screw driver. The insertion handle is then attached to the extension piece, and used in a manner similar to a Jacobs chuck to drive the nail into the medullary cavity (Figure 50-3). The nail has to be inserted by normograde technique because only one end of the nail has a trocar point. Care should be taken to ensure that the nail is adequately seated into the distal metaphysis of the bone, without accidentally going too far and penetrating the articular cartilage surface of the joint. Depth of penetration is judged by overlying a second nail of the same length, or with intra-operative fluoroscopy. After the nail is inserted, do not attempt to correct any offsets in the fracture reduction by the application of bone holders or cerclage wiring, until after the locking bolts have been inserted. Clamps or cerclage wires placed across the fracture can result in slight bending of the nail which may in turn result in inaccurate drilling and the locking bolts missing the holes in the nail.

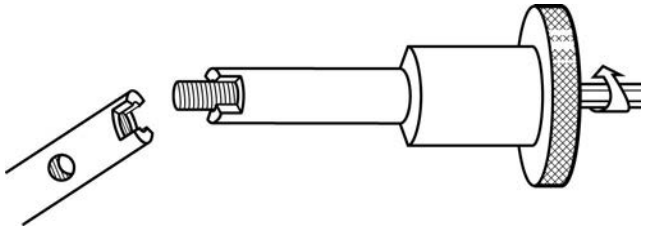

Figure 50-2. The extension piece has flanges that interdigitate with those on the end of the nail, and the connection is secured by tightening of an internal spindle.

After the nail is seated, the insertion handle is removed and the drill aiming guide is attached to the nail extension piece (Figure 50-4). Accurate drilling of the holes is the most technically challenging part of the procedure, and can be the greatest source of intra-operative frustration. Inaccurate drilling can result in the locking bolt being inserted adjacent to the nail, rather than through it. A tissue protection sleeve is inserted into the drill aiming guide in a position that corresponds to one of the distal nail holes. Then the appropriate drill guide is inserted, and a hole is drilled though the bone and the hole in the nail. Sharp drill bits with a "stick-tight" point are used to minimize the risk of the drill migrating to one side of the bone. Particular care is taken when the drill is entering the periosteal surface at an acute angle, as it has a tendency to migrate "down-hill". The diameter of the drill hole is the same as the shaft diameter of the locking bolt. The bone diameter is measured with a depth gauge, and an appropriate length locking bolt is inserted. After the two distal locking bolts have been inserted, the fracture alignment is corrected with respect to bone length and torsion with reference to anatomical landmarks. The proximal locking bolts are then inserted, and the drill aiming guide and extension piece are removed (Figure 50-5). If possible, two locking bolts should be inserted into the proximal and the distal fragments. Careful planning is needed to ensure that there are no empty holes in the nail near the fracture zone because of the risk of nail breakage. Additionally, the minimum distance from the fracture zone to the locking bolts should be 2 cm or more.

Adjunctive fixation is not required unless there are cortical fissures in close proximity to the locking bolts in which case cerclage wire can be applied. Generally comminuted fracture fragments are not disturbed. Autologous cancellous bone graft harvested from the proximal metaphysis of the humerus or tibia should be inserted at the fracture site in adult dogs if an open fracture reduction has been performed. In case of massive bone defects, large quantities of bone graft can be harvested from the wing of the ilium by using an acetabular reamer (BioMedtrix, Boonton, NJ).

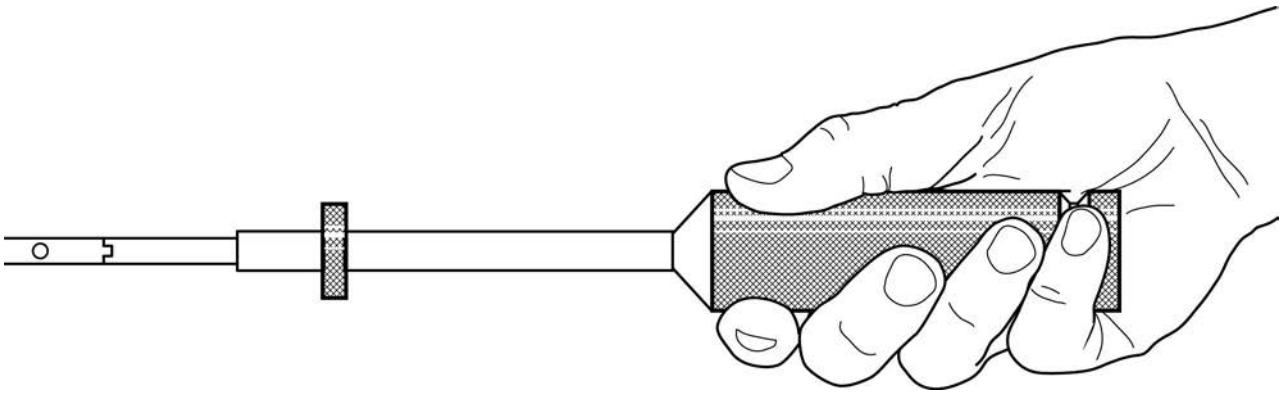

Figure 50-3. The insertion handle is attached to the extension piece, and used to drive the nail normograde into the medullary cavity.

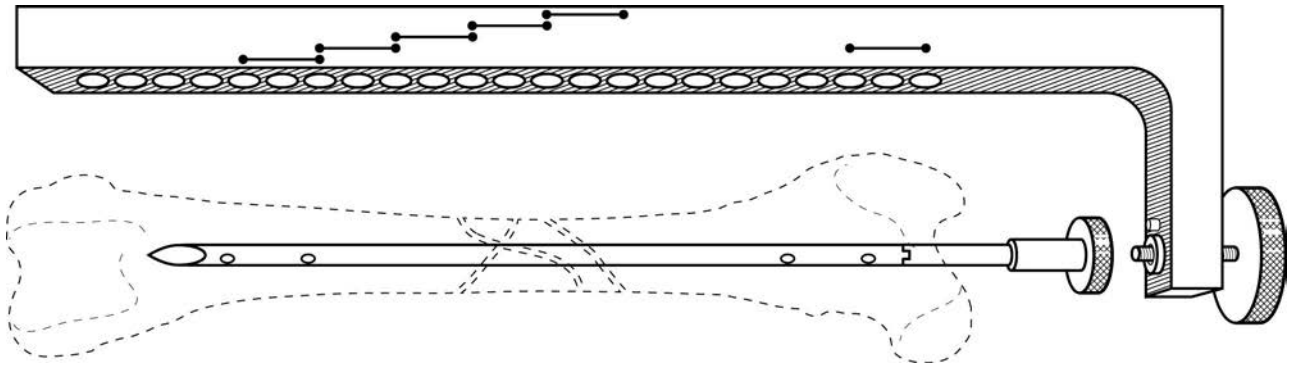

Figure 50-4. The drill aiming guide is attached to the end of the nail during surgery for accurate targeting of the drill holes into which are inserted the locking bolts.

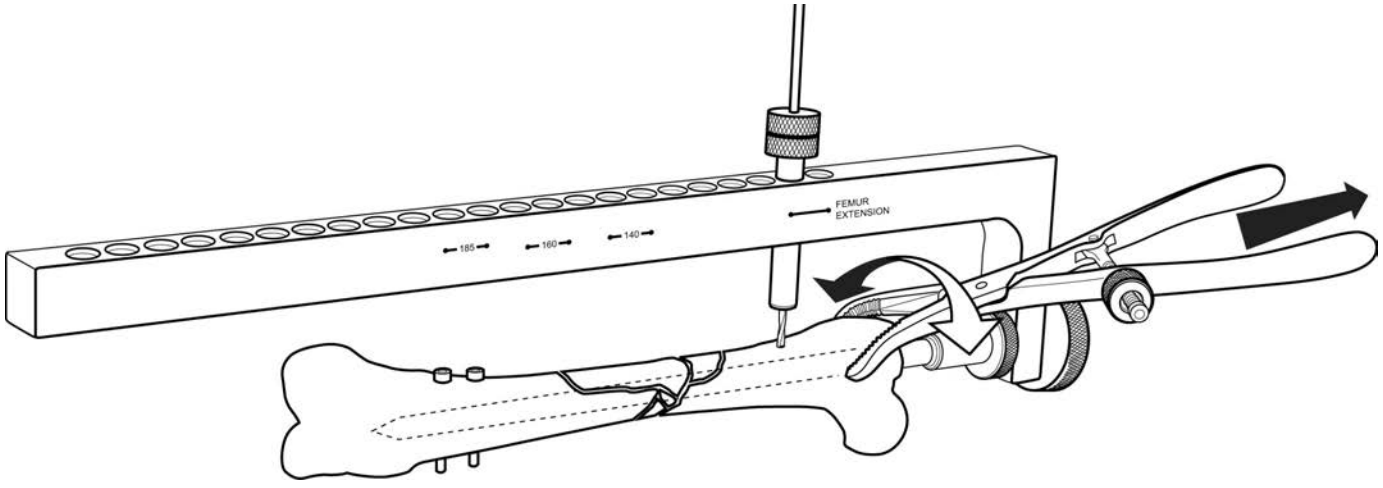

Figure 50-5. After the nail is locked into the distal fragment, alignment of the fracture is corrected for overall length and torsion, and then locked with the insertion of two proximal locking bolts.

Specific Fractures

Femur

Insertion of the nail by normograde technique in the trochanteric fossa allows it to be lateralized and thus avoid damage to the femoral head and coxo-femoral joint. The nail can be inserted by blind insertion through the gluteal muscles, or under direct visualization. The trochanteric fossa is exposed by transecting the tendon of the superficial gluteal muscle and retracting it proximally, and cranial retraction of the middle and deep gluteal muscles. Care is taken to avoid iatrogenic damage to the sciatic nerve that lies just caudal to the hip joint. Normally the femoral diaphysis of dogs has a cranio-caudal bend, or procurvatum. To overcome this curvature, two piece diaphyseal fractures may need to be axially aligned in slight recurvatum to allow the nail to be adequately seated in the distal metaphysis and condyles of the femur. In comminuted fractures in which anatomic reduction of the fragments is not the goal, this curvature is not an important factor in determining nail placement. In cats, the femoral diaphysis is generally quite straight, and can readily accommodate a small diameter nail without loss of normal bone alignment.

For more distal diaphyseal fractures, the nail can be introduced into the femur from the intercondylar notch and driven proximally. This allows the nail and locking bolts to engage more of the bone in the femoral condyles, and thus improve the stability of the fixation. Depending on the diameter of nail, and the amount of curvature in the femur, the nail may also be introduced through the articular cartilage surface at the very distal extent of the trochlear groove. However, it is important that the end of the nail is buried below the joint surface so it does not interfere with the patella. As an additional refinement to this technique, the buried end of the nail can be covered with a osteochondral plug that has been cut out of the trochlear groove with a bone trephine, prior to insertion of the nail.

Humerus

Fractures of the humeral diaphysis can be repaired via a limited lateral surgical approach to the diaphysis. It is not necessary to mobilize the brachialis muscle and radial nerve to the same extent needed for lateral bone plate fixation. For normograde insertion, the nail is started cranially on the ridge of the greater tuberosity, with the shoulder placed in slight flexion. It is not started on the most proximal point of the greater tuberosity because the inherent curvature of the humerus may prevent it from being adequately seated into the distal fragment. Alternatively the medullary canal can be reamed retrograde from the fracture site. Most humeral shaft fractures involve the distal one third of the diaphysis, and having adequate bone stock in the distal fragment and medial condyle for nail insertion will be a major consideration. In the majority of these types of fractures only single screw fixation distally is possible and thus a nail with one screw hole distally will be selected to avoid leaving an empty screw hole at the fracture site. In very large dogs the distal end of the nail can be directed medially and seated into the medial part of the humeral condyle. As with all intramedullary devices, implants should not impinge on the olecranon fossa. Distal interlocking screws are inserted with care, as they may be very close to the radial nerve.

Tibia

Closed nailing of tibial fractures may be possible, especially with the aid of fluoroscopic guidance, because the bone fragments are readily palpable. The entry point for the nail on the tibial plateau is located half way between the tibial tuberosity and the medial collateral ligament, and several mm inside the medial cortex. This point is centrally located with respect to the axis of the medullary cavity, and just cranial to the articular surface and insertion of the cranial cruciate ligament. To begin, a small diameter Steinmann pin is inserted normograde from this point and directed distally, ensuring it remains inside the medullary cavity. This hole is then enlarged with the reamer. If difficulty is encountered, retrograde reaming from the fracture site is then performed, to try to meet up with the proximal reaming tract. The tibial diaphysis is sigmoid in shape and narrowest distally, so nail diameter will tend to be smaller than that used in the femur.

A longer extension piece is used in tibial fracture so that the connection with the drill-aiming device does not impact upon the femoral condyle and patella. Due to the longer work distances, it should be recognized that there is an increased risk of deviation of the drill-aiming guide that may result in the drill missing the distal holes in the nail.

Chapter 51

Fixation with Screws and Bone Plates

Screw Fixation: Cortical, Cancellous, Lag, and Gliding

Brian Beale

Cortical and cancellous screws are commonly used for fracture repair in small animals. Cortical screws are fully threaded and are designed for use in cortical bone (Figure 51-1). Cancellous screws are fully or partially threaded and are used where cortical bone is thin and cancellous bone predominates (Figure 51-1). Cancellous screws have a steeper thread pitch, deeper threads, and a thinner core as compared with cortical screws.

Partially threaded cancellous screws are generally not used in cortical bone because removal of the screw is difficult as bone grows around the unthreaded shank. Both types of screws can be used for different purposes, including lag screws, positional screws, and plate fixation screws.

Lag screws are used for interfragmentary compression of fracture fragments (Figure 51-2). Compression occurs if the screw engages the far cortex and glides in the near cortex adjacent to the screw head. Cortical screws are selected for stabilization of cortical fragments in the diaphyseal region of the bone. The

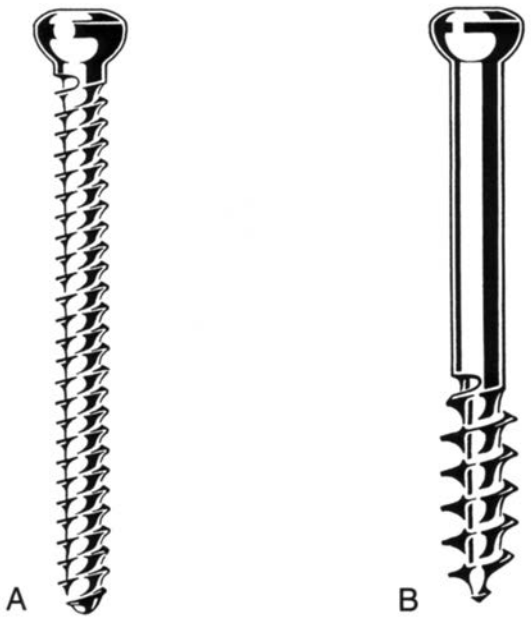

Figure 51-1. Cortical and cancellous screws. **A.** Cortical screws are fully threaded. The thread pitch is less steep as compared with cancellous screws to increase holding power in cortical bone. **B.** Cancellous screws can be fully or partially threaded and are used where cortical bone is thin and cancellous bone predominates. Cancellous screws have a steeper thread pitch and thinner core as compared with cortical screws.

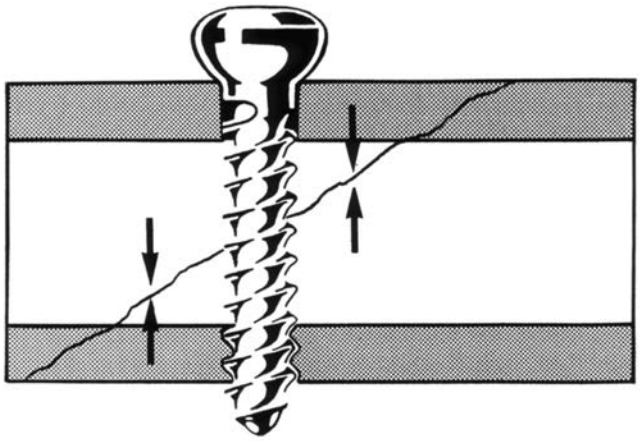

Figure 51-2. Screws can be used to provide interfragmentary compression. When using a fully threaded screw for this purpose, a glide hole must be drilled in the near cortex equal in size to the thread diameter of the screw.

fragments are reduced and are secured temporarily with an appropriate bone clamp. Predrilling of the guide hole or thread hole before reduction and temporary stabilization is sometimes advantageous because it allows accurate placement of the hole in narrow segments of the bone fragment. If predrilling is done, a pointed drill guide is used to align the predrilled hole with the opposite hole to be drilled. The use of cortical screws requires drilling of a glide hole in the near cortex, equal in size to the thread diameter of the screw, to prevent the screw from making purchase. Screw holes should be drilled in the center of the fragment to prevent shifting during tightening. The hole should be drilled in a direction that bisects the angle formed by perpendicular lines to the fracture line and the longitudinal axis of the bone in fragments having less than 40° inclination. If inclination of the fracture is greater than 40°, the hole should be drilled perpendicular to the fracture line. The holes should also be placed an adequate distance away from the edge and tip of the fragment to prevent fracture of the fragment at the screw hole. A countersink tool is optimally used in the near cortex to distribute loads transferred by the screw head to the bone more evenly, thus making fracture less likely. A drill sleeve (outer diameter equal in size to the glide hole, inner diameter equal in size to the thread hole) is inserted in the glide hole until it meets the opposite cortex. A thread hole equal in size to the core of the screw is drilled in the far cortex. A depth gauge is used to measure the length of screw needed. The selected screw should be 1 to 2 mm longer than the measured hole depth to ensure adequate thread purchase in the far cortex. The hole is carefully threaded with the appropriate tap. The surgeon must insert the tap at the same angle as the drill bit and must avoid excessive wobble during tapping to prevent stripping or microfracture of the screw hole. The appropriate screw is then inserted and tightened. Overtightening can lead to stripping of the screw threads or fracture of the bone fragment; appropriate tightness can usually be attained by grasping the screwdriver with the thumb and the first two fingers, instead of the entire hand, when tightening.

Cancellous screws are often used to stabilize fragments in the metaphyseal or epiphyseal regions (Figure 51-3). When using

cancellous screws in lag fashion, a glide hole is not needed if partially threaded screws are used. The smooth shaft should traverse the near fragment completely. Compression does not occur if screw threads engage the near fragment. The diameter of the hole in both cortices should be equal to the diameter of the core of the screw. Predrilling one fragment is often helpful for alignment of the hole in the center of the fragment. The fragments are reduced and temporarily are stabilized with a bone clamp. The hole is drilled, measured and tapped. Tapping of the hole is optional; it is often helpful to tap only the first few millimeters of the hole to assist with insertion of the screw. Pullout strength of these screws is enhanced if the entire length of the hole is not tapped. The screw is inserted and is tightened as described earlier for cortical screws.

Positional screws can be placed to hold fragments in alignment while a method of primary stabilization is applied. Small cortical fragments can be secured to the diaphysis with a screw that engages the cortices of both fragments. A glide hole is not used; therefore, compression of the fragment does not occur. This type of application is useful when compression of the fragment is likely to lead to its collapse into the medullary cavity or shifting of the fragment out of reduction.

Plate fixation screws are used to fasten a plate to bone. Glide holes are not used unless compression of fragments beneath the plate is desired. Both cortical and cancellous screws can be used, depending on the region of bone. The screws glide in the holes of the plate, thereby compressing the plate against the bone.

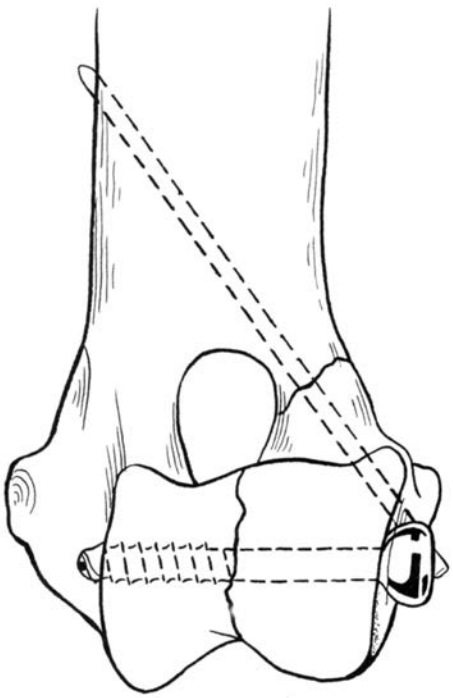

Figure 51-3. A cancellous screw and Kirschner wire are used for repair of a lateral condylar fracture of the distal humerus. When using cancellous screws in lag fashion, a glide hole is not needed if partially threaded screws are used. The smooth shaft must traverse the near fragment completely.

Application of Bone Plates in Compression, Neutralization, or Buttress Mode

Daniel A. Koch

This topic is written based on the available literature through 2010 and does not cover the most current literature on this topic.

Biology of Fracture Healing

Interfragmentary compression and internal fixation, leading to direct bone healing, have been the gold standard for treating long bone fractures in small animals for many years. Recent developments however, have led to the principle of biological fracture healing. It is characterized by minimal biological damage together with flexible fixation. The minimal biological damage is achieved by indirect reduction techniques and pure alignment of the fragments without the need for precise reduction. Maximal blood supply is preserved to avoid iatrogenic bone necrosis. Flexible fixation is achieved by wide bridging of the fracture zone using locked nails, bridge plating, internal or external fixators. Such fixation leads to indirect bone healing with callus formation.

Plate Function

If the surgeon is able to generate axial compression by the use of a tension device or with eccentric loaded screws, the plate functions as a compression plate. In most instances, this mode is only possible in simple transverse fractures. Whenever the internal fixation of a diaphyseal fracture consists of a lag screw or screws in combination with a plate (to protect the lag screw fixation), the plate functions in a neutralization mode. Such a

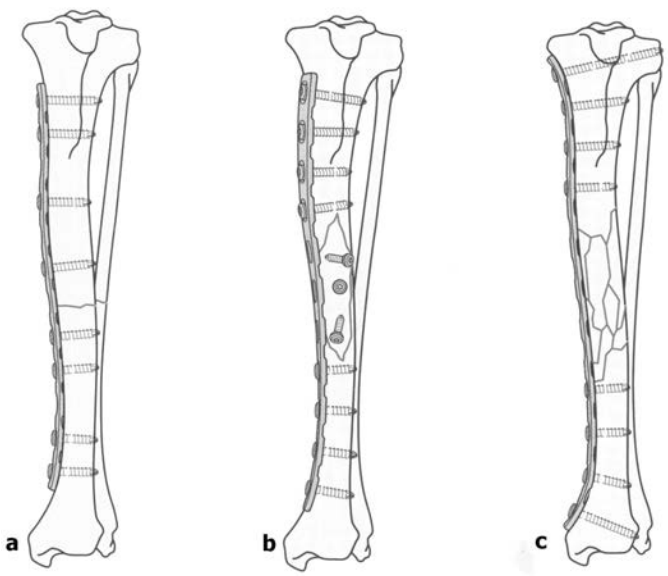

Figure 51-4. Plate function. **a.** transverse tibia fracture stabilized with a LC-DCP as a compression plate, **b.** long oblique fracture of the tibia reconstructed with lag screws and supported with a LC-DCP as a neutralization plate, **c.** comminuted non-reducible diaphyseal tibia fracture stabilized with a LC-DCP as a buttress plate. Figure 51-5. Dynamic compression principle. The horizontal movement of the screw head, as it impacts against the angled side of the hole, results in movement of the bone fragment relative to the plane, and leads to compression of the fracture. (Copyright c 2005 by AO Publishing, Switzerland. Originally published in "AO Principles of Fracture Management in the Dog and Cat". Thieme/AO Publishing, 2005)

plate protects the interfragmentary compression achieved with the lag screw or screws from all torsional, bending, and shearing forces. In comminuted fractures of the metaphysis or diaphysis, the application of axial compressive forces may lead to collapse and or angular deviation of the fractured bone. Lag screws can not overcome these forces. In order to prevent loss of bone length or proper alignment in comminuted fractures, it is necessary to supplement the fixation with a buttress plate. The function of the buttress (or bridging) plate is simply to prevent axial deformity as a result of shear or bending. This type of plate fixation is subjected to full loading. Therefore, every possible effort should be made to maintain all the soft tissue attachments and blood supply to the fragments, since healing will depend on the formation of a bridging callus rather than primary bone union. The proximal and distal ends of the plate ends must each be solidly fixed to the corresponding major bone segments by at least 3 screws. The addition of an intramedullary rod (plate-rod fixation) decreases the risk of plate fatigue by micromotion (Figure 51-4).

Dynamic Compression Plates

DCP

The dynamic compression plate (DCP; Synthes, Solothurn, Switzerland) was introduced in 1969. The veterinarian may chose from 4.5 mm (giant breed dogs), broad 3.5 mm (heavy and giant breed dogs), regular 3.5 mm (large dogs), 2.7 mm (medium and small dogs, cats) and 2.0 mm size (toy breed dogs, cats). The screw holes are best described as a portion of an inclined and angled cylinder. Tightening of a screw, which is inserted eccentrically at the inclined shoulder of the plate hole leads to movement of the bone fragment relative to the plate, and consequently, compression at the fracture site (Figure 51-5) The design of the screw holes allows for a displacement of up to 1.0 mm. Two eccentric screw insertions per fragment are possible. Depending on the application technique used, a DCP may function in compression mode, as a neutralization plate, or as a buttress plate.

LC-DCP

The limited contact dynamic compression plate (LC-DCP; Synthes, Solothurn, Switzerland) represents a further development of the DCP. Compared to the DCP, the area of the plate-bone contact (the plate "footprint") of the LC-DCP is greatly reduced. The capillary network of the periosteum is thereby less compromised, leading to a relative improvement of cortical perfusion, which reduces the osteoporotic changes underneath the plate. The geometry of the plate, with its structured undersurface, results in an even distribution of stiffness, making contouring easier, and minimizing the tendency to kink at the holes when bent. The plate holes are evenly distributed over the entire length of the plate, which adds to the versatility of application (Figure 51-6). The plate is available both in stainless steel and in pure titanium. Titanium exhibits outstanding tissue tolerance.

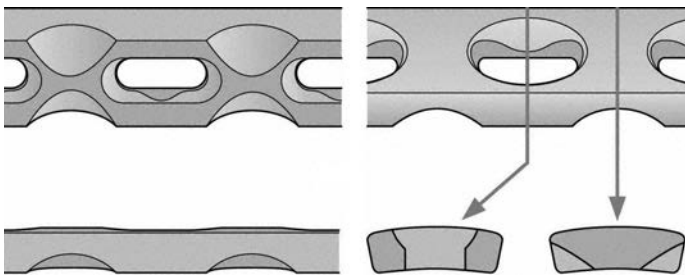

Figure 51-6. The LC-DCP with its scalloped undersurface for limited contact between plate and bone and even distribution of the holes throughout the plate. (Copyright© 2005 by AO Publishing, Switzerland. Originally published in "AO Principles of Fracture Management in the Dog and Cat". Thieme/AO Publishing, 2005)

Application Techniques

When using a 3.5 mm DCP or LC-DCP, the following steps are undertaken. The correct plate length and thickness is estimated from the radiograph. The plate is contoured with bending irons, bending pliers or a bending press. Special bending templates are available. Repeated bending is avoided, because this weakens the plate. The plate should be bent between the holes. The desired function of the screw must be determined (neutral or compression). The screw hole is drilled with the corresponding drill sleeve (standard or universal), which is slightly larger (2.5 mm) than the core of the screw (2.4 mm). The length is measured with the depth gauge. If the correct screw length is not available, the next longer screw is chosen. The hole is tapped (3.5 mm) and the screw is inserted with the screw driver (Figure 51-7).

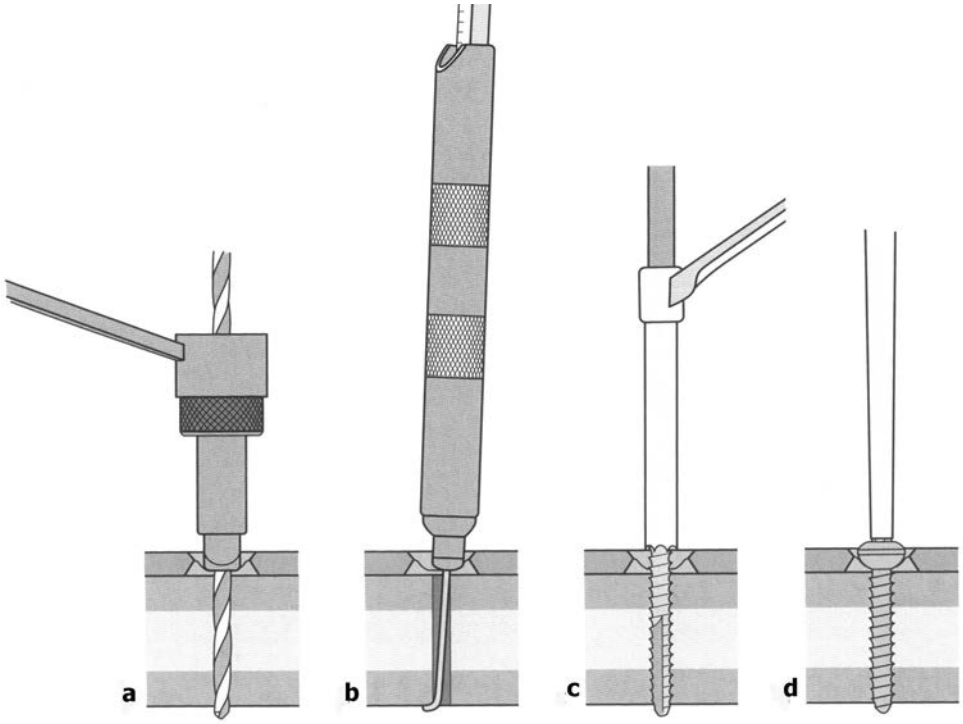

Figure 51-7. Application of a plate screw. **a.** Drilling of the hole in neutral position, **b.** measuring of the hole length, **c.** tapping, **d.** insertion of the screw. (Copyright c 2005 by AO Publishing, Switzerland. Originally published in "AO Principles of Fracture Management in the Dog and Cat". Thieme/AO Publishing, 2005)

As a rule of thumb, the following maximal forces on the screwdriver are recommended when inserting a plate screw: two fingers for a 2.0 mm screw, 3 fingers for a 2.7 mm screw and the whole hand for a 3.5 mm screw. For perfect force application, torque limiting screw drivers are available. Plate screws are applied first at the ends of the plate, then close to the fracture and finally, the remaining plate holes are filled. The screws are retightened until they are seated firmly.

Miniplates

The increasing demand for fracture treatment in cats and toy breed dogs and the ability of the veterinary surgeon, together with modern diagnostic aids, led to the development of small sized implants for stabilizing fractures in delicate areas such as the maxillofacial region.

The mini-fragment plates (Synthes, Solothurn, Switzerland) are designated for use with the 2.0 mm or 1.5 mm cortex screw. They are available as DCP, round hole plates, angled miniplate, T-miniplate or adaption plate. They are used in long bone fractures, mandibular fractures or pelvic fractures of toy breed dogs and cats (Figure 51-8).

The human Compact system (Synthes, Solothurn, Switzerland) was developed for hand and maxillofacial orthopedic surgery. The smaller sizes (1.0 mm, 1.3 mm and 1.5 mm) and varying plates are now available for veterinary use. The screws are self-tapping and are inserted with the stardrive screw driver. A similar system (Stryker, Kalamazoo MI, USA) is available with 1.3 mm, 1.7 mm and 2.3 mm plates and self-tapping screws, all made of titanium. It is especially helpful in feline orthopedics. The 2.3 mm system perfectly fits the demands, when long bones of cats or toy breed dogs are stabilized (Figure 51-9).

Special Plates

Reconstruction plates are characterized by deep notches between the holes that allow accurate contouring. The plate is considered not to be as strong as the compression plates, and

Figure 51-9. Application of a 2.3 mm plate on a feline radius. (Copyright© 2005 by AO Publishing, Switzerland. Originally published in "AO Principles of Fracture Management in the Dog and Cat". Thieme/AO Publishing, 2005)

may be further weakened by heavy contouring. The holes are oval, to allow for dynamic compression. These plates are especially useful in fractures of bones with complex 3-D geometry, as encountered in the pelvis, especially the acetabulum (See Figure 51-8). Veterinary T- and L-plates are available in different sizes from 2.0 mm to 3.5 mm (See Figure 51-8). Double hook plates are used in proximal femur fractures as well as for intertrochanteric osteotomies. Right and left triple pelvic osteotomy plates with different torque are available in 2.7 mm and 3.5 mm sizes. Tubular plates are useful in areas with minimal soft tissue coverage, such as the olecranon, distal ulna or the malleoli. In scapula fractures, the tubular plate can be applied with its convex surface laid against the scapula spine (See Figure 51-8).

Internal fixators

Biomechanics of internal fixators

The introduction of locking bone plate/screw systems has generated certain advantages in fracture fixation over other plating methods. Locking plate/screw systems are appropriately classified as internal fixators. The stability is given by the locking mechanism between the screw and the plate. The plate does not need to have intimate contact with the underlying bone, making exact plate contouring less crucial. Diminished contact between the plate and the bone may also preserve the periosteal blood supply, thereby reducing the extent of bone resorption under the plate. Internal fixators are used in neutralization or buttress mode. Bone healing under internal fixators is by callus formation (indirect healing).

Experimental studies have shown, that internal fixators offer greater stability than standard reconstruction plates without locking screws. The screws must only be inserted in the cis-cortex. This increases the versatility of internal fixators, which become extremely helpful in acetabular fractures, carpal or tarsal fractures, or in situations where double plating is indicated.

LCP and UniLock

For veterinary use, the locking compression plate (LCP) und the UniLock are available (Synthes, Solothurn, Switzerland). They both have a locking system with threads. The LCP has a so called combination plate hole, which can accommodate either a conventional screw or the new locking head screw. All standard AO plates from 2.7 to 4.5 are available with the combination hole (Figure 51-10). The UniLock comes as 2.0 mm or 2.4 mm system, together with locking screws, non-locking screws and emergency screws. All screws are self-tapping. The locking screws are inserted perpendicular to the plate. A special drill guide, which is screwed into the hole and centers the drill precisely, facilitates the locking mechanism between screw and plate (Figure 51-11).

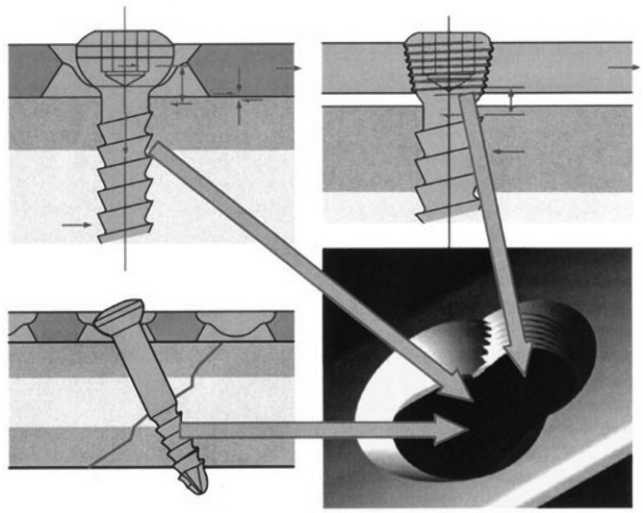

Figure 51-10. The LCP combination hole. One half has the design of the standard DCP for conventional screws, the other half is conical and threaded to accept the matching thread of the locking head screw providing angular stability and avoiding pressure between plate and bone. Technical failures and their Prevention

Some common factors leading to technical failures and strategies to avoid them are listed below. Technical failures are usually due to incomplete assessment of the fracture patient, which in turn leads to suboptimal fixation.

Consider the following factors before performing osteosynthesis:

- Animals, which sustain injuries on more than one limb, need more stable fixations than those, which are able to protect a single limb injury by non-weight bearing.
- In case of an infected and unstable fracture, rigid fixation is mandatory.
- Whenever possible, the least invasive treatment is chosen.

Consider the following factors during osteosynthesis:

- Inadvertent stripping of the bone or detachment of muscles from fragments should be avoided. It is important to preserve as much blood supply as possible to enable optimal fracture healing.
- While using power equipment, cooling with isotonic solutions is mandatory to prevent heat necrosis on the bone and subsequent loss of fixation at the implant-bone interface.

Consider the following factors after osteosynthesis:

- Postoperative resorption at the fragment ends, which were anatomically reduced, are mostly due to the fact, that plate osteosynthesis was not rigid enough for direct or indirect bone healing. Due to the strain theory, the fracture gap must be widened and callus formation will start.
- Implant related stress protection of a healing bone can lead to bone resorption and osteoporosity. Therefore, implants should be removed, as soon as clinical fracture healing has been completed.

The SOP Locking Plate System

Karl H. Kraus and Malcolm G. Ness

Introduction

The SOP (String of Pearls) was designed to serve as a locking plate system for the veterinary and human orthopedic community. As with all locking plate systems, the SOP can be thought of mechanically as internal – external fixators. The SOP consists of a series of cylindrical sections ("internodes") and spherical components ("pearls"). There are three system sizes which accommodate 3.5 mm, 2.7 mm and 2.0 mm screws. The cylindrical component, or internode, has an area moment of inertia greater than the corresponding standard DCPs. Mechanical testing using ASTM standards has demonstrated that the 3.5 SOP is 50% stiffer, and has a bending strength (load at which the plate plastically bends) of 16 to 30% greater than the 3.5 mm LCP, DCP, or LC-DCP.

The SOP can be contoured in six degrees of freedom; medial to lateral bending, cranial to caudal bending, and torsion using specially designed bending irons (Figure 51-12). Properly performed, contouring results in bending or torsion at the internode, preserving the locking function of the pearl. Mechanical testing has demonstrated that although bending a SOP will reduce its stiffness and strength by approximately one third, a SOP bent through 40 degrees remains almost (96%) as stiff as an untouched 3.5 DCP. Similarly, a SOP twisted through 20 degrees remains significantly stiffer than the new and untouched 3.5 DCP.

The spherical component of the SOP accepts a standard cortical bone screw. There is a section of standard threads within the spherical component, and a section into which the head of a standard screw recedes. As the screw head recedes into the spherical component, it comes into contact with a ridge causing the screw to press fit into the pearl. This press fitting prevents loosening of the screw during the cyclic loading of weight bearing, and results in a very rigid screw/plate construct. This concept removes critical limitations of locking plate designs employing a hole with either single, double, or conical threads. The larger diameter part of the pearl receives a drill/tap guide

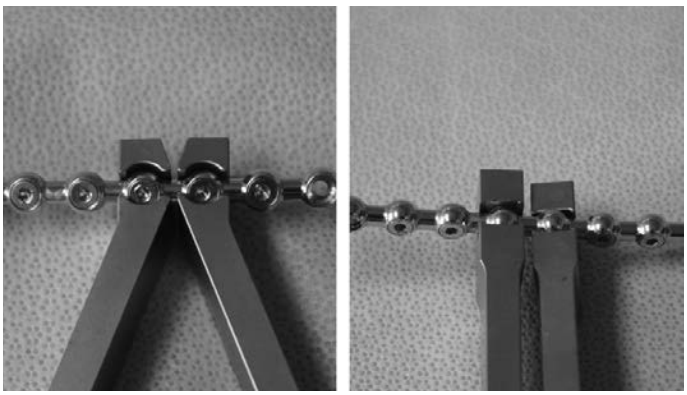

Figure 51-12. The SOP can be contured in six degrees of freedom; medial to lateral bending, cranial to caudal bending, and torsion using specially designed bending irons.

and allows drilling, measuring with a depth gauge, and tapping of the screw hole, with familiar ORIF instrumentation (Figure 51-13). The circular cross-section of the implant and the increased diameter of the pearls in comparison with the internodes gives the implant a relatively consistent stiffness profile – the screw holes are not notable "weak points". The larger size of the pearl protects it against deformation during contouring or load bearing. The use of inserts ("golf tees") placed into the pearls protects the pearl absolutely and preserves locking function completely during contouring.

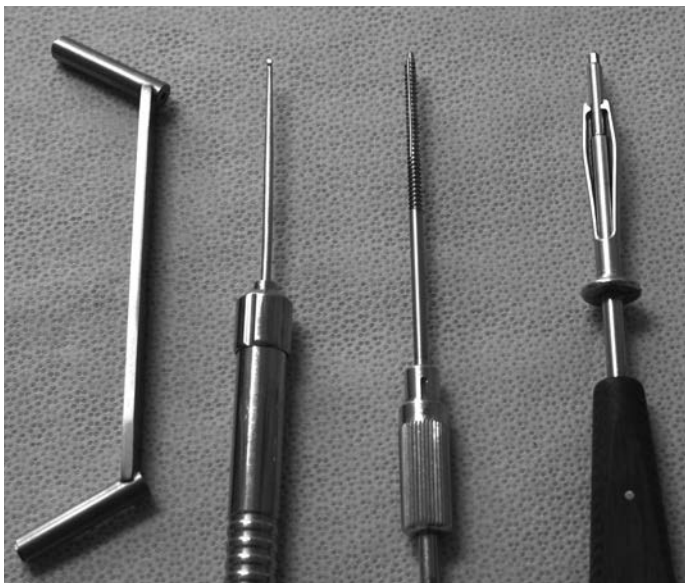

Figure 51-13. The larger diameter part of the spherical component of the SOP receives a drill/tap guide and allows drilling, measuring with a depth gauge, and tapping of the screw hole, with familiar ORIF instruments.

There is theoretical potential for the screw to cold weld, making it difficult to remove. However, this has not been seen in practice but should it happen, a section of the plate can be simply cut through an internode using a bolt cutter and the offending section removed.

Not all screws are alike. The SOP is designed to be used with high quality screws manufactured to standard tolerances for screw head and thread sizes. Self tapping screws must have triple flutes so that consecutive screws will tap without lifting the plate away from the bone. Inferior screws with unconventional design or loose manufacturing tolerances are becoming more common in veterinary orthopedic surgery as most orthopedic companies outsource screw production. Such screws may not have sufficient quality control to work in the SOP system. For this reason orthopedic screws from the supplier of the SOP should be used, or if using them from another supplier they should be tested in the SOP to assure compatibility.

Biomechanics

The biomechanics of interlocking plate systems differs fundamentally from conventional bone plates – extrapolation of experience gained using non-locking, DCP systems, is not always appropriate. Screws in conventional bone plates press the plate onto bone as the screw is tightened. The threads of the screw pull and slightly deform the bone that the threads engage. As bone is viscoelastic and remodels, the pull lessens over the first several minutes after installation due to bone relaxation, then over the next period of days and weeks due to remodeling. Oval holes allow dynamic compression and load sharing since the screw can move slightly along the long axis of the plate. The screw can pivot in the hole of the plate.

In contrast, locking systems, including the SOP, will function invariably as "buttress" systems – even when they are applied to an anatomically reconstructed fracture. The screws of interlocking plates act as transverse supporting members, subjected to cantilever bending. The primary loads on bone during weight bearing are axial, along the long axis of the bone. Axial loads of a bone encounter a screw and the load is transferred at the bone/screw interface to the screw, then to the plate, then back to the screw on the other side of the fracture, then to bone. Here, there is no pulling of the plate down to the bone so the resistance to pullout of a screw is less relevant. Importantly, the screw is integrally and always part of the transmission of forces across areas of fracture. Locking plate systems rarely utilize dynamic compression, and are acting as buttress devices. The result of die back of bone in the initial healing phase, and the reliance upon lag screws, wires or other mechanically inferior components within the reconstruction means that even where load sharing is achieved at surgery, locking systems invariably function in buttress mode.

With the difference in transmission of forces across the area of fracture, pullout strength of bone screws becomes far less important, making locking screw systems preferred choices in cancellous or osteoporotic bone. Conversely, the fatigue life of the screw/plate interface increases in importance. Clinically, this is of relatively less importance in engaging two cortexes with a bone screw, and much greater importance in increasing the number of bone screws, unicortical or bicortical, to enhance fatigue life. However, while adding a unicortical screw may be of limited benefit with conventional plates, unicortical screws within a locking system function effectively and are appropriate.

This highlights an important mechanical feature of all interlocking plate systems including the SOP. Specifically, there is a distinct stress riser at the screw/plate interface where forces are transferred from a less stiff element (the screw) to a much stiffer element (the plate or SOP). If excessive force is cyclically applied across the fracture, the shaft of the screw will cold work and become brittle. The yield point from elastic to plastic deformation will become less, and cracks will develop and propagate across the screw. This is fatigue failure and ultimately the screw will break. Theoretical considerations suggest that 4 screws in each major fragment is appropriate to protect the screws against fatigue failure. The cross sectional area of the SOP is pi r^2 or 20 mm^2. That of the shaft of a screw is about 5 mm^2. Therefore, by installing four screws on either side of the fracture the shear area of the screws will approximately equal that of the SOP. Again, the screws may be unicortical. This may be achieved by application of an additional SOP for example if the distal segment is short. A second SOP can be on the contralateral or orthogonal

side of the bone, or two SOPs can be nested side by side. The use of an intramedullary pin (SOP-rod technique) enhances the stiffness of a construct to an extent which is not appreciated by many surgeons. This increased stiffness substantially protects implants and protects against fatigue failure. The use of SOP in pairs (for example, in the spine) or in conjunction with a rod (for example, in long bone fractures) should be considered the norm.

Bone slicing is a potential problem associated with the use of locking systems in poor quality bone. With conventional plating systems applied to weak cancellous or osteoporotic bone, screw pullout is the critical factor. However, with locking screw systems screws cannot pullout, especially if there is some divergence or convergence with screws. Instead, failure will occur through slow creep of the screw through the weak bone, known as "bone slicing." Therefore, as locking plate systems are preferred in weak or osteoporotic bone, they may still exhibit this mode of failure if the bone / implant system used is not sufficiently robust. Bone slicing has not been identified in SOP cases so the importance of this phenomenon in veterinary patients is not yet known.

Application Techniques: Appendicular Skeleton

The primary utility of the SOP in the femur, humerus, tibia, radius, and ulna is in comminuted fractures. Although the SOP can be used in conventional "open approach" fracture surgery, it is especially valuable with biologic fixation methods and minimally invasive techniques. For example, techniques involving SOP and screws installed with stab incisions or mini approaches, or more open approaches where the area of comminution is preserved. The comminuted, diaphyseal femoral fracture will be used as an example of standard SOP methods (Figure 51-14).

Figure 51-14. An example of standard SOP methods for repair of a comminuited, diaphyseal femoral fracture.

Comminuted diaphyseal femoral fractures are best repaired using the SOP in combination with under sized intramedullary pins, also known as a Rod and Beam fixation. A standard surgical approach appropriate to the specifics of the fracture is made. An intramedullary pin of 1/3rd to 1/2 the diameter of the medullary cavity is placed normograde from the intra-trochanteric fossa, threading the area of comminution, into the distal femoral segment. The limb is aligned with reference to adjacent anatomical landmarks. In the femur the coxofemoral joint should be in slight anteversion while the stifle is flexed. An elevator is passed along the lateral aspect of the femur, under the biceps and vastus. Inserts should be placed into the SOP holes before contouring to prevent distortion of the holes. An SOP of appropriate length is contoured: it is helpful to have radiographic images of the opposite, un-fractured femur to guide the contour. The contour does not have to be perfect, as the SOP does not need to lie directly on bone. The distal aspect of the SOP can be contoured to follow the femoral condyles caudally and the proximal SOP can be twisted directing the screws antegrade to the femoral neck. The SOP is placed in the soft tissue tunnel, and contour is reviewed. Four screws should be engaged on each side of the fracture. Unicortical screws are appropriate and "empty" screw holes – even over the fracture – are acceptable. The IM pin will prevent bending of the SOP, so there may be a long area without screws in the center of the femur.

The drill guide is placed into a screw hole on one end of the bone and the remaining screw holes observed to make sure the SOP is positioned properly. Remember that the screw will always be directed perpendicular to the spherical component of the SOP. Though you can twist the SOP to change screw direction, this is done prior to installation of screws. The drill and tap guide will direct the drill and tap in the proper direction. The insert is removed from the SOP at the first screw location, either proximal or distal. The drill hole is made using the drill guide, then the depth is measured. A screw is placed. Standard or self tapping screws can be used according to surgeon preference. It is possible for the tap/self-tapping screw to not engage the bone hole immediately. This results in the SOP being pulled too far away from the bone. This can be prevented by applying gentle axial pressure during early placement of the tap/self-tapping screw. Note also that when using a bone tap, care must be taken subsequently when placing the screw to ensure that the screw threads engage in the bone as desired, and not 360° later. The screw should be tightened so that the screw head seats firmly into the spherical component of the SOP. If a unicortical screw is placed, the depth gage measures the minimal length the screw needs to be by the standard method of hooking the near cortex. Then the depth gage is advanced to the trans cortex or, in some cases, the intramedullary pin. A screw 0 to 2 mm longer than the measured minimum distance is chosen. Measuring the distance to the transcortex or intramedullary pin will assure that an oversized screw will not interfere with any structure. The same procedure is repeated for all screws.

Applying a SOP is similar to standard ORIF principles and procedures with these notable exceptions. First, the SOP does not need to lie directly on the outer cortical surface. It should be placed close to the bone to keep its profile as low as possible, but might

contact the bone in a few locations or not at all. This preserves the periosteal blood supply of the bone and healing callus. The screw will tighten into the plate, this does not assure that the screw is in solid bone. However, locking screws are better for soft or osteoporotic bone as screw thread holding power is not the method of transmission of forces. Some divergence of screws is desirable. The SOP can be contoured in six degrees of freedom. It is possible, and sometimes desirable, to contour the SOP in non-standard shapes, to follow the fracture configuration or tension surface of a bone. The SOP can be contoured into a spiral for example.

Technical Guidelines

Note that these are guidelines and not rules. They are provided to experienced, knowledgeable and sensible surgeons with the assumption that such experience, knowledge and common sense will be brought to bear on each individual case.

Femur

SOP-rod:
IM pin 20%-40% diameter of medullary canal,
  Normograde or retrograde
  Open or closed placement
4 screws in distal and 4 screws in proximal fragments
Single 2.7 SOP (plus rod) in patients up to 10 kg (lateral aspect)
Single 3.5 SOP (plus rod) in patients up to 35 kg (lateral aspect)
Double 3.5 SOP (plus rod) in patients over 35 kg (lateral aspect)

Humerus – diaphysis

SOP-rod:
IM pin 20%-40% diameter of medullary canal,
  Normograde or retrograde
  Open or closed placement
  Bed into medial epicondyle
  Consider reverse placement through medial epicondyle in very distal fractures
4 screws in distal and 4 screws in proximal fragments
Single 2.7 SOP (plus rod) in patients up to 10 kg (medial aspect, lateral aspect or "spiral")
Single 3.5 SOP (plus rod) in patients up to 35 kg (medial aspect, lateral aspect or "spiral")
Double 3,5 SOP (plus rod) in patients over 35 kg. (medial aspect, lateral aspect or "spiral")

Humerus – elbow "Y" or "T"

Combined medial and lateral approaches or transulnar approach (Figure 51-15)
Anatomic reconstruction with lag screws, K wires etc
Two SOPs, one medial and one lateral
Total of 4 SOP screws in reconstructed condylar fragment (not necessary to have all 4 screws in the same SOP)
Total of 4 screws in proximal major fragment (not necessary to have all 4 screws in the same SOP)
Two x 2.7 SOPs in patients up to 20 kg
Two x 3.5 SOPs in patients over 35 kg

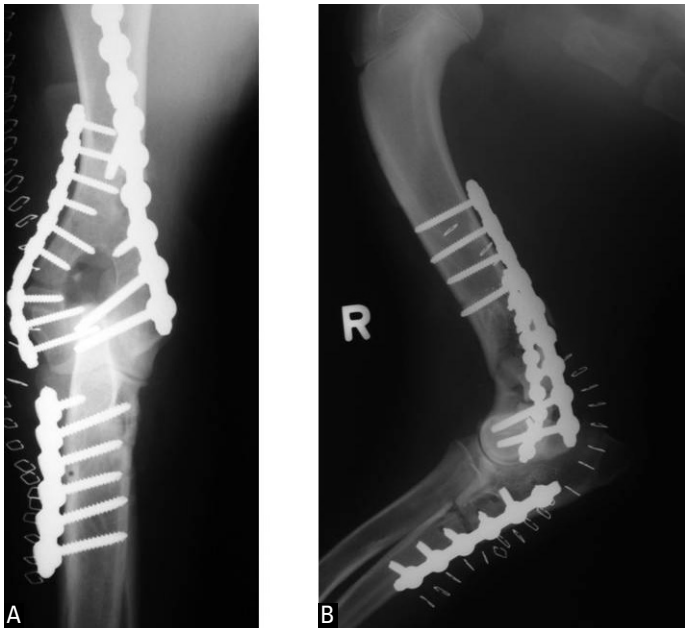

Figure 51-15. Combined medial and lateral approaches **A.** or transulnar approach **B**.

Tibia – diaphysis

IM pin 20% to 40% diameter of medullary canal,
  Normograde
4 screws in distal and 4 screws in proximal fragments
Single 2.7 SOP (plus rod) in patients up to 10 kg (medial aspect)
Single 3.5 SOP (plus rod) in patients up to 35 kg (medial aspect)
Double 3.5 SOP (plus rod) in patients over 35 kg.(medial aspect)

Ulna – Radius

Small IM pin in ulna
  Normograde or retrograde
SOP on radius
4 screws in proximal and 4 screws in distal fragment
SOP on medial or dorsal aspect distally
SOP on cranial aspect proximally
Avoid overlong screws transfixing radius and ulna
2.7 SOP in patients up to 10 kg
3.5 SOP in patients over 10 kg

Spine – Fractures or Distraction-fusion

The SOP serves well as a locking spinal fixation system, much like a pedicle screw system or locking cervical fusion devise (Figure 51-16). It does not lag onto bone which accommodates irregularities of the vertebral column. The SOP is applied to the dorsal lateral aspect of the spine, directing the screws at 30 to 40 degrees from the mid saggital plane into the vertebral bodies. Two SOP plates are applied to the left and right sides of the spine. With vertebral luxations, two three hole SOPs are applied with four screws engaging the vertebral bodies on either side of the luxation. With vertebral fractures and instabilities, longer plates are applied and may engage two vertebrae on either side of the instability. As the SOP is not lagged onto bone, the irregularities do not pose a problem as seen in applying standard orthopedic plates. The cylindrical shape lies on the pedicle and avoids compression of nerve roots exiting the intervertebral foramen.

Figure 51-16. The SOP serves well as a locking spinal fixation system, much like a pedicle screw system or locking cervical fusion device.

As the angle of screw placement is greater in the thoracolumbar area compared to the lower lumbar area, the SOP can be twisted to vary the screw angles.

The SOP can be used for cervical fracture repair, or cervical fusion in cases of instability. Two SOPs are applied to 4 adjacent vertebrae. In this way a minimum of 4 screws are on either side of the fracture or instability. The screws are directed slightly laterally. The screws need not penetrate the vertebral canal. It is important to direct the screws without damaging the spinal cord, nerve roots, venous sinus, or vertebral artery.

Always use SOPs in pairs

Cervical – ventral aspect of vertebrae

Thoracic, T-L, Lumbar - SOPs bilaterally on lateral aspects with screws directed ventro – medially

Lumbo-sacral – bilateral SOPs with screws directed ventro-medially into lumbar vertebral bodies. Caudally the SOP can be twisted and contoured to engage the iliac shaft.

Minimum of 3 scews in each vertebral body (not necessary to have all screws in the same SOP)

Use longest possible screws to engage maximum amount of vertebral bone

Penetration of far cortex is not essential but should be performed when possible

Stand SOP off spine to avoid damage to emerging nerve roots

2.7 SOP in patients up to 10 kg

2.7 and 3.5 SOPs can be used in combination

Pelvis

SOP can be used successfully in most pelvic fractures. The reconstructed pelvis is inherently fairly stable by virtue of its shape and extensive musculature. Potentially disruptive forces tend to be very much smaller than those encountered in long bone fractures. Consequently, pelvic implants can be relatively smaller than those needed for long bones and, similarly, pelvic fracture fragments can often be effectively stabilized with relatively few screws.

Ilium

Gluteal roll-up approach – can be extended caudally by trochanteric osteotomy

SOP applied to lateral aspect of pelvis

Minimum 2 screws cranial and 2 screws caudal

Twist SOP cranially to optimise stability in thin bone

2.7 SOP in patients up to 20 kg

3.5 SOP in patients over 15 kg

Two SOP plates nested whenever possible (Figure 51-17)

Acetabulum

Open reduction and temporary fixation with K wires, bone forceps etc.

SOP applied to dorsal aspect of acetabulum (Figure 51-18).

Minimum 2 screws cranial to fracture and 2 screws caudal to fracture

Single locked screw in stable butterfly fragment is acceptable

2.7 SOP in patients up to 35 kg

3.5 SOP in patients over 35 kg

Miscellaneous Applications

SOP has been used successfully in a variety of other situations including shoulder arthrodesis, pan-tarsal arthrodesis, augmentation of TPLO and TPO procedures and in the revision/salvage of failed fracture and arthrodesis surgeries. The information provided in these guidelines and the recommendations given for "standard" cases will provide the surgeon with a starting point for implant selection and surgical planning in non-routine applications.

Chapter 52

Plate-Rod Fixation

Application of Plate-Rod Constructs for Fixation of Complex Shaft Fractures

Donald A. Hulse

Introduction

Bone healing occurs by direct or indirect union. Direct bone union is characterized by remodeling of existing haversian systems through simultaneous bone resorption and bone deposition. Indirect bone union occurs through the sequential deposition of tissues with increasing mechanical strength: immature connective tissue - fibrocartilage - woven bone. Another method of indirect bone union, and possibly the mechanism associated with indirect fracture reduction techniques, is by omitting the stage of fibrocartilage deposition proceeding directly to the formation of woven bone. For either direct or indirect bone union to occur, certain biologic and mechanical events must be satisfied. Biologically, adequate vascular supply and appropriate histochemicals (BMP, growth factors) are needed to support existing bone cells and provide stimulus to differentiate pluripotential cells. Mechanically, the fixation must be strong and stiff enough to prevent excessive micromotion (strain) at the fracture interface but allow sufficient micromotion to stimulate bone formation. To satisfy mechanical conditions, surgeons often choose to apply a neutralization plate or a compression plate to provide interfragmentary compression. Coupled with atraumatic technique conditions are met to achieve direct bone union and an early return to clinical function. However, if in the application of the bone plate small fracture gaps are present on the transcortical surface, high local strain will occur (small fracture gaps concentrate strain). Additionally, with highly comminuted fractures, the vascular envelope is often damaged during reduction of fracture fragments delaying the appearance of the biological elements needed for bone union. High local strain and vascular compromise act synergistically in delaying the healing response. The delay in healing is coupled with the fact that the without the integrity of the bone column stress is carried by the plate and may lead to cyclic failure of the plate. The concept of indirect reduction is one which strives to preserve the biologic envelope of the fracture area. This is chiefly applied to comminuted fractures where reduction of fracture fragments is likely to destroy vascular attachments. Experience suggests that it is preferable not to disturb bone fragments or the fracture hematoma thereby preserving the biologic milieu. The surgeon should regain spatial alignment of the limb and then bridge the fractured zone with a buttress plate being careful to limit manipulation of the soft tissues to a minimum.

From a mechanical perspective, the plate must limit the strain at the fracture site to a level that is compatible for direct or indirect bone union. Comminuted fractures distribute strain over a large

surface area which lowers interfragmentary strain to a level compatible with direct or indirect bone union. However, if the bony column is not reconstructed, the bone plate is placed under considerable stress since it must carry all the imposed physiologic load until callus (bio-buttress) is formed (Figure 52-1). If a standard plate is used, empty plate holes will be present overlying the area of comminution. In that an empty plate hole serves as a stress concentrator, plate failure can occur in this area. One method to reduce plate strain is to combine the use of an IM pin with that of the bone plate – i.e. a plate-rod construct (Figure 52-2).

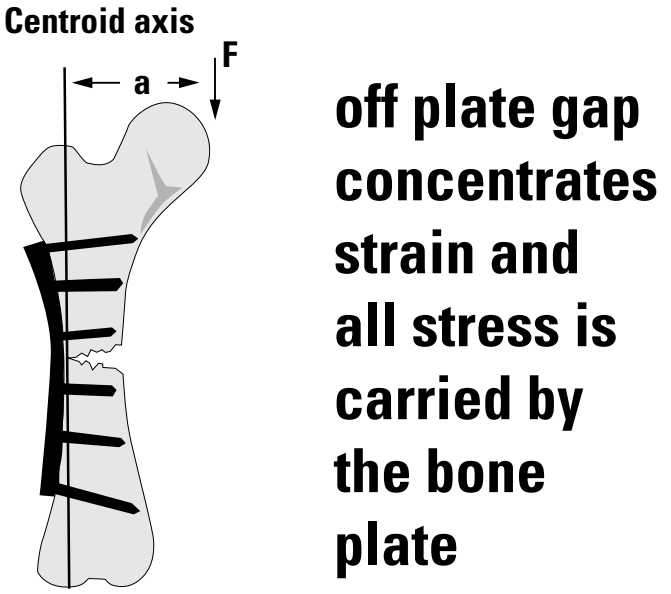

Figure 52-1.

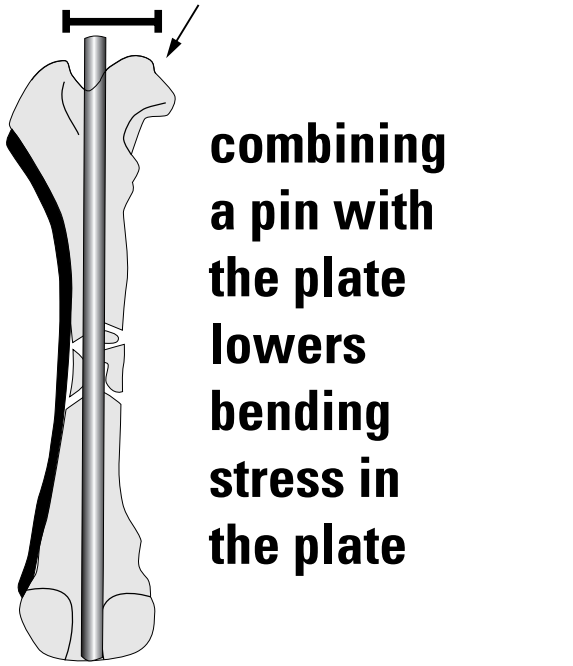

Figure 52-2.

Clinical Indications

Indications for application of plate-rod constructs are fractures where biological assessment indicates prolonged healing, mechanical assessment indicates the implants must sustain maximum stress, and clinical assessment indicates a comfortable, low maintenance system is needed. An example of a patient which fulfills these requirements would be a middle aged or older large or giant breed dog, having sustained multiple limb injuries with one injury being a multifragmented fracture with severe disruption of the soft tissue envelope. The plate/rod technique is mostly applied in the femur and humerus but may be applied to the tibia and radius as well.

Technique

Fractures of the Femur

Use a minimally invasive exposure or one employing the concept of OBDNT (Open But Do Not Touch). Insert (retrograde or normograde) an IM pin which occupies 40% the diameter of the marrow cavity. An IM pin of this approximate size reduces the stress on the plate by 50% or more. More importantly, the fatigue life of the plate is extended at least 10 fold. However, an IM pin which only occupies 25% of the marrow cavity reduces the stress in the plate by a factor of 10%. Therefore, the appropriate pin size is critical. Inserting the intra-medullary pin establishes varus-valgus alignment and assists in regaining appropriate length. Apply a buttress plate to the tension surface of the bone and contour it to the anatomic shape of the bone. Use a radiograph of the intact bone of the opposite leg as a template to help contour the plate if the bone of the affected leg is severely comminuted. Apply a plate of appropriate length to the tension surface of the bone. When applying minimally invasive technique, the plate must span the length of the bone from proximal metaphysis to distal metaphysis. Insert the most proximal and distal plate screws so that they avoid the IM pin and engage both near and far cortices. At this point examine for proper rotational alignment: As a general guide, the internal and external rotation of the hip should be equal when starting at a neutral position. Once rotational alignment is established, insert additional screws; place an additional screw proximally and an additional screw distally for a total of two screws in the end plate holes proximally and two screws in the most distal plate holes (Figure 52-3).

If it is necessary to place screws in more central plate holes, insert the plate screws so that they engage only the near cortex – i.e.monocortical screws (Figure 52-4). If large fragments are identified without disruption of the soft tissue envelope, they can be gently "lassoed" with absorbable suture and pulled into alignment. A cancellous bone graft should be harvested from the ipsilateral humerus or ilium and packed into the area of comminution.

Fractures of the Humerus

Use a minimally invasive exposure or one employing the concept of OBDNT (Open But Do Not Touch); the lateral approach is commonly used. The intra-meduallary pin should approximate 40% the diameter of the marrow cavity. An IM pin of this approximate size reduces the stress on the

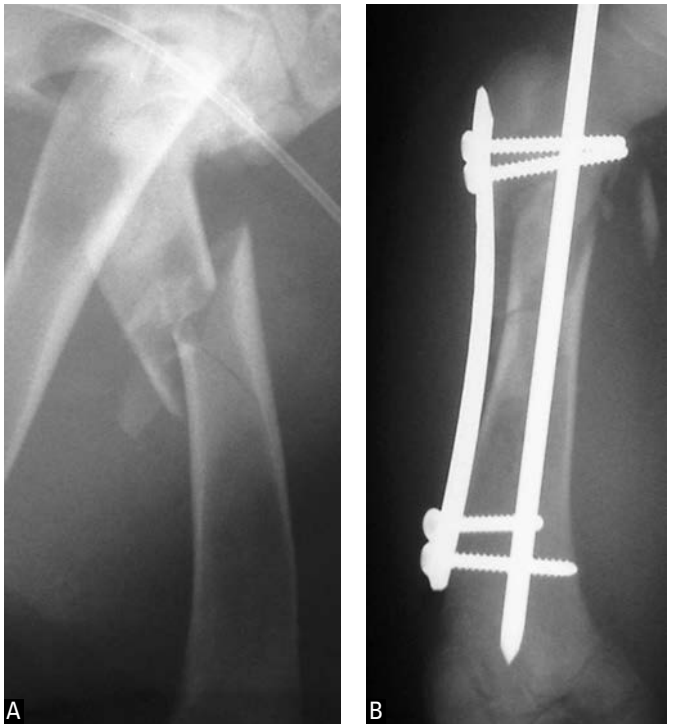

Figure 52-3. A. and **B.**

Figure 52-4. A. and **B.**

plate by 50% or more. More importantly, the fatigue life of the plate is extended at least 10 fold. The pin may be retrograded or normograded. Apply a plate of appropriate length to the tension surface of the bone. When applying minimally invasive technique, the plate must span the length of the bone from proximal metaphysis to distal metaphysis. Insert the most proximal and distal plate screws so that they avoid the IM pin and engage both near and far cortices. At this point examine for proper rotational alignment: As a general guide, the internal and external rotation of the shoulder should be equal when starting at a neutral position. Once rotational alignment is established, insert additional screws; place an additional screw proximally and an additional screw distally for a total of two screws in the end plate holes proximally and two screws in the most distal plate holes. If central screws are inserted, they should be monocortical screws (Figure 52-5).

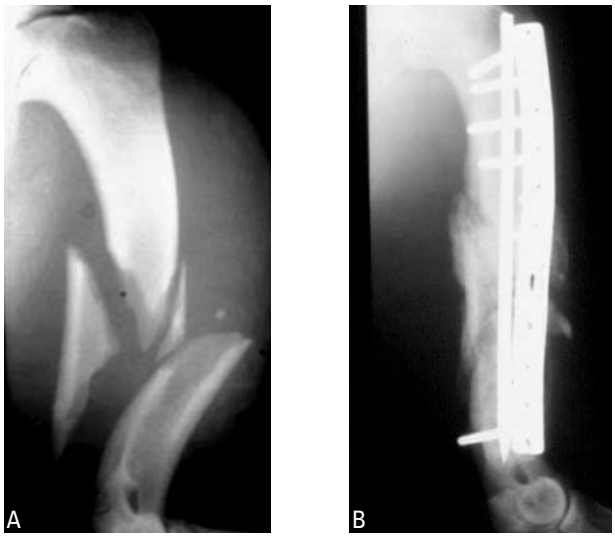

Figure 52-5 A. and **B.**

Fractures of the Tibia

Use a minimally invasive exposure or one employing the concept of OBDNT (Open But Do Not Touch); the anteromedial approach is commonly used. The intra-meduallary pin should approximate 40% the diameter of the marrow cavity. An IM pin of this approximate size reduces the stress on the plate by 50% or more. More importantly, the fatigue life of the plate is extended at least 10 fold. The pin must be normograded; the pin will assist in re-establishing appropriate varus-valgus alignment and length. Rotation alignment is judged by aligning the fabella of the femur with the medial and lateral malleoli of the distal tibia. Apply a plate of appropriate length to the medial surface of the bone. When applying minimally invasive technique, the plate must span the length of the bone from proximal metaphysis to distal metaphysis. Insert the most proximal and distal plate screws so that they avoid the IM pin and engage both near and far cortices. Place an additional screw proximally and an additional screw distally for a total of two screws in the end plate holes proximally and two screws in the most distal plate holes. If central screws are inserted, they should be monocortical screws (Figure 52-6).

Fractures of the Radius/Ulna

Use a minimally invasive exposure or one employing the concept of OBDNT (Open But Do Not Touch); the anteromedial approach is commonly used for the radial exposure, whereas a posterolateral approach is used for the ulna. The intra-meduallary pin is placed in the ulna for this construct. The size of the pin approximates the diameter of the marrow cavity of the ulna. The pin can be normograded or retrograded and should be placed prior to applying the plate on the radius. The pin will assist in re-estab-

lishing appropriate varus-valgus alignment, rotational alignment and length. Next apply the bone plate to the cranial surface of the radius. When applying minimally invasive technique, the plate must span the length of the bone from proximal metaphysis to distal metaphysis. All the plate screws are inserted as bicortical screws (Figure 52-7).

Chapter 53

External Skeletal Fixation

Basic Principles of External Skeletal Fixation

James P. Toombs

Introduction

The external skeletal fixation (ESF) system integrates the use of transfixation pins, an external frame, and sometimes an intramedullary pin connected to the frame for definitive fixation. Clinical use of the ESF system may include supplemental interfragmentary fixation techniques such as lag screws, K-wires, and cerclage wires when appropriate. Bone plate and screw fixation and the interlocking nail are examples of other fixation systems. All three of these major fixation systems are used for similar indications including fracture management, arthrodesis, and corrective osteotomy repair. Each fixation system has its unique advantages and disadvantages, and no single fixation system is preferred in all instances. They all provide suitably rigid fixation of fractures. The two internal fixation systems provide the advantage of more straight forward postoperative care compared to the ESF system. ESF, however, provides better opportunity to maximize the biologic potential for healing within the fracture zone. Specific advantages and disadvantages of the ESF system are summarized in Table 53-1.

Table 53-1. Attributes of the ESF System

Unique Advantages
• Closed or minimally-invasive application techniques are possible
• Fracture alignment can be easily adjusted during and after surgery
• Fixation rigidity can be changed to suit the physiologic needs of the tissues throughout the fracture healing process
• ESF devices are relatively inexpensive and many of the components are reusable
Disadvantages which must be Overcome
• Fixation pins penetrate soft tissues between the skin and bone and may impair the function of neurovascular bundles and musculotendinous units
• Pin tracts represent an avenue of entry for contaminating bacteria
• External fixation frames must be placed distant to the central axis of the bone and thus are at a mechanical disadvantage when confronted with disruptive forces acting at the fracture site – the fixation frame must be designed to overcome this disadvantage
• Postoperative care is more demanding and must address such issues as pin tract hygiene and the potential for the externally placed elements to injure the patient or owner

This section will cover terminology and basic principles of external skeletal fixation applicable to all of the different ESF devices commonly used in North America. Subsequent sections will cover specific application techniques for the acrylic and pin external fixator (APEF), Securos external fixator, IMEX-SK external fixator, circular external fixator, and hybrid external fixator. All of these devices provide stronger, more reliable fixation that is easier to apply compared to earlier experience with the Kirschner-Ehmer (KE) external fixator. For these reasons, the second generation veterinary external fixation devices mentioned above have for the most part replaced the KE splint in current clinical usage.

Nomenclature of ESF

An external fixator has two fundamental elements regardless of the device being used. These are the fixation pins and the connecting column (fixation frame). Fixation pins are percutaneous devices that engage both the near cortex and far cortex of major bone segments for attachment of the fixator to the bone. Originally, fixation pins were smooth Steinmann pins with trocar points that were passed at convergent or divergent angles relative to the long axis of the bone. Angling of this type of fixation pin was necessary to limit pin migration attributable to poor security of the pin-bone interface with smooth implants. One of the most important improvements in veterinary ESF was the development of affordable, properly-sized, threaded fixation pins with a raised thread profile (positive profile thread). These modern fixation pins have significantly reduced the morbidity formerly experienced with ESF due to the fact that they provide reliable, long-term pin-bone interface security. The most recent development in veterinary fixation pin technology is an intelligently designed negative profile threaded pin with a taper run out junction to alleviate the stress concentration point normally found at the junction between the threads and the shaft of the pin (Duraface pins – IMEX Veterinary Inc.). Owing to a larger pin shaft diameter, Duraface pins have been shown to be mechanically superior to positive profile pins of the same thread diameter.

Fixation pins are classified as either half-pins or full-pins. Half-pins penetrate the near side soft tissues to transfix the bone with the end-threaded portion of the pin, and they are attached to a single connecting column (Figure 53-1). Full-pins go through the near side soft tissues to transfix the bone with centrally

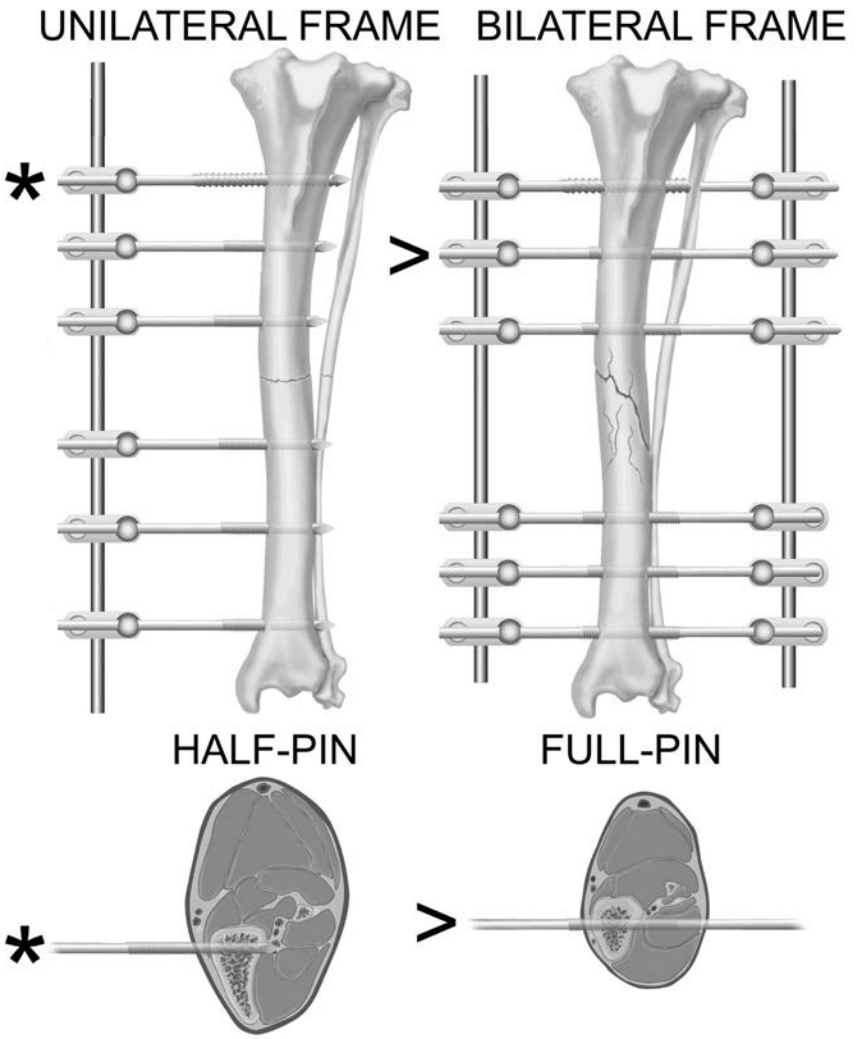

Figure 53-1. Cranial views of a unilateral frame and a bilateral frame applied to the tibia and corresponding cross-sectional views at the level of an end-threaded half-pin *(*)* and a centrally-threaded full-pin *(>)*. Note that the half-pins attach to a single medially placed connecting column (unilateral frame), whereas the full-pins attach to two connecting columns, one medially and one laterally.

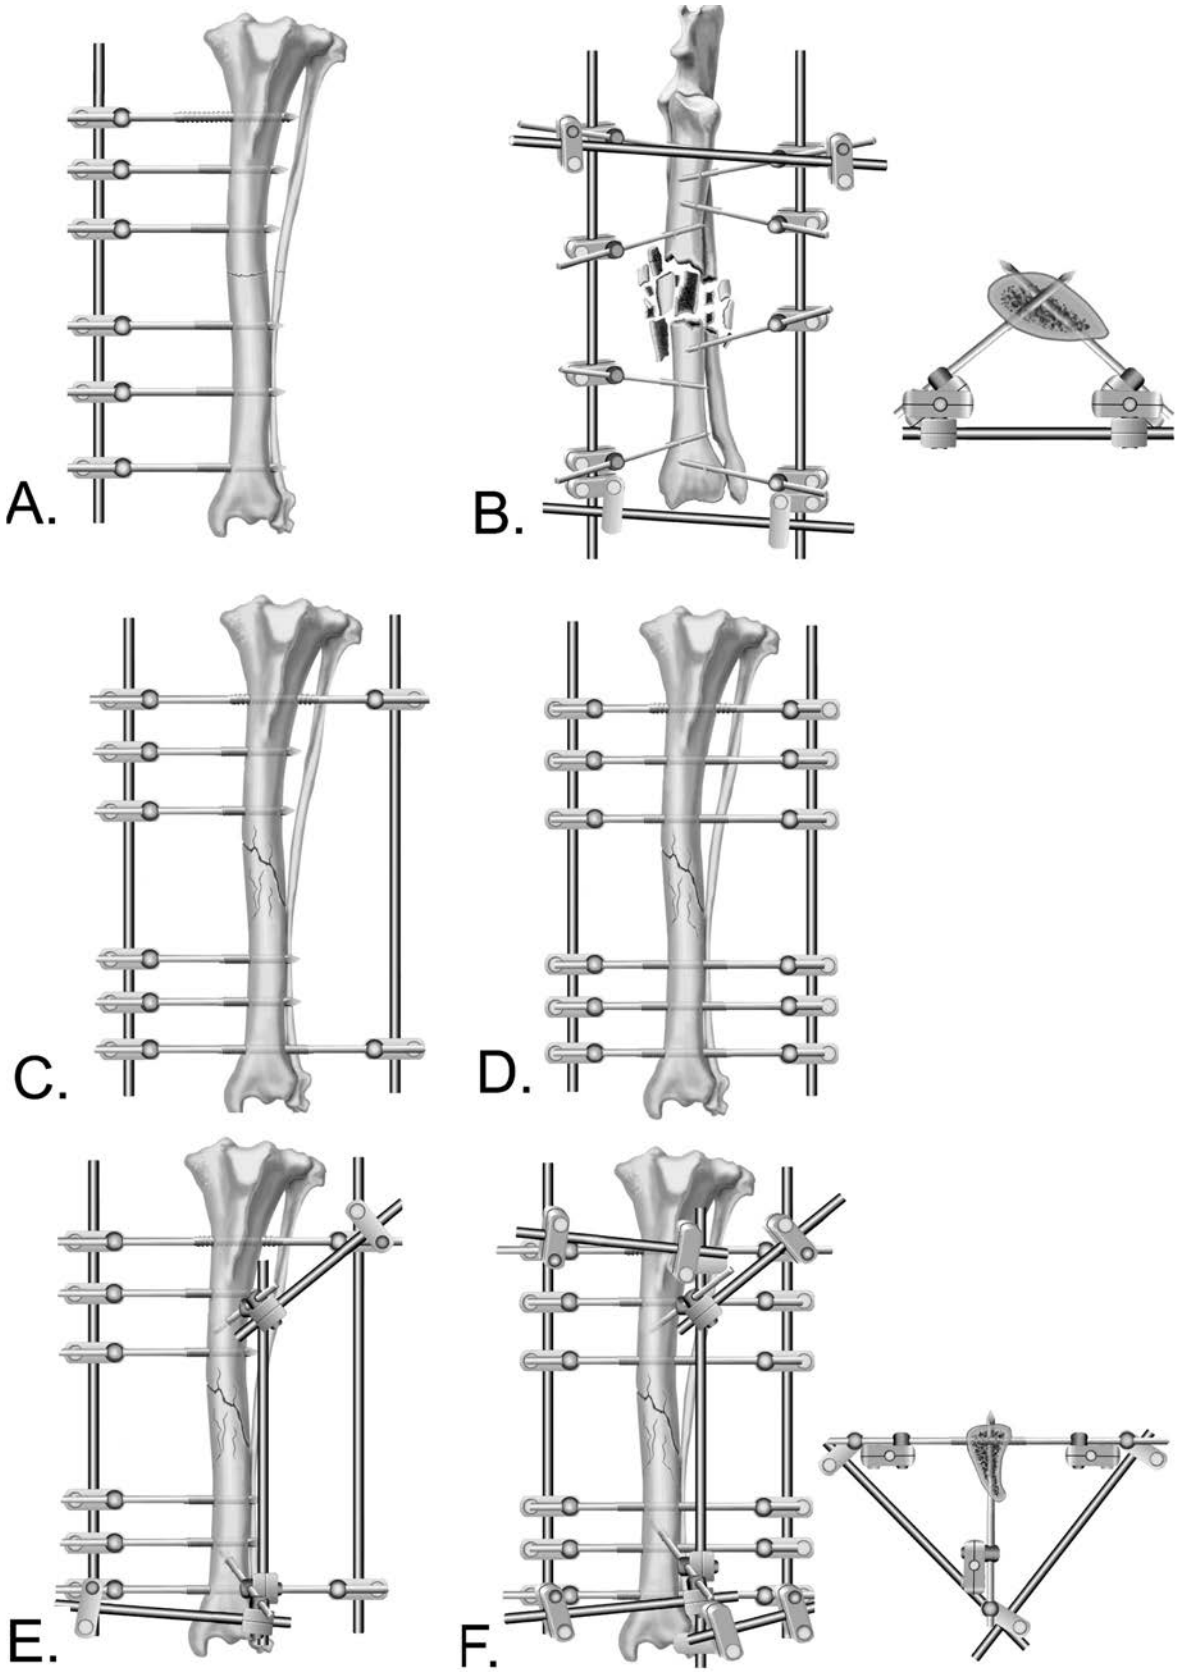

Figure 53-2. Different frame configurations. **A.** Type I-a (unilateral uniplanar) frame applied to the medial aspect of the tibia. **B.** Type I-b (unilateral biplanar) frame applied to the cranial aspect of the radius. The corresponding cross-sectional view shows the craniomedial and cranilateral pin planes that were used to build this construct. **C.** Minimal Type II (bilateral uniplanar) frame applied to the tibia. One full-pin has been applied both proximally and distally and the remaining positions are completed with half-pins placed from the medial side of the bone. **D.** Maximal Type II (bilateral uniplanar) frame applied to the tibia. Full-pins have been applied at all positions to build this construct. **E.** Minimal Type III (bilateral biplanar) frame applied to the tibia. **F.** Maximal Type III (bilateral biplanar) frame applied to the tibia. The corresponding cross-sectional view shows the medio-lateral and cranial pin planes that were used to build this construct.

placed threads, proceed through the far side soft tissues, and are attached to two different connecting columns, one on the lateral side of the limb and one on the medial side (Figure 53-1).

Connecting Columns are fastened to and interconnect the fixation pins, thus providing support for the fixation pins and the fractured bone. It is in the design of the connecting columns that the different ESF devices find their uniqueness. Similar to the KE splint, the Securos fixator and the IMEX-SK fixator use clamps and rods to form the connecting column or fixation frame. However, both of the newer devices are superior to the KE splint in terms of strength and versatility. The APEF uses acrylic cement to both grip and interconnect the fixation pins. Low cost and greater freedom in terms of the shape of the frame are the inherent advantages of the APEF frame. The clamp and rod devices offer the advantages of reusable components and greater ability to easily make adjustments of the frame in terms of fracture alignment and fixation rigidity. Once the acrylic frame has cured into a rigid solid, frame adjustments are laborious and messy.

Classification of different external fixator frame configurations is useful in that it evokes a mental picture of what a given construct looks like, and furthermore, the classification predicts the mechanical performance of one construct versus others. The most commonly used classification system initially considers whether a fixator is unilateral (connecting column on one side of the limb) or bilateral (connecting columns on both sides of the limb), and then further considers whether it is uniplanar (all fixation pins placed in more or less a single plane) or biplanar (fixation pins placed in two distinctly different planes). This consideration results in four different classification types (Figure 53-2). In order of weakest to strongest they are: Type I-a (a one column construct that is unilateral and uniplanar); Type I-b (a two column construct that is unilateral and biplanar); Type II (a two column construct that is bilateral and uniplanar); and Type III (a three column construct that is bilateral and biplanar). At each step forward in this progression, construct rigidity increases (i.e Type I-a is the weakest and Type III is the strongest).

Type I-a configurations (Figure 53-2A) may be appropriate for straight forward fractures in patients that are likely to heal quickly (i.e not comminuted fractures in patients that are elderly or have other medical problems that will delay bone healing). Type I-a frames are generally applied to the medial aspect of the tibia, the lateral aspect of the femur and humerus, and the craniomedial aspect of the radius. They may be supplemented with a small intramedullary pin (one that fills approximately 40% of the medullary cavity) and there are mechanical advantages to attaching this pin to the external fixation frame. This is called an intramedullary (IM) pin tie-in configuration (Figure 53-3). This strategy is most often employed with external fixators applied to the femur or humerus. The increased distance of the frame from the central axis of these bones (because of thick overlying soft tissue) makes the external fixator extremely vulnerable to disruptive bending forces without the additional strength provided by the centrally placed IM pin. The IM pin tie-in strategy is seldom used for the tibia, and is contraindicated for the radius. An acceptable alternative for the bones of the antebrachium involves placing a small IM pin in the ulna and applying an external fixator to the radius.

A Type I-b configuration (Figure 53-2B) is basically the combination of two Type I-a frames placed on different aspects of the bone. Mechanical performance is optimized when the second frame is placed in an orthogonal position relative to the first (i.e. the plane of the fixation pins of one frame is 90° different from the plane of the fixation pins of the second frame). On the tibia this would translate as a medial frame and a cranial frame. The two pin planes on the radius are usually craniomedial and craniolateral (coming in on either side of the extensor muscles) and the degree of separation between the pin planes is often less than 90°.

Anatomical restrictions necessitate the construction of modified Type I-b frames for the femur and humerus (Figure 53-4). The major safe corridor for pin placement is found laterally, although a reasonably safe craniolateral corridor may also be used in the proximal 25 to 30% of these bones. Two different modifications are shown: a two-frame construct supplemented with an IM pin tie-in (Figure 53-4A); and a three-frame construct (Figure 53-4B). The major frame has been placed laterally in both cases. Fixation pins placed in a craniolateral plane enable the construction of a second craniolateral frame. If a full-pin is placed through the distal metaphysis, the medial aspect of this pin provides the opportunity for construction of a third (craniomedial) frame. The three-frame construct can also be supplemented with an IM pin tie-in (not shown in Figure 53-4B). Modified Type I-b frames are sometimes used on other bones as well (Figure 53-5).

In order for a fixation frame to qualify for Type II status, it must have a minimum of two full pins, one in the proximal segment

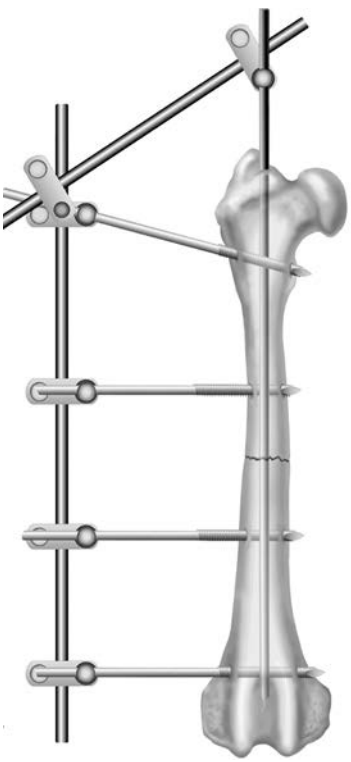

Figure 53-3. Type I-a frame applied to the lateral aspect of the femur. Note that a small intramedullary pin supplements the external fixator and is connected to the fixation frame. This is referred to as an IM pin tie-in construct.

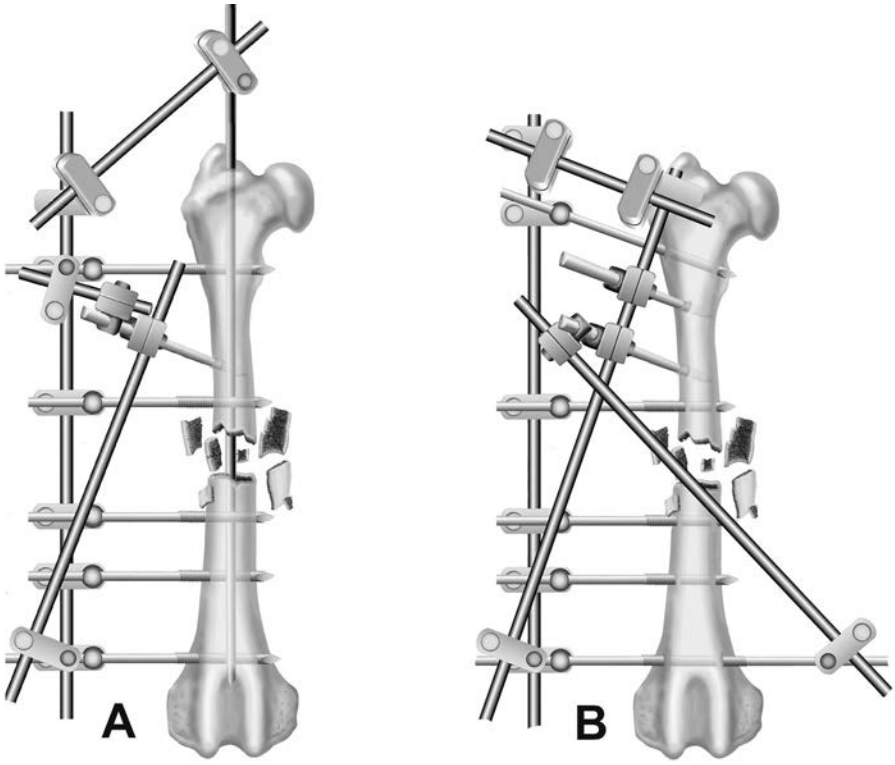

Figure 53-4. Cranial views of modified Type I-b frames applied to the femur. **A.** Two-frame Type I-b construct with an IM pin tie-in. The major frame has been applied laterally and the secondary frame is constructed off of a craniolaterally placed half-pin in the proximal segment of the bone. **B.** Three-frame Type I-b construct. The major frame has been applied laterally. The secondary frame is constructed off of several craniolaterally placed half-pins in the proximal segment. The tertiary frame is applied to the medial aspect of a distally placed full-pin and connected to one of the craniolaterally placed half-pins.

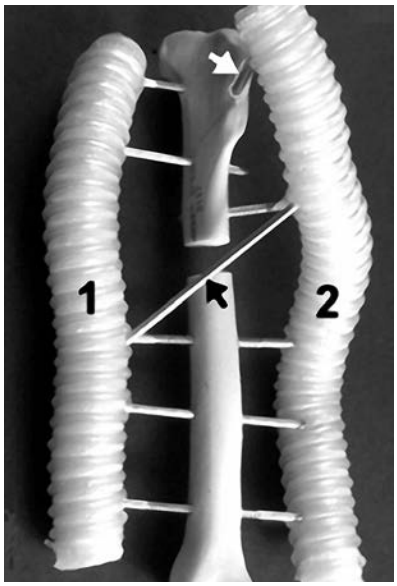

Figure 53-5. Craniomedial view of a Type I-b acrylic frame fixator (APEF) applied to the tibia. The major frame *(1)* has been applied medially. The secondary frame *(2)* was placed laterally along the distal aspect and contoured to grip half-pins placed craniolaterally and cranially in the proximal segment. This cannot be called a Type II frame because no full-pins have been place in the proximal segment of the bone.

and one in the distal segment. In a minimal Type II frame, all of the rest of the fixation pins in the construct are half-pins (Figure 53-2C). If full-pins are used at all positions within the construct, this constitutes a maximal Type II frame (Figure 53-2D). The creative APEF construct shown in Figure 53-5 falls just short of being a Type II configuration due to lack of a proximal full-pin. Although it has two connecting columns and multiple full-pins, all of the fixation pins applied to the proximal segment are half-pins. This is another example of a modified Type I-b construct. It has two connecting columns (medial and craniomedial) but it is not bilateral proximally, and it has groups of fixation pins placed in distinctly different planes (i.e. a two column configuration that is unilateral and biplanar).

General Strategies for External Fixator Application

The following general principles are important for the proper application of an external fixator regardless of the specific device being used. A complete work-up including good quality, properly positioned radiographs (two orthogonal projections including the injured bone and the joint above and below it), thoughtful pre-operative planning, and aseptic surgical technique are required similar to other orthopedic procedures.

The Hanging Limb Technique

The hanging limb technique (Figure 53-6) and four-corner patient draping are performed so that the surgeon has access to the

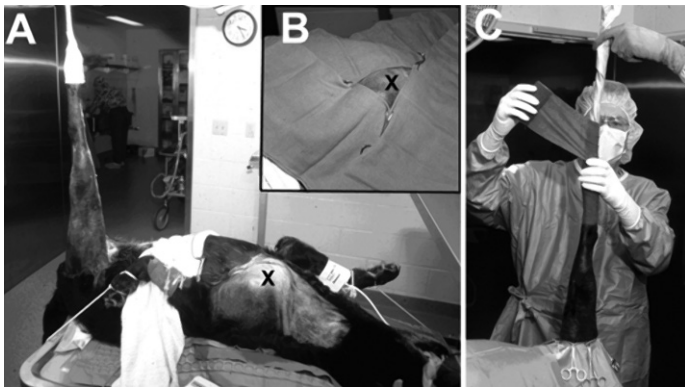

Figure 53-6. The hanging limb position and surgical draping in a dog with a comminuted midshaft fracture of the left tibia. **A.** The dog is placed in dorsal recumbency on the surgical table and the injured limb is suspended via an adhesive tape stirrup to a hook in the ceiling. The left proximal humerus *(x)* has been clipped and prepared to enable harvesting of a cancellous bone graft. Note that the limb has been secured caudally to facilitate easy access to the greater tubercular region of the humerus. **B.** Sterile towels were applied to isolate the cancellous bone donor site *(x)*. This site is covered with paper drapes during four-corner draping of the patient. When cancellous bone graft is harvested, the towel clamps are palpated through the paper drape and a window is cut through to for access to the donor site. **C.** Four-corner draping of the patient has been completed and a sterile covering is being placed over the tape stirrup used to suspend the leg.

entire circumference of the limb. If a cancellous bone graft is needed, the patient must be clipped, prepped, and draped to accommodate this as well.

Important aspects of the hanging limb technique are as follows. The equipment needed to hang the limb is a sturdy hook positioned in the ceiling directly over the surgery table and a surgical table that can be raised and lowered. Adhesive tape is secured to the paw of the injured limb leaving very long ends to form a stirrup. The tape should be placed on the paw securely so that it will not fall off with tension, but should not be so tight that it will constrict blood supply to the foot. Elevation of the surgical table should position the injured segment of the limb at a convenient working height for the surgeon when the limb is suspended from the hook with the tape stirrup. The surgical table is then lowered until the injured hindquarter or forequater is suspended about 1cm above the surface of the table. The hook, tape stirrup, and limb should form a straight vertical line when viewed cranially or caudally and laterally. The paw and the proximal limb should be palpated through the drapes to ensure that there is no rotational malalignment.

Suspension of the injured leg is often maintained throughout surgery when an external fixator is being applied to either the radius or the tibia. This provides a linear traction force that provides approximate alignment of the fracture and proper positioning of the overlying soft tissues. The distal portion of the leg and a portion of the tape used to suspend it are covered with sterile drape material to prevent contamination of the surgery site. If the surgeon needs to move the joints above and below the fractured bone during surgery to check for proper rotational alignment, the surgery table can be temporarily raised thus relieving traction on the limb. After proper alignment is verified, the table is lowered to restore traction on the limb. This provides a much more stable working environment greatly facilitating external fixator application.

Keeping the limb suspended throughout surgery is not recommended for application of an external fixator to the femur or humerus. The larger muscle mass surrounding these bones effectively resists the ability of traction to restore proper alignment of the fractured bone. Additionally, a small IM pin is often used to supplement the external fixator, and placement of this pin is extremely difficult with the limb suspended. For fractrures of the femur or humerus, the hanging limb technique is used to prepare the leg for surgery, but after the limb is draped, the paw is grasped with a piece of sterile drape material and the tape suspending the limb is cut. The distal portion of the limb is then covered by wrapping it with the sterile piece of drape material.

Open Versus Closed Repair Techniques

The choice of various open versus closed repair techniques should be based upon the specific bone involved, the type of fracture, and what can be accomplished in terms of restoring meaningful load-sharing.

Invasive open technique involves a panoramic surgical approach to the fractured bone and no restrictions in terms of handling intermediate fragments within the fracture zone. This method results in a variable degree of disruption of blood supply to the injured tissues. The goal of invasive open technique is anatomic reconstruction of fracture segments and fragments to restore a load-sharing bony column. Invasive open technique should not be used unless achievement of this goal is relatively certain.

Open but do not touch technique (OBDNT) is a relatively atrumatic method with a goal of restoring normal alignment of the major proximal and distal fracture segments. No attempt is made to reduce intermediate fracture fragments. A panoramic approach is made to the fractured bone to facilitate proper alignment of the fracture. The major proximal and distal segments can be grasped at a safe distance away from the fracture zone and manipulated to restore axial alignment, normal length of the injured limb segment, and proper rotational alignment. The surgeon accepts a "hands off" (do not touch) philosophy with regard to the fracture zone and the intermediate fragments and fracture hematoma that are found within it. Intermediate fracture fragments are left in situ to act as a living bone graft. Liberal application of cancellous bone graft over the fracture region is usually done as well. The OBDNT technique is extremely useful for treatment of comminuted shaft fractures, especially those involving the femur or humerus where thick overlying soft tissues often complicate the process of restoring normal fracture alignment.

Miniexposure technique is more invasive than OBDNT but less invasive than the open repair technique. This method involves making a small incision over the fracture region to enable manipulation of the proximal and distal segments with the goal of improving alignment or achieving anatomic reduction. A two-piece oblique midshaft fracture of the tibia is a clinical example of where the

miniexposure technique would be helpful. In this case a limited incision would be made over the medial aspect of the bone. The incision should be of sufficient length to allow for reduction of the fracture and application of several lag screws to maintain it. The bone would then be spanned with an external skeletal fixator for definitive stabilization. Similar to other open repair techniques, application of a cancellous bone graft should be considered to offset the negative biologic effects of the surgical approach when the miniexposure technique is used.

Closed Technique preserves the biological environment of the hard and soft tissues in that no surgical approach is made to the fracture region. Functional alignment of the fractured bone rather than anatomic reduction is the goal of this technique. Closed repair technique is most applicable to comminuted shaft fractures of the tibia and radius/ulna. It is seldom a useful technique for dealing with similar fractures of the femur or humerus due to the large muscle mass surrounding these bones. Approximate alignment of the fracture is obtained by use of the hanging limb technique. Fixation pins of the external fixator are placed through separate 1cm long access incisions over the bone. Alignment of the fracture is adjusted, if necessary, as a spanning external fixator is placed to stabilize the fractured bone.

Principles of Fixation Pin Selection

Threaded pins with a raised (positive) thread profile and Duraface negative profile threaded pins provide for optimal pin-bone interface security and longevity. Other negative profile threaded pins and smooth (nonthreaded) fixation pins are notorious for loosening prematurely and should be avoided. There are two basic types of positive profile threaded pins: end-threaded half-pins; and centrally-threaded full-pins. Further details about the fixation pins available from different manufacturers can be found in the later sections of this chapter on specific ESF devices (APEF, Securos Fixator, and IMEX-SK Fixator).

Fixation pins must be appropriate in size relative to the bone in which they are placed. The threaded diameter of the fixation pin selected should be approximately 25% of the bone diameter. The ability of a pin to tolerate disruptive forces increases exponentially with increasing diameter, but using too large a pin weakens the bone and increases the risk of secondary fracture through the pin-bone interface when it is confronted with postoperative weight-bearing loads.

Use of fixation pins with deeper and broader threads (cancellous thread) in areas of soft metaphyseal bone will prolong the pin-bone interface at these locations. In hard diaphyseal bone, fixation pins with a standard (cortical) thread pattern should be used. The difference between cancellous thread and cortical thread is shown in Figure 53-7. Hardness of the bone can be gauged during pre-drilling, but when in doubt the surgeon should select fixation pins with cortical thread. Placement of cancellous thread pins in hard cortical bone results in microfractures that compromise pin-bone interface security. The most appropriate locations for the use of cancellous thread fixation pins are the proximal metaphysis of the humerus and tibia, and the distal metaphysis of the femur.

Figure 53-7. End-threaded half-pins with cortical thread **A.** and cancellous thread **B**.

Principles of Fixation Pin Insertion

Optimal pin-bone interface security depends upon fixation pins being placed in mechanically intact bone. This requires pin application a safe distance away from fracture lines and fissure lines. The safe distance has been stated to be 1 cm away from the fracture zone. A more useful guideline suggests that the safe distance is equal to one bone diameter. This guideline adjusts up and down according to patient size which is entirely appropriate, as 1 cm can be a dauntingly long distance in the bone of a tiny kitten, yet a negligible distance in the bone of a Great Dane.

Pin-bone interface security also depends upon fixation pins being properly centered within the bone. When there is maximal distance between where the pin penetrates the near cortex and the far cortex, the pin is optimally centered within the bone (Figure 53-8A). Pre-drilling of the bone should precede fixation pin insertion. The surgeon must pay careful attention while pre-drilling to make sure that the hole is correctly centered in the bone. With a properly centered hole, there is initial resistance as the bit cuts through the near cortex, followed by no resistance as the bit falls some distance across the medullary cavity. A second point of resistance is encountered as the bit cuts through the far cortex. If these separate resistance points are not felt during pre-drilling, the hole is probably through the side of the bone (Figure 53-8B). When this problem is encountered, the surgeon should abandon that hole and drill another one that is properly centered a safe distance away from the poorly positioned hole.

When a bone is approximately round in cross-section, what feels like the center when walking the drill sleeve across it is the proper location for the pre-drilled hole. The proximal tibia is

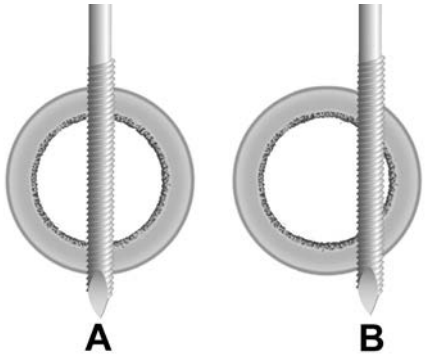

Figure 53-8. Fixation pin centering as seen in cross-sectional images of the bone. **A.** Optimal centering of the fixation pin maximizes the distance between where the pin engages the near and far cortex of the bone. **B.** This distance in reduced with poor pin centering which predisposes secondary fracture through the pin hole.

triangular in cross-section. At this location a properly centered hole should be placed slightly caudal to what feels like the center of the bone in order to increase the distance between the points of near cortical and far cortical engagement.

Fixation pins are typically placed through separate release incisions at least 1 cm in length that are made over the center of the bone. With minimally invasive technique, the surgeon is frequently unable to see the bone. To determine the location of the bone, the surgeon can probe through the overlying soft tissues with sterile hypodermic needles and mark the edges with strategically placed needles. An incision centered over the bone is then made through the skin and subcutaneous tissues with a scalpel blade. The release incision through deeper tissues is made by blunt dissection down to the bone using a mosquito hemostat or Metzenbaum scissors. Muscle tissue should be divided parallel to the direction of its fibers (usually parallel to the long axis of the bone). Exposure can be maintained by placement of mini Gelpi retractors in the release incision.

A drill sleeve is passed through the incision down to the level of the bone and walked along its surface to locate the edges. Once the drill sleeve is centered over the bone, a drill bit is inserted through it and a hole is pre-drilled in the bone. The diameter of the drill bit should be equal to or slightly smaller than the diameter of the smooth shaft of the pin to be applied. The drill must be spinning in a clockwise direction for the drill bit to cut through the bone. Operation of the drill at high speed during pre-drilling is safe because the flutes of the bit allow an escape channel for debris, thus avoiding thermal necrosis of the bone. In contrast, the drill must be spinning clockwise at a much slower speed when the threaded fixation pin is applied to the bone. This is due to the lack of an escape channel for debris as the threads of the pin cut corresponding threads into the bone. If the pin is allowed to spin too quickly, thermal necrosis of bone immediately surrounding the pin will occur, thus jeopardizing the security of the pin-bone interface.

Once the threads of a positive profile pin cut the initial threads in the near cortex of the bone, the slow clockwise rotation of the pin will advance it through the bone by gear effect. Any attempt of the surgeon to speed this up (e.g. applying greater pressure on the drill or using it a higher speed) is detrimental to the pin-bone interface and should be avoided. The full threaded diameter of the pin should engage the far side of the far cortex in order to obtain a mechanically optimal pin-bone interface. This means that the trocar tip of the pin will extend into the soft tissues on the far side of the bone when a half-pin is applied. The surgeon can usually palpate the tip of the pin exiting the far cortex through the overlying soft tissues in order to judge proper length. Ideally, only the trocar tip of the pin exits the far side. If a longer portion of the pin protrudes and there are no vital anatomic structures near it, it is better to leave the pin "too long" instead of switching the drill to reverse (counterclockwise spin) and backing it up. Two-way insertion of a fixation pin (going in too far and then partially backing out) has been shown to weaken the pin-bone interface.

The greater the amount of soft tissue that a fixation pin must traverse before reaching the bone, the greater the likelihood that it will cause postoperative morbidity. Cross-sectional anatomy of the limb at various levels proximal to distal on the injured bone should be carefully considered in order to select the safest soft tissue corridors to be used for fixation pin placement sites. It is important to avoid large muscle bellies, tendons, blood vessels, and nerves. If penetration of a muscle belly cannot be avoided, an ample release incision to prevent soft tissue tension on the fixation pin is necessary in order to keep morbidity low. Preferred pin placement corridors in different bones are summarized in Table 53-2. The importance of ample release incisions at every pin placement site cannot be overemphasized. When placement of the external fixator is complete, the surgeon should release traction on the leg and move the joints above and below the

Table 53-2. Preferred Pin Placement Corridors for Different Bones

Bone	Optimal Pin Placement Zones	Secondary Acceptable Zones
Tibia	Medial aspect due to minimal soft tissue coverage	Cranial aspect of the distal 75% of the bone; avoid tibial tuberosity region
		Lateral aspect of the distal 75% of the bone is useful for Type II frames
Radius	Craniomedial aspect has minimal soft tissue coverage	Craniolateral aspect for 2nd frame of Type I-b constructs
		Medio-lateral plane for Type II frames
Femur	Lateral aspect of the diaphyseal region	Craniolateral aspect in the proximal 25% of the bone for 2nd plane of Type I-b constructs
		Lateral and medial aspects of the distal metaphysis and center portion of the condyles laterally and medially
Humerus	Lateral aspect of the diaphysis but be careful distally to avoid the radial nerve	Craniolateral aspect in the proximal 35 % of the bone
	Lateral and medial aspects of the central portion of the condyle	Lateral and medial aspects of the distal metaphysis as long as pin position does not interfere with elbow function

NOTE: Fixation pins should be placed at a safe distance away from the proximal and distal joint surfaces of the bone (i.e. at least 1 bone diameter away).

injured bone through full ranges of motion. If there is soft tissue tension detected at a pin placement site during movement of the joints, the release incision should be enlarged to relieve it.

Principles of Frame Construction

Significant mechanical gains occur with the application of additional fixation pins in a fracture segment up to and including the 4th pin. As a general rule, the surgeon should strive to place a minimum of three fixation pins proximal to the fracture region and three fixation pins distal to it. Fixation pins in different planes can be summed to achieve this goal (i.e. a Type I-b fixator with two medially placed pins and one cranially placed pin in the proximal fracture segment would provide the recommended minimum of three fixation pins per segment).

The working lengths of the fixation pins and the fixation frame (Figure 53-9) should be kept as short as possible to optimize the mechanical performance of the external fixator. The concept of working length can be appreciated by taking a 1/8" (3.2 mm) Steinmann pin and applying a controlled amount of bending force to it. When the pin is grasped with both hands, one at each end of the pin (long working length) and force is applied, the pin feels quite flexible. When the pin is grasped more toward the middle portion (i.e. short working length) and the same amount of force is applied, it feels more rigid. Fixation pin working length is the distance between where the pin attaches to the frame (where it exits the bolt of the pin-gripping clamp) and where it enters the near cortex of the bone. Soft tissue thickness over the bone basically dictates the fixation pin working length. Some degree of postoperative swelling should be anticipated and the fixation frame should be positioned far enough away from the skin to accommodate this. It is recommended that the nearest portion of the fixation frame (usually the inner aspect of the fixation clamps) should be positioned about 1cm away from the skin. This keeps fixation pin working length relatively short, but allows a small amount of space for postoperative swelling. Fixation frame working length is the distance between the fixation pins placed immediately proximal to and immediately distal to the fracture zone. These implants should be placed as close to the fracture as possible while respecting the guideline of safe distance, which is one bone diameter away from the fracture region. Frame working length is mainly determined by the length of the fracture zone.

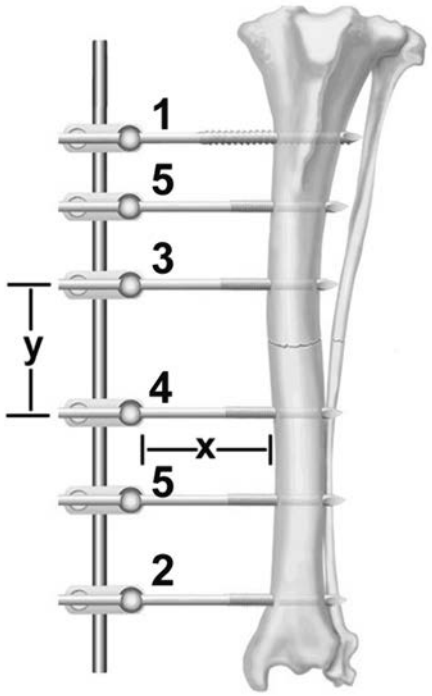

Figure 53-9. Fixation pin and frame working lengths and the order of pin placement. Fixation pin working length *(x)* is the distance between the near cortex of the bone and the inside of the pin-gripping clamp. Frame working length *(y)* is the distance between the fixation pins that are closest to the fracture. Fixation pins are generally placed in the following order in relation to the fracture: the pins farthest away are placed first *(pins 1 and 2)*; the pins closest to the fracture are placed next *(pins 3 and 4)*; and finally pins are applied between the far and near pins in each segment *(pins 5 and 6)*.

Clamps should be positioned on the connecting rod such that fixation pin working length is kept as short as possible. When the clamp is positioned such that the pin-gripping bolt is between the connecting rod and the skin surface (Figure 53-10A), this is referred to as the "clamp-in" position. This is the preferred position because it shortens fixation pin working length. When the clamp is positioned such that the pin-gripping bolt is toward the outer aspect of the connecting rod (Figure 53-10B), this is referred to as the "clamp-out" position". This unnecessarily increases fixation pin working length. The clamp-out position should only be used when it provides a unique angle required to place the pin in a safe region of the bone that cannot be obtained with the clamp-in position.

Fixation pins should be placed in a specific order during construction of the frame (Figure 53-9). Pins are initially placed at the proximal and distal ends of the bone. A connecting rod is attached to the proximal and distal pins with clamps. The surgeon should check at this point to make sure that acceptable alignment of the bone has been achieved before proceeding. The proximal and distal clamps can be loosened to permit adjustment of fracture alignment if needed. Adjustments are easy to make at this early phase of frame construction, but become increasingly difficult as additional fixation pins are added to each segment of the bone. The fixation pins closest to the fracture zone are

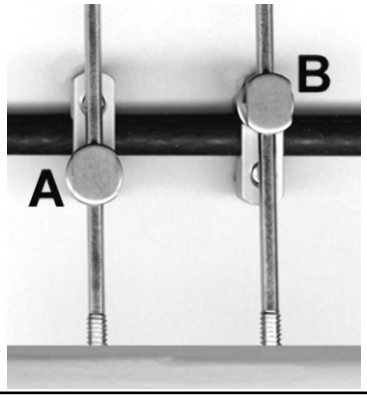

Figure 53-10. Clamp-in position **A.** positions the pin-gripping bolt of the clamp closer to the bone compared to the clamp-out position **B.** Note that fixation pin working length is shorter when the preferred clamp-in position is used.

applied next. Empty clamps are placed on the connecting rod and pre-drilling is done via a drill sleeve passed through the pin bolts of these clamps. This far-far-near-near strategy of pin placement relative to the fracture zone provides for optimal mechanical performance of the fixation frame. Additional fixation pins are placed in the middle portion of each fracture segment until sufficient stability is obtained.

The simplest frame configuration that will provide adequate stability for a given fracture should be used. For relatively straight forward two-piece midshaft fractures, a Type I-a frame is often sufficient on the tibia or the radius. With this type of fracture in the femur or the humerus, use of a Type I-a frame with an IM pin tie-in is recommended. If intraoperative evaluation by palpation of the fracture reveals that a Type I-a frame is allowing too much deflection of the fracture, it is easy to add a second frame in another plane thus converting it to a stronger Type I-b construct. This strategy is applicable to all four bones mentioned. For challenging comminuted shaft fractures or the tibia or radius, the surgeon should plan for a stronger frame and start with either a Type I-b or a Type II construct. Challenging fractures of the femur and humerus can often be more reliably managed with internal fixation techniques such as interlocking nail (see Chapter 50), bone plate and screw fixation (see Chapter 51), or plate-rod fixation (see Chapter 52).

When application of the external fixator is complete, do not trim the fixation pins short until acceptable fracture alignment has been verified with postoperative radiographs. The ability to make adjustments is often compromised once the fixation pins have been cut short. Once acceptable alignment has been obtained, all fixation pins should be trimmed such that the cut edge of the pin does not extend beyond the outer edge of the clamp. Even shorter than this is preferable, when possible (the size and style of the pin cutter often determines the degree to which pins can be trimmed).

Postoperative Care

Effective postoperative management of an external fixator is defined by the following goals: 1) a healthy patient that walks comfortably on the limb throughout the healing period; 2) clinical union of the fracture and removal of the fixator as quickly as possible; and 3) avoidance of fixator induced injuries to the patient, owner, and veterinarian. Achieving these goals depends upon a carefully structured program of controlled physical activity, soft tissue care, pin tract hygiene, bandaging of the fixator, and appropriately timed staged disassembly of multiplanar frames. Because the fixator is external to the limb and has many edges (some of which are sharp), it can potentially injure the patient or owner if it is not properly bandaged. Worse yet, if the fixator becomes entangled in elements of the animal's environment (i.e. chain-link fence, etc.) and the animal struggles to free itself, the repair may be torn apart. Careful bandaging of the fixator allows it to bounce off of environmental objects rather than being caught up in them and protects the owner and the patient from being injured by the sharp edges of the fixator. Postoperative care of the soft tissues surrounding the fixation pins is equally critical to patient comfort during the early stages of healing. Excessive pin tract inflammation will increase patient morbidity and decrease use of the limb. This inflammatory response is attributed to the presence of a contaminated foreign object (the fixation pin), inadequate drainage, and too much soft tissue motion around the fixation pins.

Careful attention to wound management during the first five to seven days after ESF application is critical in order to control of pin tract contamination and soft tissue inflammation. The pin tracts are vulnerable to infection until the proliferative stage of healing (fibroblasts and neocapillaries) leads to development of a bacteriostatic lining of granulation tissue. The more contaminated the early pin tract wound becomes, the longer it remains in the debridement stage of wound healing (polymorphonuclear leukocytes and macrophages). The longer the pin tract remains in the debridement stage the greater the likelihood of infection. This is because the microorganism load will begin to overwhelm regional defense mechanisms. Infection will further prolong the debridement stage, creating even more inflammation. This negative cycle of events leads to high patient morbidity, eventual disruption of the pin-bone interface, and finally to loosening of the fixator. To avoid this vicious cycle, the microorganism load of the pin tracts must be kept as low as possible to enable a brief debridement stage, rapid onset of the proliferative stage, and development of healthy granulation tissue around the fixation pins.

Reduction of soft tissue motion can be attained by packing the area around the pins and between the skin surface and the fixator frame with a bulky wad of gauze as part of the standard postoperative bandaging regime. It makes little difference to the pin tract microflora whether the fixation pin is moving in the soft tissues or the soft tissue is sliding along the pin. The effect is the same, that being increased pin tract inflammation, and pain. All pins will cause some degree of inflammation and drainage. This drainage will inevitably contain bacteria. When the fluid can drain freely, secondary infection is rare unless the pin is loose in the bone or the soft tissues are moving excessively on the pin. If this drainage is blocked, secondary infection of the pin tract is likely.

Adequate release incisions facilitate drainage and regularly changed gauze packing acts like a wick to pull it out from the wound. Clinical signs distinguish normal drainage (usually serous) from that associated with pin tract sepsis. Signs suggestive of an infected pin include excessive drainage (usually thick and foul-smelling), pain, lameness, induration or erythema of the soft tissues, and pin laxity. Failure to keep the pin tract clean and freely draining and failure to relieve soft tissue tension on the pin can promote infection, increase patient morbidity, and lead to pin loosening.

Early Postoperative Management

Systemic antibiotics are given throughout surgery and during recovery from general anesthesia and are usually discontinued thereafter. Immediate post-op pain management is generally achieved with morphine. The day after surgery, a 1 week course of carprofen (2.2 mg/kg per os BID) is started.

Pin tract wounds should be covered with a sterile dressing for the first five to seven days (or until healthy granulation tissue develops). Pin-skin junctions are cleaned with dilute hydrogen peroxide solution to remove blood clots, serum crusts, etc. A thin film of triple antibiotic ointment (polymyxin, neomycin, bacitracin) is applied to the skin around each pin placement site. Wads of "fluffed-up" gauze sponge are packed around the pins and between the skin surface and the fixator frame to immobilize the soft tissues, to keep the pin tracts clean, and to wick drainage away from the wounds. Gauze packing is held in place with an overwrap of Kling bandaging gauze. This sterile dressing is covered with a modified Robert Jones bandage for at least the first 36 to 48 hours to prevent swelling in the distal portion of the limb. The fixator dressing is changed at 36 to 48 hours and every other day thereafter until healthy granulation tissue develops. Application of a Robert Jones bandage over the dressing should be continued during the first week after surgery.

After about 1 week, the Robert Jones bandage is usually abandoned in favor of a simpler "bumper" bandage. This is intended to pad and cover the edges of the frame to reduce the likelihood of it causing injury or entanglement. At each bandage change the same methods of skin hygiene and gauze packing described above are used. Physical activity is limited to short walks outside on a leash for urination and defecation.

Care at Home

After granulation tissue develops the owner is instructed to change the bandage and packing on an as needed basis, usually every 3 to 5 days. If the bandage becomes wet or dirty, if wound drainage increases, if odor is detected, or if the animal is licking or biting the wrap, more frequent bandage changes may be necessary. Physical activity is restricted to leash walks. Running, jumping, and playing with other animals or children should be discouraged. Walking up and down stairs should be kept to a minimum. Good functional usage of the limb is expected throughout the healing period. If this suddenly declines the animal should be re-examined as soon as possible. If the owner is willing, rechecking these patients every other week even if they are doing well is recommended. Radiographic examination at about 6 weeks after surgery should be done to assess healing and to enable staged disassembly of the fixator.

Staged Disassembly of the External Fixator

It is biologically advantageous to reduce the stiffness of the fixator (via staged disassembly) during the later stages of fracture healing. This involves the sequential removal of fixation elements to allow the healing bone to be stimulated by carefully controlled increases in axial stress. During the early stages of bone healing, rigid fixation benefits revascularization of the fracture region, maintains tissue strain at a low enough level to enable the formation of bridging callus, and allows the patient to walk comfortably on the limb. During the later stages of bone healing, strategic reduction of fixation rigidity transfers a greater percentage of axial weight bearing forces to the injured bone while continuing to protect against disruptive bending and rotational forces, and stimulates bony remodeling according to Wolff's Law.

Research has shown that there is an "optimum time window" for initiating staged disassembly. In mature patients this interval is generally felt to be at 6 to 8 weeks after surgery. In young growing patients, this window probably occurs several weeks earlier. The decision to begin staged disassembly is based upon radiographic appearance and palpation of the fracture. When there is scant evidence of bridging callus and palpable instability of the fracture, staged disassembly is delayed.

When disassembly is determined to be appropriate, the following guidelines are applied: 1) The external fixator is examined for any fixation pins that are showing signs such as excess drainage or inflammation. If there are "problem pins", the disassembly strategy should include their removal. 2) Consider removing any pins that have the potential to cause morbidity. Examples would include a pin in the soft bone of the distal femur, or one that goes through the thick lateral soft tissues of the proximal tibia. 3) When possible, it is best to remove frames rather than just individual pins. 4) When a Type II or Type III configuration is present, conversion to a Type I-a or Type I-b to encourage axial loading of the bone is recommended. When a Type I-b is present, down-staging to a Type I-a is appropraite. 5) When an IM pin "tie-in" configuration is present, the IM pin is usually removed last in an attempt to encourage axial loading while protecting against bending stress. It is advisable to retain one proximal fixator pin to enable maintenance of the "tie-in" in order to prevent IM pin migration. However, if the IM pin is a significant source of morbidity, it may be the first element of the fixation to be removed. 6) Staged disassembly is different and individualistic for each and every case depending upon the progression of healing. With some cases, disassembly may be a one or two step process and for others more steps may be required. 7) Once the frame has been simplified to a Type I-a construct, removal of central pins will increase the working length of the frame and reduce fixation stiffness.

External Fixator Removal

Radiographic exams are scheduled based upon the expected healing time for a particular fracture and patient. When radiographic evidence of healing is sufficient, the frame is loosened and the limb segment is palpated to verify clinical union. If the bone has united, the remaining portion of the fixator is removed. Exercise restriction should continue for about 4 to 6 weeks after fixator removal while the empty holes in the bone begin to heal. These empty holes can act as stress raisers predisposing to fracture of the healed bone through a bony pin tract.

Application of the Acrylic and Pin External Fixator (APEF)

James P. Toombs and Erick L. Egger

Introduction

Acrylic frame fixators are devices in which the pin-gripping clamps and connecting rods are replaced with acrylic columns (methyl methacrylate) to form the external fixation frame. A powder component (polymer) is added to a liquid component (monomer) to form a liquid or dough that can be poured or molded. The mixture undergoes an exothermic reaction and forms a rigid solid about 8 to 12 minutes after mixing. The resulting acrylic column grips and interconnects the fixation pins thus forming the fixation frame. Different sizes of fixation pins can easily be used in the same construct and frames can be built to any shape that the surgeon desires (i.e. fixation pins do not have to line up to connect with a linear rod as they do with the clamp and rod ESF devices). The use of curved acrylic columns, when needed, does not compromise the stiffness of the frame.

Acrylic frame fixators can be applied to most bones but they are particularly useful for mandibular fractures and transarticular applications because the acrylic connecting columns are easily contoured to the shape of the body and joint angles. The acrylic used is radiolucent, which does not interfere with radiographic assessment of initial reduction or fracture healing. The first reports of acrylic frame fixators involved the use of Steinmann pins or very long orthopedic screws as fixation pins. The screws were inserted in the bones leaving the heads extended externally where they were connected with a column of dental acrylic. Homemade acrylic-pin splints are similarly constructed using methyl methacrylate that is available as hoof repair or dental molding acrylic. "Plumber's Epoxy" has also been described for similar applications. The APEF System[a] utilizes acrylic and positive profile threaded fixation pins and provides all of the basic components required to facilitate the construction of an acrylic frame fixator.

Components of the APEF System

The acrylic frame is constructed with acrylic bi-packs, plastic sidebar tubes for molding liquid acrylic, and end caps to plug the molding tubes. A temporary frame alignment device is useful for maintaining fracture reduction/alignment while the applied acrylic frame is setting.

Acrylic Bi-Packs (Figure 53-11) offer pre-measured volumes of polymer and monomer packaged in separate compartments of a mixing bag. When the ends of the bag are pulled, a plastic divider strip pops off and the mixing bag becomes a single compartment. Acrylic is mixed for 2 to 3 minutes until a smooth consistency is achieved and then the corner of the bag is cut off. The acrylic is poured into plastic sidebar tubes that have been pushed onto the ends of the fixation pins thus providing an injection mold for the acrylic. The effect of acrylic column diameter has been studied. In general, bending strength increases proportionally with the diameter of the column until about 2.5 cm, at which point

Figure 53-11. Acrylic bi-pack *(1)* with liquid monomer in the top compartment and powdered polymer in the bottom compartment. Sidebar tubes are available in three sizes: 21 mm standard tube *(2)*, 15 mm small tube *(3)*, and 10 mm mini tube *(4)*. End caps for each size are shown below the tubes.

increasing diameter may result in heat-generated "vaporization" of the acrylic monomer creating voids in the column and strength loss. While an objective rule for optimal acrylic column diameter for every fracture is not possible, a convenient guideline is that the acrylic diameter should be the same size or larger than the outer diameter of the bone being stabilized. For more complex, unstable, or slower healing fractures, this relationship may be augmented by increasing the diameter of a single column or by using multiple columns. This bi-pack preparation and application technique minimizes the mess and odor associated with mixing acrylic (compared to Caulk Dental Acrylic and Technovit Hoof Acrylic used in "homemade" versions of the acrylic frame fixator), but the surgeon does pay an increased price for this convenience. Acrylic Bi-Packs are available in five different volumes: a triple pack contains 150 ml of mixed acrylic and will fill approximately 18 inches of the 21 mm tubing (enough to apply a Type III frame to a large dog); a double pack contains 100 ml of mixed acrylic and will fill 12 inches of 21 mm tubing (sufficient for a Type I-b frame or a Type II frame in a large dog); a single pack contains 50 ml of mixed acrylic and will fill 6 inches of 21 mm sidebar tube or 12 inches of 15 mm tubing (enough for a Type I-a frame in a large dog, or either a Type I-b or Type II frame in a small dog or a cat); a half pack contains 25 ml of mixed acrylic and will fill one small tube (sufficient for a Type I-a frame in a small dog or a cat); and a quarter pack contains 12.5 ml of mixed acrylic that is generally used with the 10 mm diameter sidebar tube (sufficient for an acrylic frame in a small bird or other small exotic pet).

[a]Innovative Animal Products LLC, 5812 Highway 52 North, Rochester, MN 5590

Sidebar Tubes (Figure 53-11) are pushed onto fixation pins to provide a mold for liquid acrylic to form a cylindrically-shaped mass that acts as both a linkage device and a connector. The result is a neat, professional-looking frame (unlike some of the acrylic frames made by hand-molding dough stage acrylic onto fixation pins). Sidebar tubes are less prone to leak liquid acrylic than other types of tubes used for improvised versions of the acrylic frame external fixator. Stock sidebar tubing is sold as 48 or 60 inch long segments that are easily cut with scissors to the desired length. Sidebar tubes are available in three different diameters: standard sidebar tubes are 21 mm (appropriate for patients 8 to 10 kg or larger); small sidebar tubes are 15 mm (appropriate for small dogs, cats, and some avian patients); and mini sidebar tubes are 10 mm in diameter (appropriate for very small puppies and kittens, small birds, and other small exotic pets).

End caps are available in three sizes (21, 15, and 10 mm diameter) to plug the dependent ends of sidebar tubes. This prevents leakage when liquid acrylic is poured into the sidebar tube to form the frame.

Frame Alignment Device (Figure 53-12.) This is used to as a temporary mechanical splint to maintain fracture alignment or reduction until the primary splint (the acrylic frame) becomes rigid. This is referred to as a bi-phase technique. The frame alignment device consists of four universal clamps (that can be tightened without a wrench) and stainless steel connecting rods. The clamps can be applied close to the skin, just inside the sidebar tubes, and can be easily removed after the acrylic frame has become rigid. With bi-phase technique utilizing K-E components for the temporary splint, the clamps must be placed external to the sidebar tubes to enable their later removal. Because of their closer proximity to the bone, the frame alignment clamps have a mechanical advantage over traditional mechanical clamps in maintaining fracture alignment. Additionally, the position of the frame alignment clamp inside of the sidebar tube ensures that the frame will be at least 1 cm away from the skin. Maintaining this distance is important to avoid thermal injury to soft and bony tissue that can occur during the exothermic phase of the acrylic setting period.

Technique for APEF Application

The APEF system is usually applied using bi-phase technique (application of a temporary mechanical splint to maintain alignment while a definitive acrylic frame is applied and sets up). Key steps for application to a fracture involving the radius and ulna are illustrated in Figure 53-13. The injured limb is prepared for surgery and suspended using the hanging limb technique. Aseptic technique must be maintained throughout the pin placement and wound closure phases of the procedure.

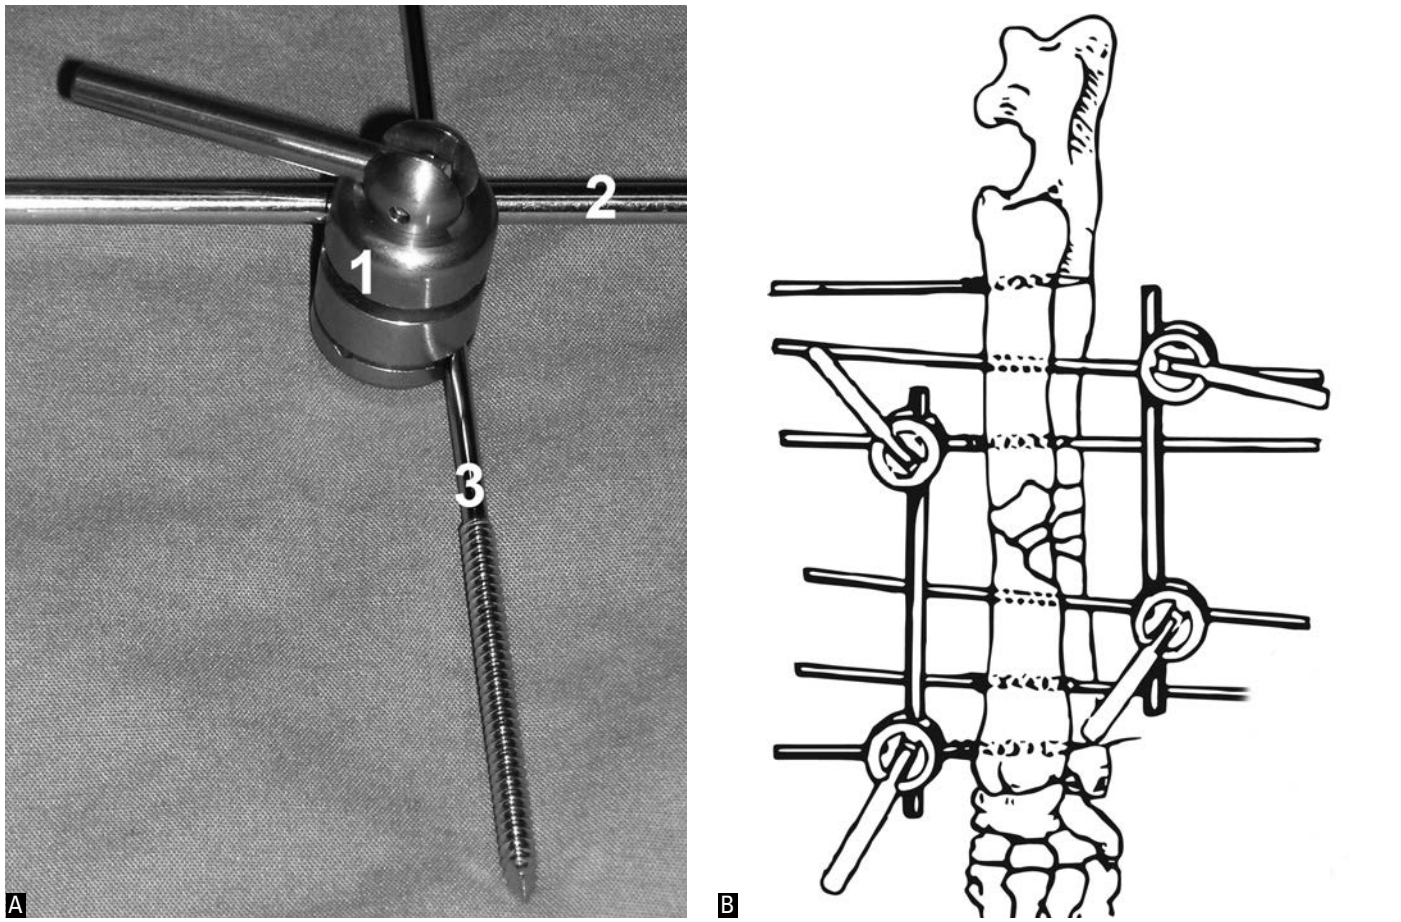

Figure 53-12. A. The frame alignment device uses a special clamp *(1)* that temporarily grips a connecting rod *(2)* and a fixation pin *(3)* to provide for fracture alignment. A wrench is not required to tighten the special clamp which includes a tightening arm at the top of the clamp **B.** Clamps and rods have been applied above and below the fracture and the frame alignment device has been tightened to temporarily maintain fracture alignment so that the acrylic frame can be applied. After the acrylic sets, the frame alignment clamps and rods are removed.

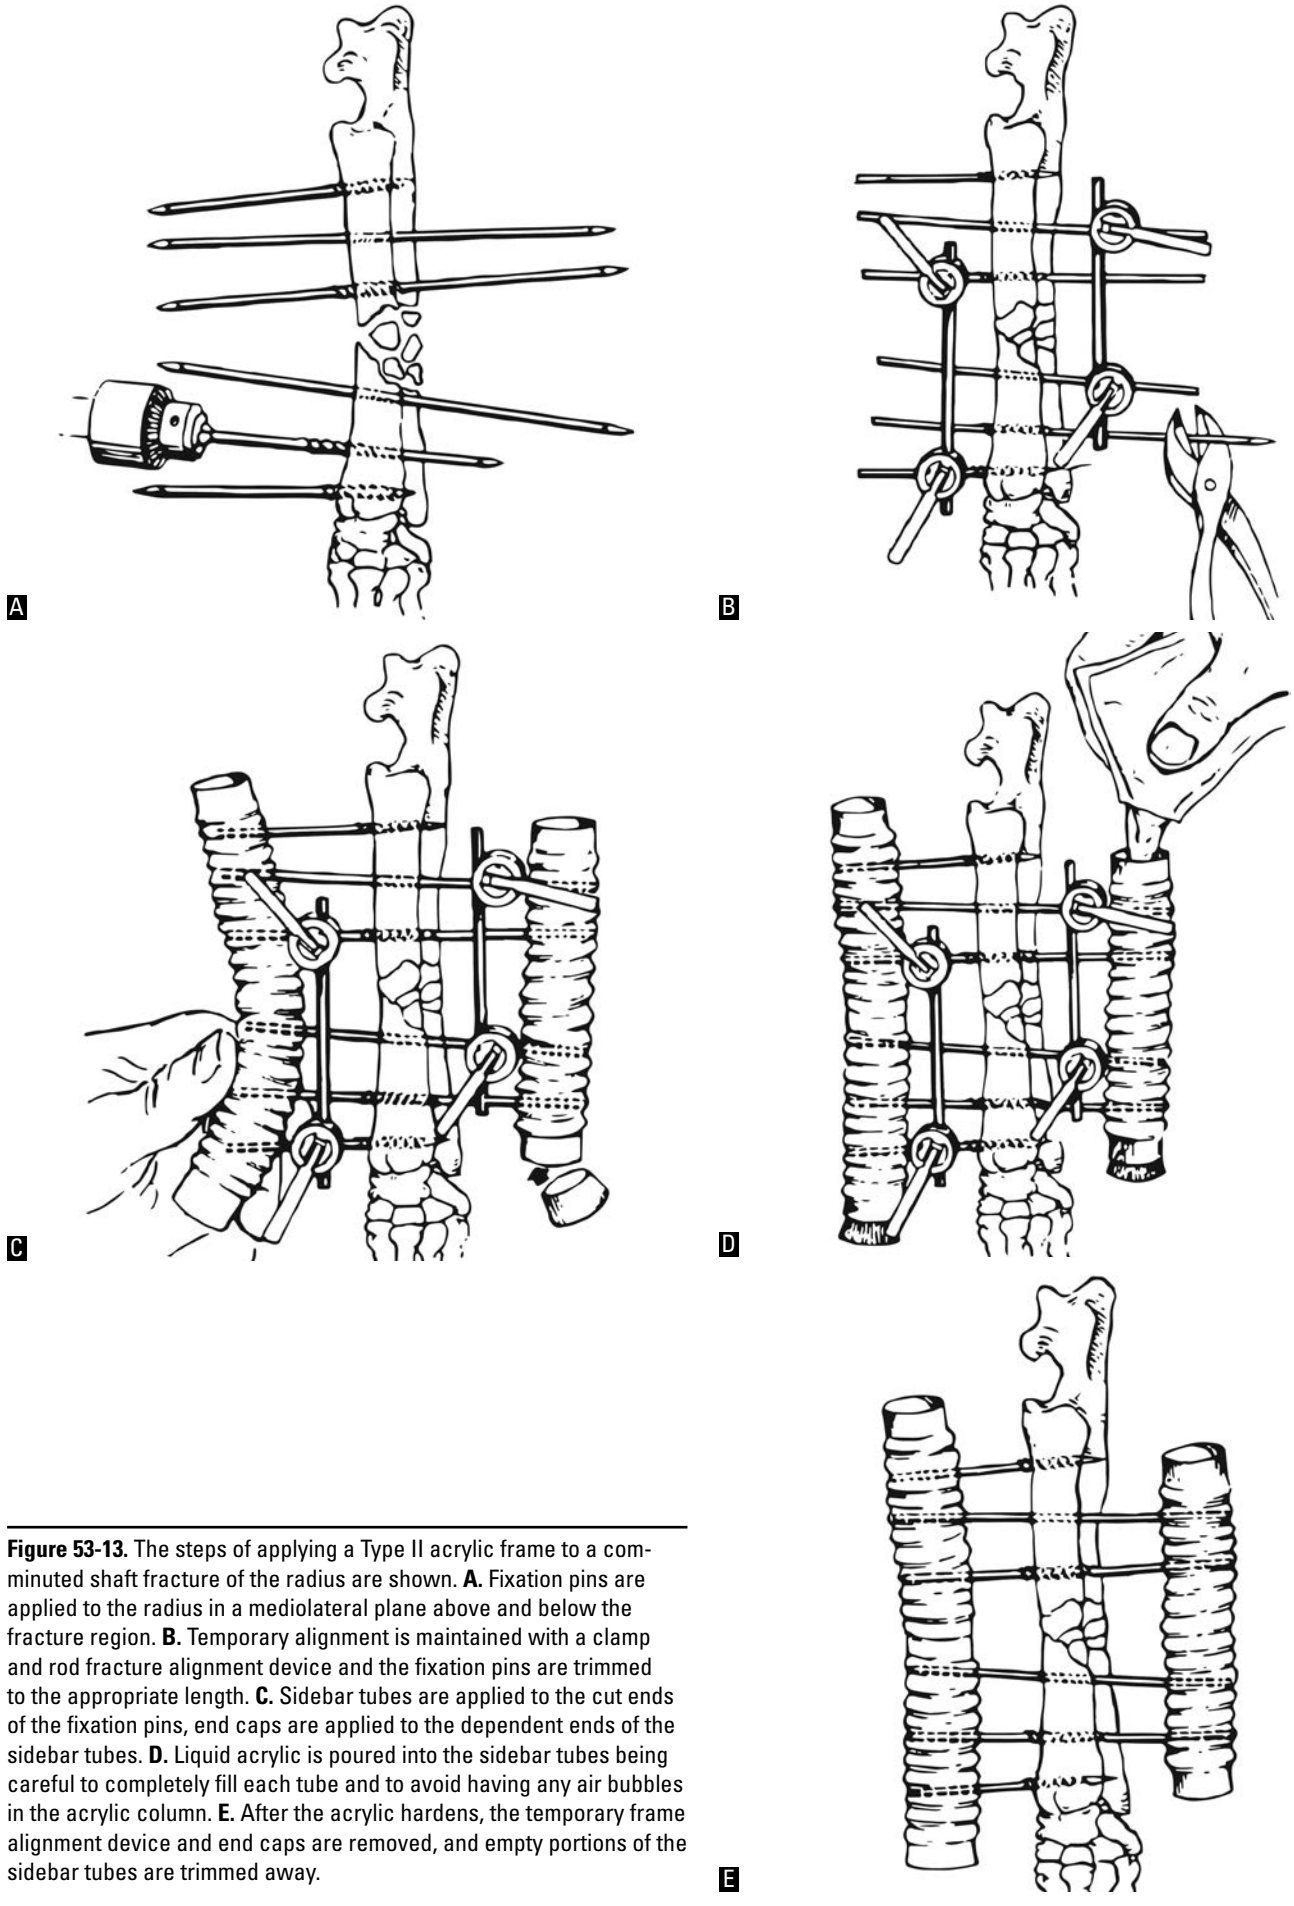

Figure 53-13. The steps of applying a Type II acrylic frame to a comminuted shaft fracture of the radius are shown. **A.** Fixation pins are applied to the radius in a mediolateral plane above and below the fracture region. **B.** Temporary alignment is maintained with a clamp and rod fracture alignment device and the fixation pins are trimmed to the appropriate length. **C.** Sidebar tubes are applied to the cut ends of the fixation pins, end caps are applied to the dependent ends of the sidebar tubes. **D.** Liquid acrylic is poured into the sidebar tubes being careful to completely fill each tube and to avoid having any air bubbles in the acrylic column. **E.** After the acrylic hardens, the temporary frame alignment device and end caps are removed, and empty portions of the sidebar tubes are trimmed away.

Fixation pins are placed using appropriate insertion techniques (pre-drilling of the bone, proper centering of the pin, and slow-speed power insertion). Pin orientation and order of pin insertion are not restricted by frame or clamp design. Typically, at least 3 pins are applied proximal to the fracture region, and 3 more are applied distal to it (Figure 53-13A). Phase 1 reduction is obtained by applying a temporary clamp and rod device (alignment frame). The alignment frame is attached to pins, the fracture reduced, and the clamps tightened to maintain reduction (Figure 53-13B). Open reduction incisions are sutured, and pins are cut off one tube diameter away from the clamps. From this point on, aseptic technique is not required as some of the components used to build the frame are supplied from the manufacturer clean, but not sterile. Our current research is finding that either using knurled pins or placing at least five notches in the portion of the pin that will reside within the acrylic column will increase the strength of the pin-connecting column interface to approximately that of the pin-bone interface when positive profile threaded pins are used. Sidebar tubing is pushed onto the cut ends of the fixation pins such that the pins penetrate the inner wall of the tube and stop short of penetrating the outer wall. The dependent ends of tubes are plugged with end caps (Figure 53-13C). Acrylic is mixed for 2 to 3 minutes after removing the bi- pack divider. The corner of the acrylic bi-pack bag is cut off and acrylic is poured or injected into the open ends of the sidebar tubes (Figure 53-13D). Any acrylic that leaks out from the tube (at points of pin penetration) can be caught in a paper cup and poured back into the top of the tube. Studies of significantly curving the acrylic column (as usually occurs in a transarticular application) reveal a decreased resistance to axial compressive forces. Consequently, we often add a 1/8 to 3/16" diameter Steinmann pin link from one end of the curve to the other to restore overall construct strength. Similar linkages are also commonly placed to connect different columns in biplanar frames (Type I-b and Type III constructs).

After the acrylic hardens (approximately 10-12 minutes), the alignment frame and end caps are removed, and any excess tube length, if present, is cut away (Figure 53-13E).

Readjustment of a Completed Acrylic Frame

If unacceptable fracture alignment is evident in postoperative radiographs, adjustment of the fixation frame is more difficult than would be the case with clamp and rod ESF devices. Splint adjustment requires removing a short segment of the acrylic column with a saw or cast cutter. The plastic molding tube is peeled back from each end and several holes are drilled in the cut ends of the acrylic to provide a base for the patch. A small amount of new acrylic is mixed and hand molded to fill the gap and overlap the existing column ends. The fracture is then manipulated into correct alignment and is held in this position while the acrylic cures. More fixation pins can be added to either replace existing pins or increase overall frame stability. The plastic molding tubing is removed from the existing acrylic column and several 1/8" diameter holes are drilled in the acrylic adjacent to the proposed pin insertion site. After aseptically preparing the skin and acrylic column surface, the new fixation pin is inserted using appropriate technique. The free end of the pin is bent to contact or cross the column. A mini pack of APEF acrylic or other acrylic is mixed to dough consistency and molded around the new pin and existing column to incorporate it.

Staged Disassembly of an Acrylic Frame

Progressive staged disassembly of an acrylic frame is done by cutting fixation pins to disengage them from the frame and/or by removal of portions of acrylic column (Figure 53-14). Acrylic frames can be cut with a cast saw, Gigli wire, OB wire, or a hacksaw blade. Different options available for staged disassembly of a Type II acrylic frame are shown in Figure 53-14. These include: 1) Removal of central segment of the lateral connecting column converts the construct to a Type I-a configuration (i.e. the lateral portion of the frame is now irrelevant mechanically). This strategy simplifies protective bandaging of the fixator compared to the next option; 2) Conversion to a Type I-a frame can also be accomplished by cutting all of the fixation pins as they exit laterally. This strategy may increase morbidity and make safe bandaging of the fixator more complicated; and 3) Cutting the central fixation pins on the medial aspect of the limb can be done as a later staged disassembly. This increases working length of the medial frame which, in turn, decreases frame stiffness.

Acrylic Frame Removal

Frame removal is achieved by cutting each fixation pin between the skin and acrylic column. Each pin is then removed using a hand chuck or pliers. Alternatively, the acrylic connecting bar can be cut between pins and each pin removed using the small block of acrylic as a handle.

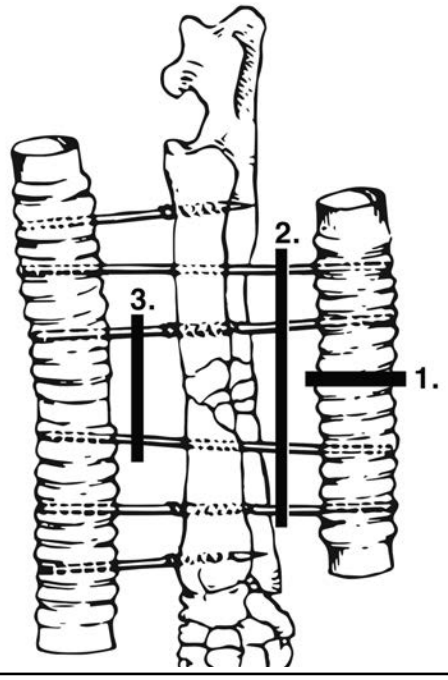

Figure 53-14. Different options for staged disassembly of a Type II frame. *1.* Removal of an acrylic segment from the central portion of the lateral column effectively converts the frame to a Type I-a construct. *2.* Cutting the fixation pins on the lateral aspect of the leg enables removal of the lateral column, another method of downstaging to a Type I-a frame. *3.* Cutting the central two pins on the medial side of the leg increases the frame working length of the remaining medially placed column, which reduces its stiffness.

Application of the Securos External Fixator

Karl H. Kraus

Introduction

The Securos external fixation system was designed to be a simple and economical orthopedic device, which clinically enables state-of-the-art techniques to optimize mechanical and biologic requirements for bone healing with external fixators. These techniques include adding and subtracting fixator clamps transversely, stronger connecting frames, guide for pre-drilling pilot holes and placing full pins, radially preloaded positive profile fixation pins, and axial dynamization. The Securos and SK systems have supplanted the Kirschner-Ehmer fixator system in veterinary surgery.

Fixation Pins and Connecting Rods

Fixation pins are available in four sizes: 1.6 mm (1/16th inch), 2.4 mm (3/32nd inch), 3.2 mm (1/8th inch), and 4 mm (5/32nd inch) shaft diameters. Both end threaded and center threaded pins are available in each size. The pins are made of 316L stainless steel that has been hardened to 210,000 psi, far greater than the stiffness of Steinman pins, and act much like locking orthopedic screws. The thread profile is like an orthopedic screw called a buttress thread and is self-tapping (Figure 53-15). This thread profile results in less bone being removed during insertion therefore less damage to the bone. The diameter of the core of the pin in the area of threads is 2% larger than the pilot hole and shaft diameter of the pin. As the pin is inserted, the slightly larger diameter in the area of the threads that engages bone expands on the hole slightly. This effect, called radial preload, enhances the pin-bone interface. The connecting rods are 9.5 mm for large, 4.8 mm for medium and 3.2 mm for small fixators. The small and medium connecting rods are 308 stainless steel, which is stiffer and stronger than 316 stainless steel. The connecting rods for the large fixator are either carbon fiber, or titanium which are both stronger and lighter than 316 stainless steel.

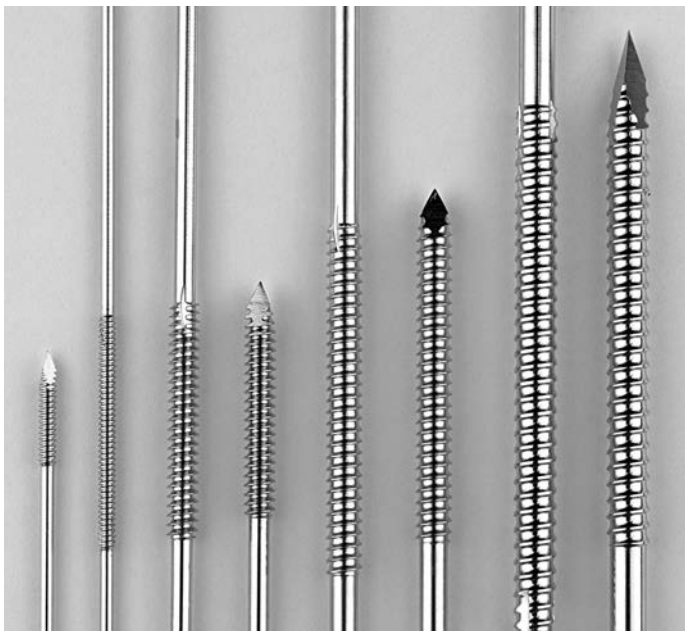

Figure 53-15. Fixation pins End threaded and center threaded fixation pins. The thread profile is a buttress thread that decreases the amount of bone removed. They are made of spring hardened 316L stainless steel making them much stiffer than a standard Steinman pin.

Clamps

There are three sizes of clamps. Small and medium sized clamps are composed of three components, a U-shaped body, a pin-gripping head, and a bolt (Figure 53-16). Similar components comprise the large clamp except that the clamp body has two parts (Figure 53-16). The large clamp accommodates 3.2 mm and 4mm fixation pins, the medium clamp accommodates 3.2 mm and 2.4 mm inch fixation pins, and the smaller clamp accommodates 2.4 mm and 1.6 mm fixation pins. The U-Shaped part and the head can be placed together then slid over a fixation pin and snapped transversely on a connecting rod (Figure 53-17). A bolt screws into the head component. As the head part is drawn into the U-shaped part a bevel on the head part contacts the connecting rod. At this contact area there is a small deformation of the stainless steel that rigidly unites the clamp, pin, and connecting rod, much like a spot weld. The U-shaped component only bends elastically. Thereby during use it is acting like a lock washer preventing loosening. The clamps do not plastically deform with proper usage and therefore can easily be reused. Double connecting clamps are made by using two U–shaped components, a head

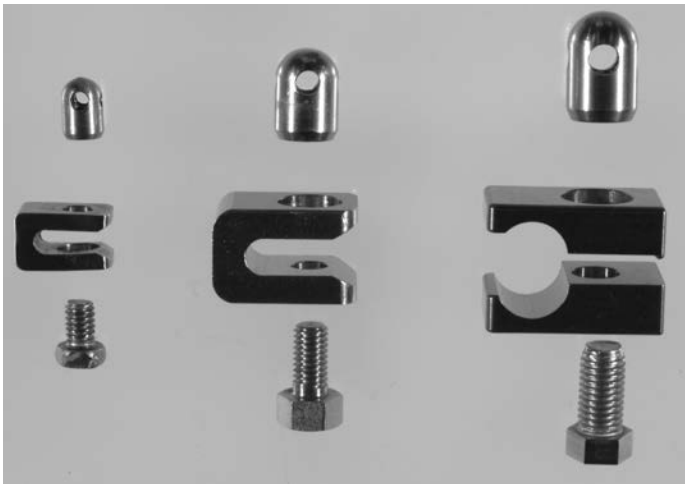

Figure 53-16. Clamps. The small and medium Securos clamp consists of three components, a U-shaped clamp body, a pin-gripping head, and a bolt. The large clamp consists of four components. The clamps are applied transversely onto a connecting rod.

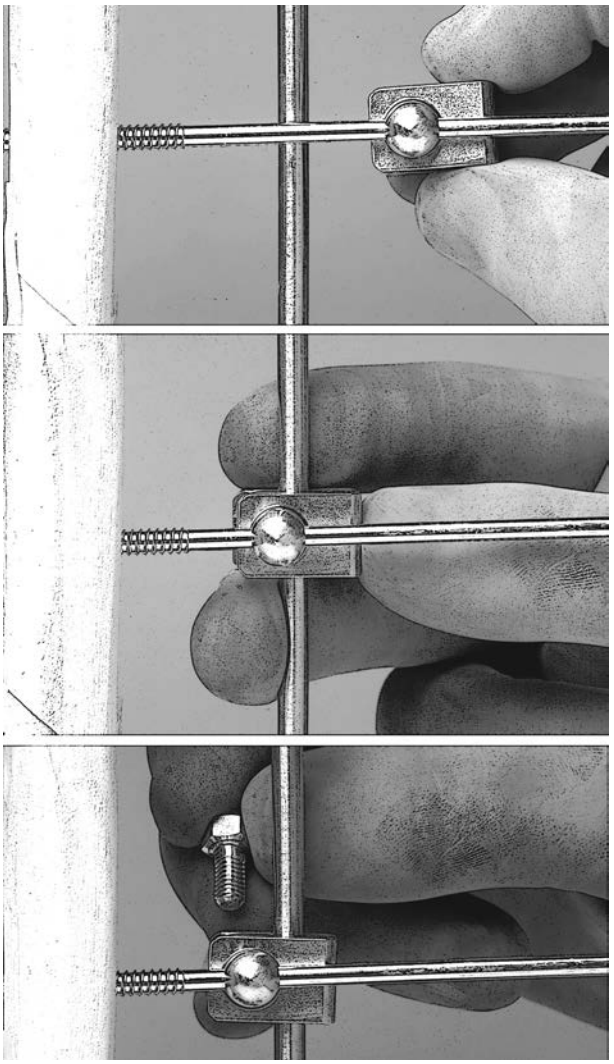

Figure 53-17. Transversely adding clamps. Small and medium clamps are transversely added by placing the U-shaped component and head component together and sliding them down a fixation pin (top panel). The clamp is snapped onto the connecting rod (middle panel), then a bolt is applied (bottom panel). The large clamps are assembled on the connecting rod.

component, a longer bolt, and small sleeve (Figure 53-18). Two new or used U-shaped components and one new or used head component can be used with the longer bolt and sleeve, obviating the need for separate complete double clamps.

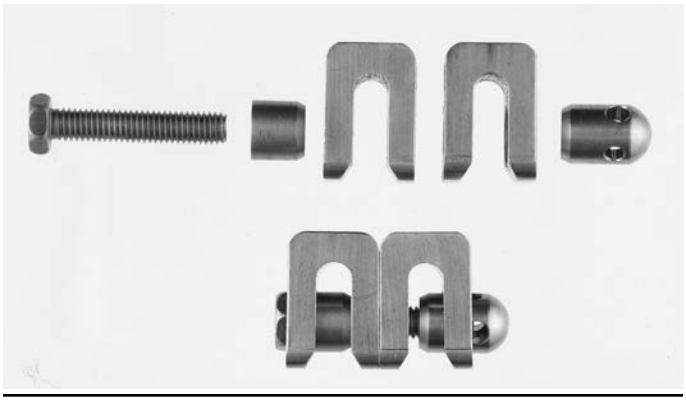

Figure 53-18. Double clamps. Double clamps are composed of two U-shaped components, a head component, and a sleeve and longer bolt. Double clamps use components of regular fixation clamps.

Aiming Instrument

An aiming instrument is available for all three sizes and allows simple pre-drilling of pilot holes, and accurate placement of half-pins or full-pins (Figure 53-19). The handle contains a drill sleeve for drilling pilot holes for fixation pins. Once two pins are placed and connecting rods are installed, the handle connects to the connecting rod. The drill guide places a fixation pinhole in exact relationship to the connecting rod for application of a clamp. The pin can be angled proximally and distally up to 30 degrees, and can also be angled either cranially or caudally. With the drill sleeve removed, the handle directs the fixation pin to the pilot hole. If a full-pin is being installed, an arm on the aiming instrument is used to direct the fixation pin to the exact

Figure 53-19. Aiming instrument. An aiming instrument is used to pre-drill pinholes, guide fixation pins into the pilot hole, and place full pins accurately to the opposite connecting rod.

position on the opposite connecting rod to install a clamp. The pilot hole and fixation pin can be directed to either side of the opposite connecting rod and angled proximally and distally as much as 30 degrees.

A unique feature of the Securos system is a method of simply changing the fixation frame to allow weight bearing forces to go through the long axis of the bone (axial dynamization) without removing fixation pins. In bilateral fixators, the clamp bolt can be replaced with one that is slightly longer. This bolt has a square head instead of a hexagonal head for easy identification. This allows the clamps to slide along the connecting rod, but the pin is fixed to the clamp (Figure 53-20). Therefore weight bearing will cause pure axial loads to be exerted on a healing fracture while the bone is supported in torsion, translation and bending.

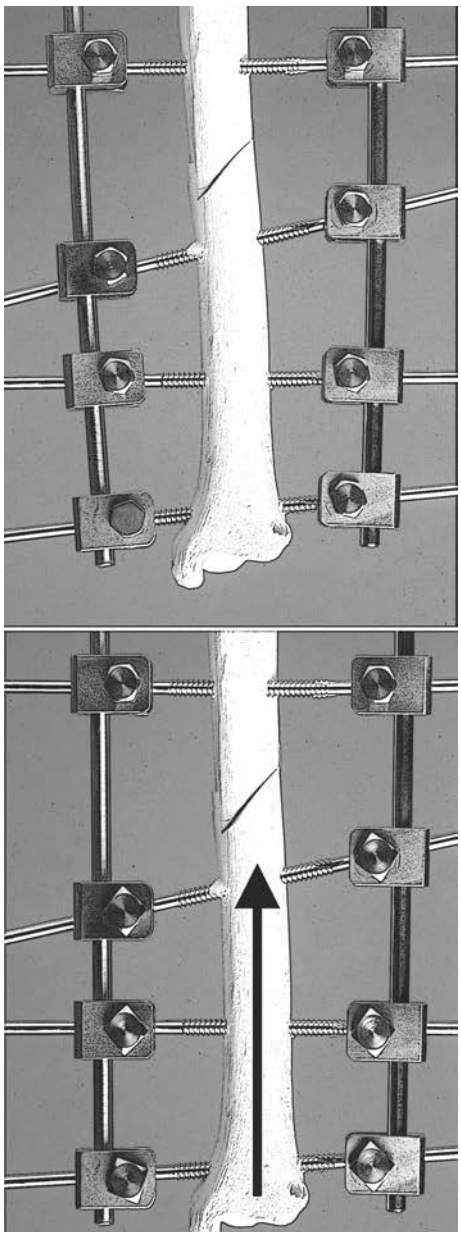

Figure 53-20. Dynamization bolts. Axial dynamization is achieved in bilateral fixators by replacing the bolt of the fixation clamp with a slightly longer bolt with a square head (for identification) either proximal or distal to the fracture. This allows the fracture to carry axial loads (arrow) while being supported in torsion, translation, and bending.

Application Technique

The fracture is reduced and a proximal fixation pin and distal fixation pin are placed near the ends of the long bone. Connecting rods are secured to the fixation pins with clamps and the clamps are tightened. Clamps are not pre-placed on the connecting rods. The aiming instrument is used to place additional fixation pins. In placing half-pins, only the handle of the aiming tool is used (Figure 53-21). It is placed on the connecting rod and a drill sleeve is inserted. An intramedullary pin is advanced to the desired

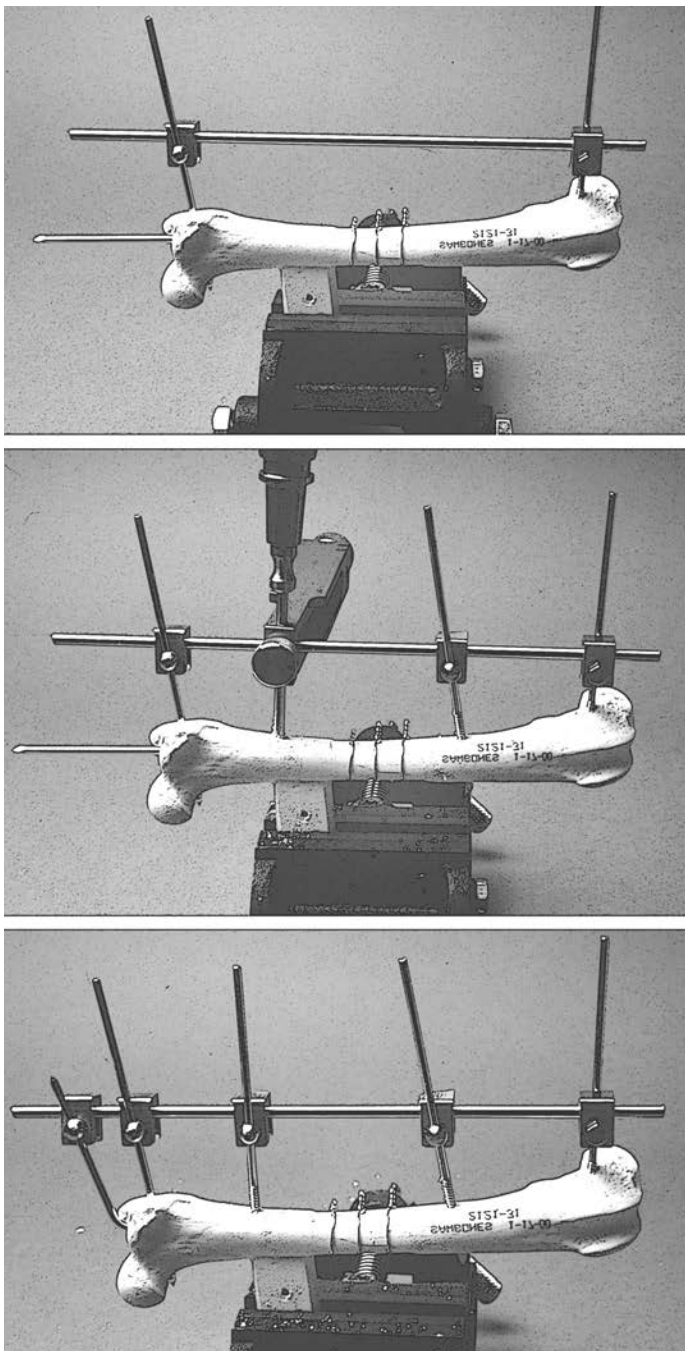

Figure 53-21. Application of unilateral fixator frames. Unilateral fixators are applied placing the first two pins and connecting rod in standard fashion. Consecutive fixation pins are added using the aiming instrument by drilling a pilot hole, inserting a fixation pin through the device, removing the device and snapping on a clamp. An intramedullary pin can be easily tied in.

location and used as a trochar to locate proper placement in bone. The aiming instrument is tightened to maintain its position on the connecting rod. A releasing incision is made and the drill sleeve is advanced to bone. The Steinmann pin is removed then a pilot hole is drilled with a twist drill bit. A pilot hole the same diameter of the shaft of the fixation pin is used (1.6 mm, 2.4 mm, 3.2 mm, 4 mm). There is a separate drill sleeve for each drill bit size.

After the pilot hole is drilled, the drill sleeve is removed and the fixation pin is inserted. The aiming instrument will guide the fixation pin to the pilot hole. The pin should be placed with a power drill capable of spinning a low speed while still providing high torque. The fixation pin is placed so that it penetrates both corticies such that only the trocar point can be felt protruding from the far cortex. The aiming instrument is then removed. A clamp is then applied by placing the U-shaped body component with the head shaped component and sliding it over the fixation pins. Together, they are snapped on the connecting rod. The bolt is then inserted and tightened. The larger clamp is placed somewhat differently in that the two body components are placed on the connecting rod, then the head component, then the bolt.

Full-pins in bilateral fixators are placed in similar manner, but the arm on the aiming instrument is used. The most proximal and distal fixation pins are placed with connecting rods on both medial and lateral aspects of the limb. The aiming instrument is placed on either connecting rod with the arm in place (Figure 53-22). There are two grooves on the far end of the arm. The arm is slid so that the opposite connecting rod rests in either one of these two grooves. A Steinman pin is inserted into the drill sleeve and through skin to see whether it will contact bone. A Steinman pin is also inserted

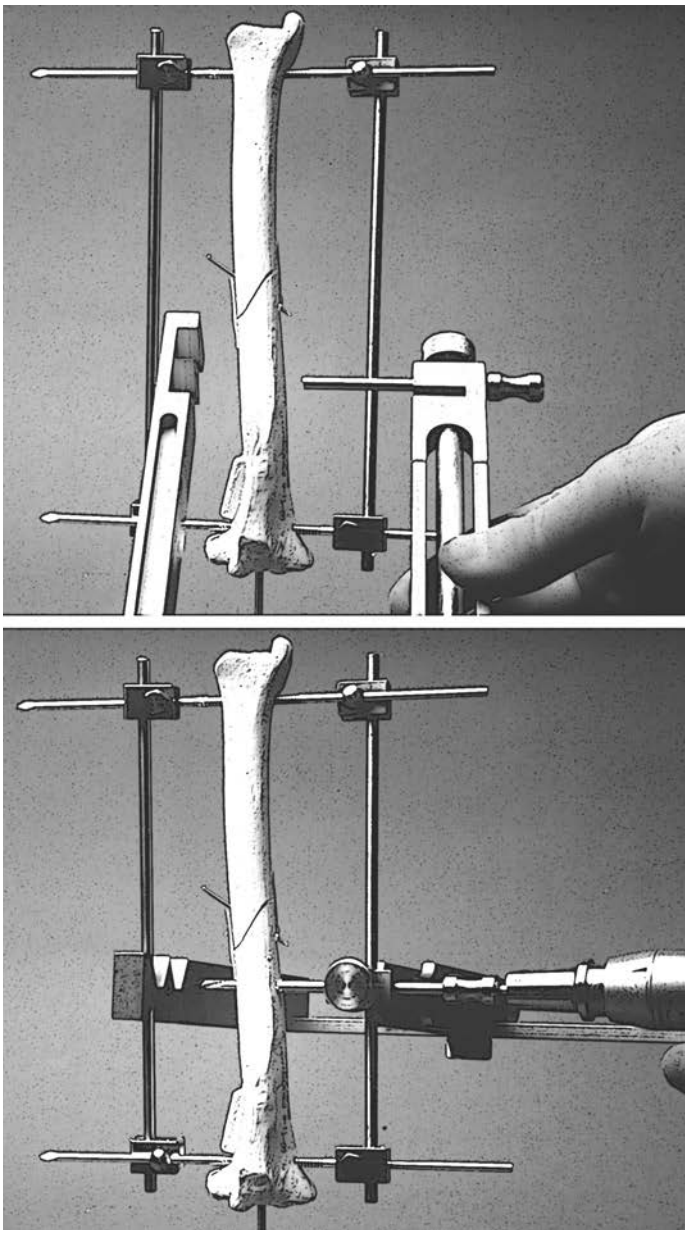

Figure 53-22. Application of bilateral fixator frames. Bilateral fixators are constructed by applying the first two pins and connecting rods in standard fashion. Additional fixation pins are applied by used the aiming instrument with its arm for full pins. Full-pins need not be placed in one plane and can be placed in front or back of either connecting rod allowing four pin orientations to the connecting rods. Pilot holes are drilled, then the fixation pins placed in accurate orientation to both connecting rods.

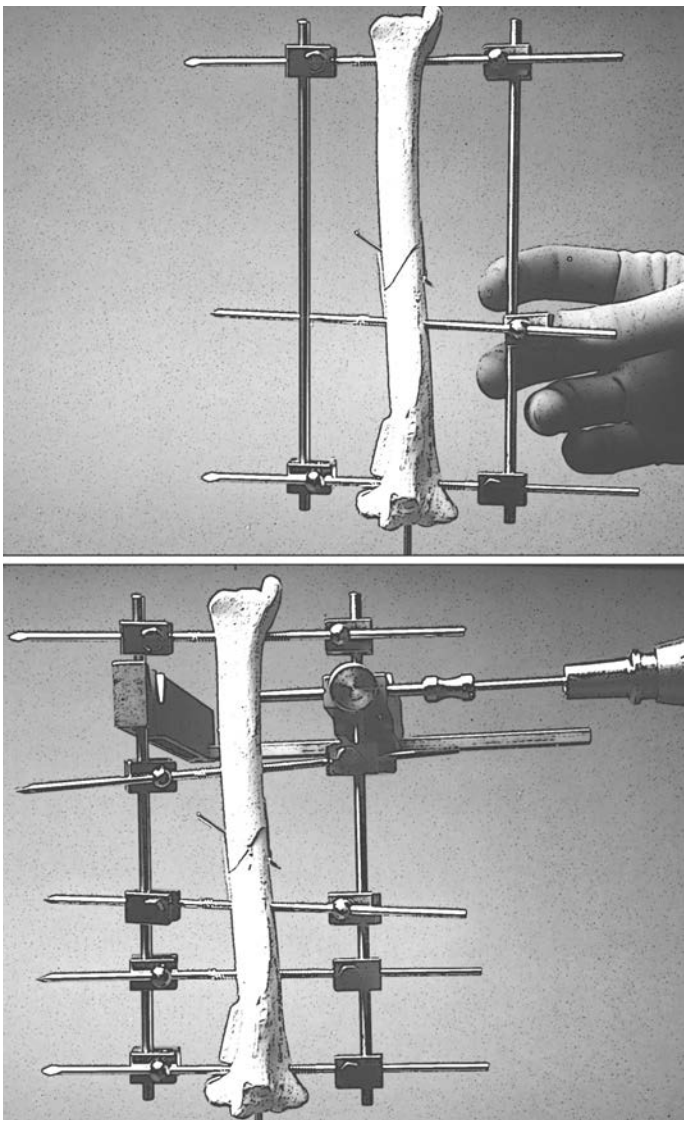

Figure 53-23. Application of multiple full pins. Once the fixation pin is in place, clamps are applied which connect the fixation pin with connecting rods. Additional full-pins or half-pins can be applied at the discretion of the surgeon.

in a hole between the two grooves on the arm and through skin, again to see whether it will contact bone. This assures that in this position a full-pin will have sufficient bone purchase. If in the first position there is not sufficient pin purchase, then the other groove in the arm of the aiming tool is used. If these two positions do not result in adequate pin purchase, the handle of the aiming instrument is flipped over so that the fixation pins starts from the opposite side of the connecting rod. This allows four possible positions to accomplish secure full-pin fixation. If none of these positions result in being able to place a properly-centered full-pin, then a half-pin is placed instead. Pilot holes for full-pins are drilled in similar manner to that described for half-pins, the drill sleeve is removed, then the full fixation pin is placed. It will advance through the hole on the arm of the aiming instrument. The instrument is then removed and clamps slid on the fixation pins then snapped on the connecting rod and tightened (Figure 53-23).

Application of the IMEX-SK External Fixator

James P. Toombs

Introduction

In order to improve the performance of external fixators in small animal patients, newer devices have addressed the following problems characteristic of the Kirschner-Ehmer (KE) splint: 1) weak frame components often necessitate the use of complex full-pin frames; 2) single clamps do not easily accommodate positive profile fixation pins; 3) fixation pin size is dictated by clamp size and the use of different pin diameters within a single construct is difficult; 4) clamps are susceptible to permanent deformation and loosening; and 5) clamps cannot be easily added to or subtracted from the middle portion of a construct. The IMEX™ SK™ external fixator was designed to overcome all of these problems.

Application of axial compression to a unilateral K-E splint in a fracture gap model reveals the connecting rod to be the weak link in the construct. With the K-E splint, this weakness is compensated for by using an aggressive Type II or Type III frame when dealing with an unstable comminuted fracture. Although use of multiple full-pins improves mechanical performance of the external fixator, it often does so at the expense of increased patient morbidity attributable to full-pins traversing a thick layer of soft tissue on one side of the limb.

Design of the SK fixator is based upon the use of larger connecting rods made of strong, light-weight material (carbon fiber composite or titanium). Increased connecting rod strength enables the use simpler, half-pin, Type I-a or Type I-b frames to successfully manage unstable comminuted fractures with the SK™ device. This in turn reduces the amount of soft tissue that will be penetrated by the fixation pins, thus reducing patient morbidity.

Components of the SK External Fixator

Clamps

Both single clamps and double clamps are available (Figure 53-24). Single clamps are used for attaching fixation pins to a connecting rod and double clamps are used for making rod-to-rod connections between fixation frames that have been applied in different planes. SK clamps are available in 3 different sizes: mini, small and large (Figure 53-25).

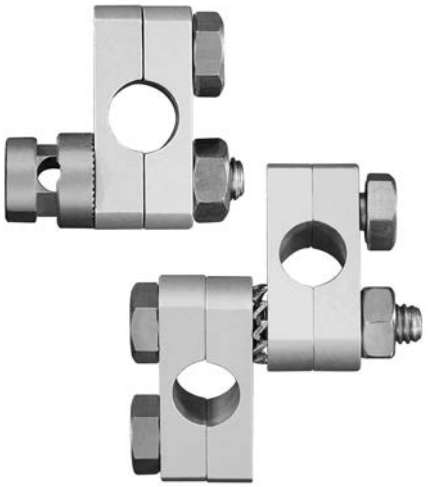

Figure 53-24. SK single clamp (top) used for securing a fixation pin to the connecting rod, and SK double clamp (bottom) used for making rod-to-rod connections between frames (also see Figure 53-34).

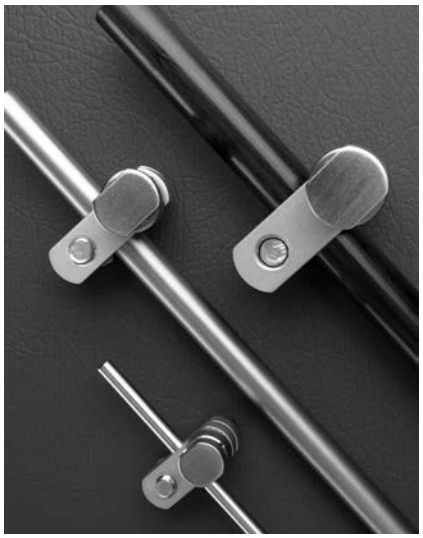

Figure 53-25. The 3 different sizes of SK clamps: large clamp with 9.5 mm carbon fiber connecting rod (top); small clamp with 6.3 mm titanium connecting rod (middle); and mini clamp with 3.2 mm stainless steel connecting rod (bottom).

The SK single clamp is comprised of B-1 and B-2 aluminum body parts, and stainless steel components including a primary pin-gripping bolt with a slotted washer, a nut to tighten the primary bolt, and a secondary bolt. Correct assembly of the clamp is shown in (Figure 53-26). The clamp is symmetrically tightened by a secondary bolt on one side of the clamp and by a primary bolt and a nut at the opposite end of the clamp. The slotted washer on the primary pin-gripping bolt enables the clamp to securely grip a wide variety of different fixation pin diameters. Fixation pin sizes, connecting rod materials and diameters, and the appropriate wrench size specific to each clamp size are summarized in Table 53-3.

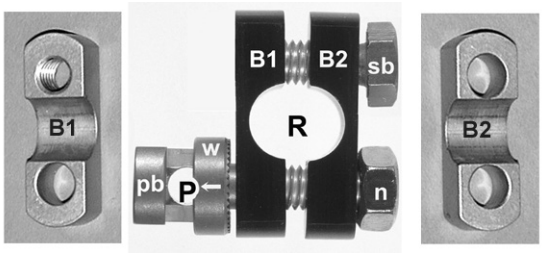

Figure 53-26. Anatomy of the SK single clamp. The modular aluminum clamp body has been manufactured with either a silver or black finish and has two slightly different components. The *B1* body part has a threaded hole that enables the secondary bolt *(sb)* to tighten the top of the clamp by lag effect, whereas the *B2* body part has a smooth gliding hole in this location. The rod-gripping channel *(R)* is in the center of the clamp. The pin-gripping bolt *(pb)* has a sliding washer *(w)* with a slot or meniscus *(arrow)*, enabling a wide range of different pin diameters to be securely grasped in the pin-gripping channel *(P)* of the bolt. The bottom half of the clamp is tightened by a nut *(n)* applied to the end of the pin-gripping bolt.

Table 53-3. Pin, Rod, Wrench and Bolt Sizes for Different Sizes of the SK Fixator

Clamp Size	Fixation Pin Shaft Diameter	Connecting Rod Diameter	Wrench/ Bolt/Nut Size
MINI	0.035" to 3/32" (0.9 mm to 2.5 mm)	3.2 mm[a.]	7 mm
SMALL	5/64" to 5/32" (2.0 mm to 4.0 mm)	6.3 mm[b.]	8 mm
LARGE	~7/64" to 3/16" (3.0 mm to 4.8 mm)	9.5 mm[c.]	10 mm

Superscript letters indicate types of rods available: [a.]stainless steel; [b.]carbon fiber composite and titanium; [c.]carbon fiber composite and aluminum.

Connecting Rods

Mini SK connecting rods are 3.2 mm in diameter, available in lengths ranging from 50 mm to 150 mm, and are made of stainless steel. Small SK connecting rods are 6.3 mm in diameter, available in lengths ranging from 50 mm to 250 mm, and are made from either carbon fiber composite or titanium. Small carbon fiber composite rods have similar bending stiffness to the 4.8 mm stainless steel connecting rods utilized by the size medium K-E splint, whereas small titanium connecting rods are twice as stiff. Large SK connecting rods are 9.5 mm in diameter, available in lengths ranging from 50 mm to 350 mm, and are made from either aluminum or carbon fiber composite. Large SK rods offer a four-fold increase in bending stiffness compared to small titanium connecting rods.

Fixation Pins

During the 1980s, small animal surgeons began to use positive profile threaded fixation pins in external fixator constructs. Early experience was gained with some of the smaller diameter implants designed for human patients such as the centrally-threaded skeletal traction pin (Synthes) and the end–threaded Turner hip pin (Zimmer). Although improved results were seen with these implants compared to the use of smooth fixation pins, many of the pins specifically designed for ESF in humans were too large to enable safe use in dogs and cats. The negative profile end-threaded fixation pins designed for small animal patients (Ellis™ pin from Kirschner and SCAT™ pin from IMEX) offered only modest improvement compared to results obtained with smooth pins. In the early 1990s positive profile threaded pins were developed specifically for use in small animal patients. These implants have greatly improved the success rate of ESF in challenging fracture cases.

Positive profile end-threaded half-pins (INTERFACE™ pins) and centrally- threaded full-pins (CENTERFACE™ pins) made for the SK fixator are summarized in Tables 53-4 and 53-5. These fixation pins are available with a standard or cortical thread profile for use in diaphyseal bone, and a cancellous thread profile for use in soft metaphyseal bone (Figure 53-27). Cancellous thread versions feature a greater thread diameter, deeper threads and a larger pitch than compared to pins with cortical thread. Use of cancellous pins should be confined to the proximal metaphysis of the tibia, the distal metaphysis of the femur, and the proximal metaphysis of the humerus. Their use in hard diaphyseal bone is contraindicated. Fixation pins with extended thread length are available and are occasionally required in order to fully purchase the increased diameter of the bone in some metaphyseal locations.The majority of pin sizes are available with either

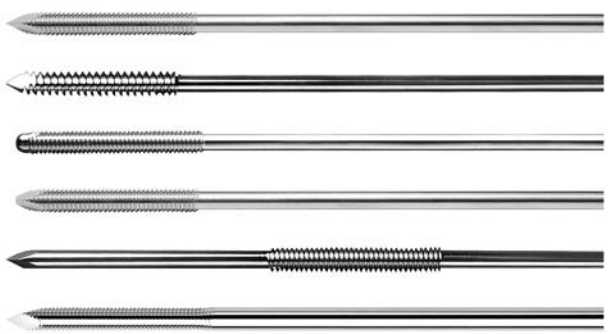

Figure 53-27. Different types of fixation pins (from top to bottom): INTERFACE half-pin with cortical (standard) thread; INTERFACE half-pin with cancellous thread; first version of INTERFACE NP half-pin with cortical thread and atraumatic rounded tip; revised version of INTERFACE NP half-pin with blunt trocar tip; CENTERFACE full-pin with centrally placed cortical thread; and DURAFACE half-pin with taper run-out junction and cortical thread.

a trocar point or with an atraumatic NP (no point) tip (see Figure 53-27). Since NP pins to not have a cutting trocar point, the surgeon is forced to use proper pre-drilling technique to apply them. Compared to pins with a trocar point, NP pins require slightly greater insertional force until the initial threads engage and cut threads in the near cortex of the bone. After that, the gear effect of pin threads moving on bone threads allows the fixation pin to smoothly advance across the bone. The first version of the NP pin had a rounded tip, and its ability to accurately center itself in the pre-drilled hole was slightly less than that of a pin with a trocar tip. The tip of the NP pin was later revised to a blunted trocar tip to improve the ability of the pin to properly center within the pre-drilled bone hole.

The most recent development in fixation pin technology is the DURAFACE pin (Figure 53-27). It is a pin with a larger diameter smooth shaft and a taper run-out junction leading to a negative profile thread at the end of the pin. Unlike other negative profile

pins, this implant has improved mechanical performance compared to other pins with the same thread diameter, but does not have a stress concentration point at the smooth-threaded junction that could predispose bending or breakage of the implant. DURAFACE pin options are summarized in Table 53-5.

Application Techniques

The slotted washer on the primary pin-gripping bolt enables the use of a wide range of different pin sizes for each SK clamp size (Tables 53-3 and 53-6). The curvature of the meniscus in the washer corresponds to the smallest pin shaft diameter that can be gripped by the primary bolt. The hole in the primary bolt is large enough to accommodate sleeved pre-drilling and application of a positive profile pin directly through the bolt. The diameter of the pin-gripping channel in the primary bolt determines the maximum diameter of a positive profile threaded pin that can be passed through it. When a larger threaded pin is desired, sleeved pre-drilling of the bone is done through the clamp, the clamp is temporarily removed, the pin is applied to the bone, the pin-gripping bolt is applied to the smooth shaft of the pin, and the clamp is re-assembled to attach the pin to the rod. This technique is applicable when a size medium cancellous INTERFACE half-pin is used with a small SK clamp at positions other than the most proximal and most distal ones within a construct. The shaft and thread diameters of this pin are 3.2 mm and 4.8 mm respectively, and the diameter of the pin-gripping channel in the primary bolt of a small clamp is 4.0 mm. Although the threaded diameter won't pass through the clamp, the primary bolt is able to grip the shaft diameter of the pin.

The slotted washer of the primary bolt has a multi-toothed surface that engages the outer surface of the clamp body when the clamp bolt is tightened (Figure 53-28). This provides positive retention between the washer and the clamp body thus eliminating pin-bolt slippage in relation to the connecting rod. The circular shape of the serrated area on the washer makes its positive retention capability function at any desired angle using either half-pins or full-pins.

The split body design of the SK clamp allows for easy addition or subtraction of a clamp from a construct without taking the frame apart (as would be necessary with a KE splint). Primary and secondary bolts enable symmetrical tightening of the clamp to securely grip both the fixation pin and the rod. This is accomplished without deforming the clamp body.

In the early phase applying a linear fixator, disruptive torque forces produced by the tightening of the first several clamps may cause loss of fracture reduction or alignment. SK clamps have a feature that makes it easy to counter these forces. The flat surfaces on the end of the primary pin-gripping bolt and the flat surfaces on the assembled clamp body (Figure 53-29) are the same dimension as the wrench used to tighten the clamp. A second wrench can be applied to either of these surfaces to counter disruptive torque forces during clamp tightening.

While the secondary bolt allows for symmetrical tightening of the SK clamp, it also enables an empty clamp to serve as a targeting device. For example, when the surgeon wants to place a pin in

Table 53-6. Pin Size versus SK Clamp Size

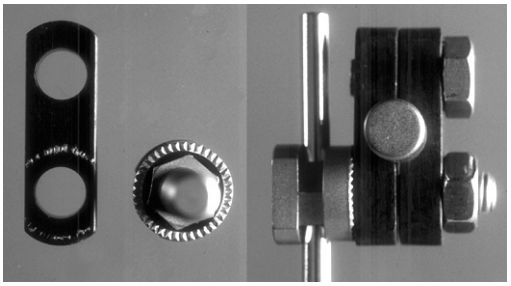

Figure 53-28. Small SK single clamp tightened to grip a medium INTERFACE pin and a 6.3 mm titanium connecting rod (right image). Note that the teeth of the washer engage the clamp body. Portions of the disassembled clamp (left image) show that the teeth of the washer have made indentations in the B1 body part which improves the mechanical performance of the clamp.

the same plane as the pin adjacent to it, this is accomplished a follows. A drill sleeve is inserted through the pin-gripping channel of the primary bolt (Figure 53-30) of a loose clamp placed on the connecting rod. The clamp is rotated until the long axis of the drill sleeve is a plane identical to that of the fixation pin adjacent to it. The secondary bolt is tightened to maintain this orientation and the nut on the primary bolt is partially tightened to secure the drill sleeve (NOTE – over-tightening of the nut will crimp the wall of the drill sleeve which is to be avoided). The bone is pre-drilled through the sleeve, the primary bolt is loosened to remove the sleeve, and the threaded fixation pin is inserted through the clamp and into the bone. Regardless of the desired plane of pin insertion, the secondary bolt can be used to stabilize the position of the clamp/drill sleeve unit to facilitate accurate pre-drilling.

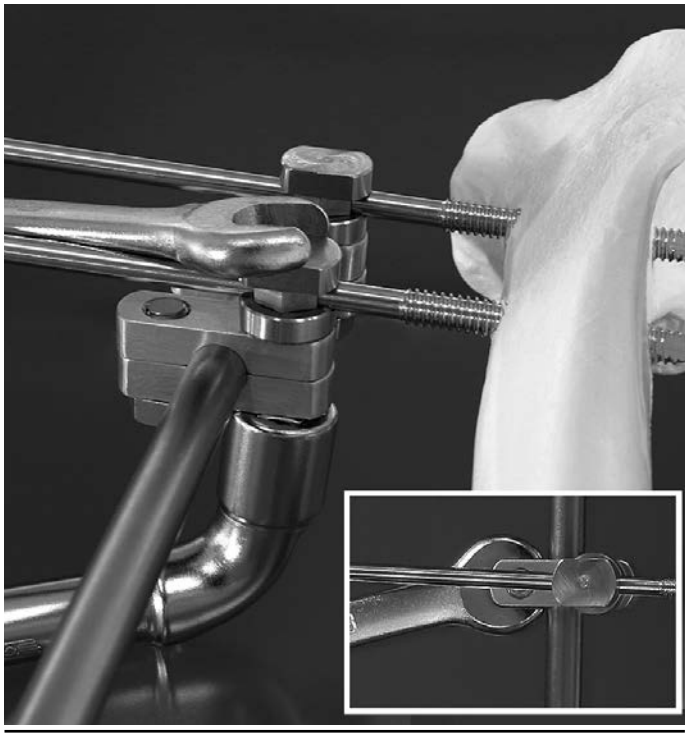

Figure 53-29. Two wrench technique for tightening of the clamp. An open end wrench is applied to the flat surfaces of the head of the pin-gripping bolt (large picture) or to the proximal and distal surfaces of the clamp body (inset picture) to neutralize torque forces that could disrupt fracture alignment during the process of tightening the clamp with the L-shaped combination wrench.

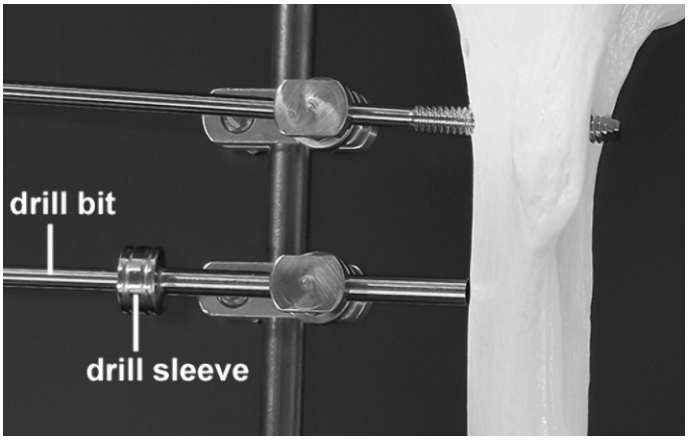

Figure 53-30. Use of a drill sleeve placed through a clamp to assist with proper targeting of the fixation pin. If desired, the surgeon can position the drill sleeve in the same plane as a previously placed pin (proximal-most pin in this picture). This orientation is maintained by tightening the secondary clamp bolt to secure the position of the clamp on the rod, and light tightening of the nut on the primary clamp bolt to secure the position of the drill sleeve. This same strategy can be used to insure that multiple full-pins are placed in the same plane for Type II fixators.

Application of a Type I-a Construct

The fracture is reduced (hanging limb technique is useful for accomplishing this in fractures of the radius / ulna or tibia) and a proximal fixation pin and a distal fixation pin are placed near the ends of the bone. The example shown in Figures 53-31 and 53-32 involves fixator application to the tibia, in which the fixation pins are passed in a mediolateral plane through the medial aspect of the bone (preferred anatomic corridors for fixation pins in other bones has been covered in the earlier chapter – Basic Principles for the Application of External Fixators). At each intended pin placement site, a liberal release incision at least 1 cm in length

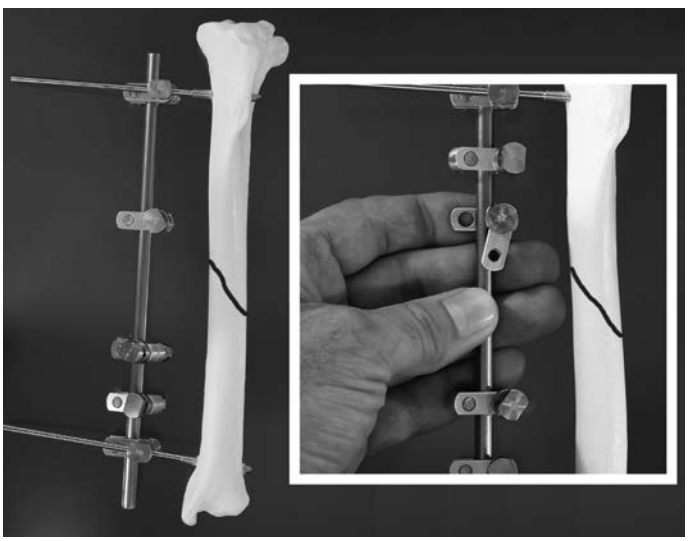

Figure 53-31. Completing the middle portion of the frame. The desired number of single clamps can be placed on the connecting rod prior to attaching it to the proximal and distal fixation pins (left image). In a typical case, 3 fixation pins should be placed both proximal and distal to the fracture. In the example shown, the surgeon has failed to place a sufficient number of clamps on the rod to accomplish this goal. This is easily corrected by assembling an additional clamp on the rod of the existing assembly (inset picture).

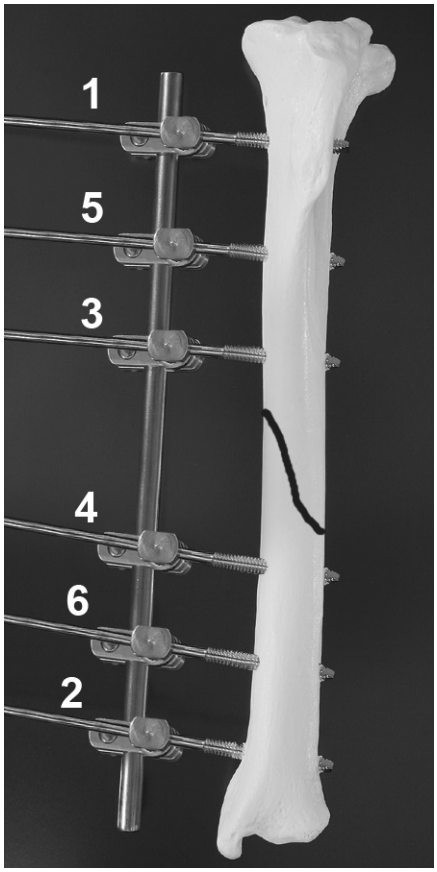

Figure 53-32. Far-far-near-near-middle-middle order of pin placement in the application of an external fixation frame. Fixation pins are initially placed at the ends of the bone *(pins 1 and 2)*. The next two pins are placed immediately above and below the fracture *(pins 3 and 4)*. The middle portion of each pin cluster is then completed *(pins 5 and 6)*.

is made through the skin and soft tissues over the center of bone. Placement of a miniature Gelpi retractor in the incision is helpful for maintaining exposure. Pre-drilling is done through the release incision using a drill sleeve to protect the soft tissues and a drill bit that is equal to the core diameter of the fixation pin. Each fixation pin is applied to the pre-drilled hole using slow speed power insertion technique. A connecting rod is secured to the first two pins using SK single clamps. Considerable torque force occurs as these clamps are tightened. A second wrench should be used to neutralize forces that could disrupt fracture alignment as the clamps are tightened.

Empty clamps to accommodate the anticipated number of additional fixation pins required can be pre-placed onto the connecting rod or added later (Figure 53-31). A release incision at least 1 cm in length is made at the next pin placement site. An empty clamp is positioned over the release incision and a drill sleeve is inserted through the hole in the clamp bolt down to the level of the bone. After the clamp and drill sleeve are oriented to provide proper centering of the hole that will be pre-drilled through the bone, this position is maintained by tightening the secondary bolt and gently tightening the nut on the primary bolt to secure the drill sleeve. Pre-drilling of the near and far cortex is done with a twist drill bit. The nut on the primary bolt is loosened to enable removal of the drill sleeve and a fixation pin is applied through the hole in the primary clamp bolt and advanced into the

pre-drilled hole in the bone using slow speed power insertion technique. It is important for the threads of the pin to fully engage the far side of the far cortex of the bone. In order to accomplish this, several millimeters of the tip of the pin must extend into the soft tissues beyond the far cortex. If vital anatomic structures are likely to be present in this location, a NP pin should be used. The clamp is secured by alternate tightening of the secondary bolt and the nut on the primary bolt. These steps are repeated at each pin placement site until at least three fixation pins have been placed both proximally and distally. The order of pin placement is generally as follows: the most-proximal and most-distal pins are placed first; the central pins immediately above and below the fracture region are placed next; and pins in intermediate locations are placed last (Figure 53-32). Fixation pins should not be trimmed until acceptable fracture alignment has been verified on post-operative radiographs. Each pin should then be trimmed such that the cut edge stops short of the outer surface of the clamp.

Application of a Type I-b Construct

For comminuted shaft fractures, a Type I-a construct may not provide sufficient stability. In these cases, a second Type I-a frame is applied in a different plane (orthogonal to the first frame is optimal mechanically). For the tibia this would involve application of fixation pins in a craniolateral plane through the cranial aspect of the bone (Figure 53-33).

Linkages are sometimes made between the lateral frame and the cranial frame to improve construct rigidity. These connections can be made proximally and distally (See Figure 53-33) or diagonally (Figures 53-34 and 53-35). Diagonal connections provide greater strength because they span the fracture region. Linkages can be built using double clamps (Figures 53-33 and 53-34) or by leaving selected fixation pins long and placing additional single clamps on the pins external to the frames (Figure 53-36) and connecting these "stacked" clamps with a rod.

Application of a Type II Construct

Some surgeons prefer to use a Type II frame (instead of Type I-b) for challenging shaft fractures. For the tibia, this entails application of at least two full-pins in a mediolateral plane through the medial aspect of the bone. The remainder of the frame is often built with medially applied half-pins resulting in a minimal or modified Type II construct (Figure 53-35).

A full-pin is applied using the same techniques described for the placement of a half-pin except that a second release incision must be made laterally to enable the full-pin to exit on the opposite side of the leg. After a full-pin has been placed in both the proximal and distal ends of the bone, these are connected medially and laterally with connecting rods and SK clamps (Figure 53-36). The remainder of the construct is completed by

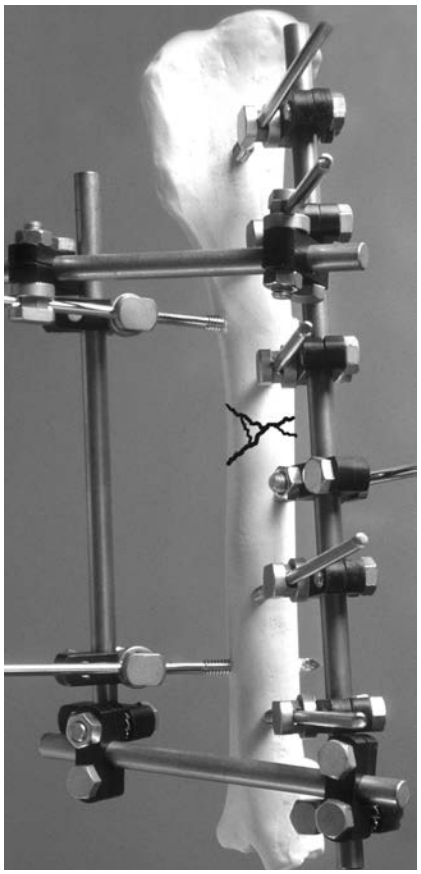

Figure 53-33. Medial view of a small SK Type I-b (unilateral-biplanar) external fixator on the tibia. A 6-pin frame has been applied medially, and a 2-pin frame has been applied cranially. The two frames have been interconnected with proximal and distal linkages using double clamps and titanium connecting rods.

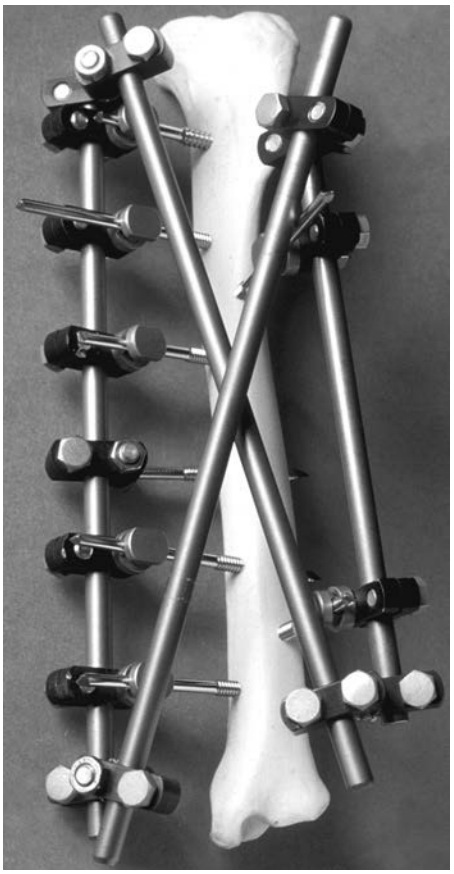

Figure 53-34. Craniomedial view of a small SK Type I-b construct on the tibia. Note that the medial and cranial frames have been interconnected with double diagonal linkages using double clamps and titanium connecting rods.

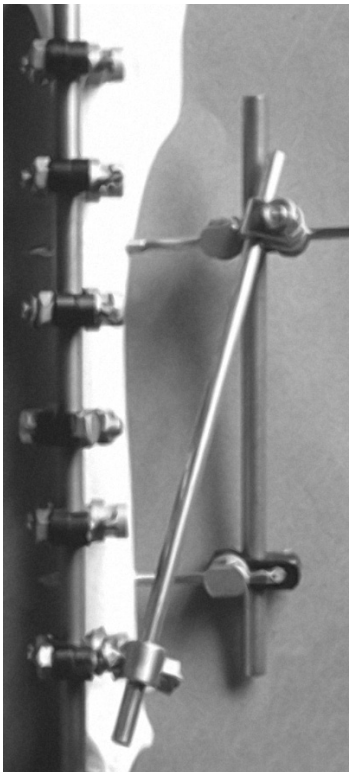

Figure 53-35. Medial view of a small SK Type I-b construct on the tibia. The medial and cranial frames have been connected with a single diagonal linkage using KE clamps and a stainless steel connecting rod. This same linkage could have been made with SK clamps and a titanium or carbon fiber composite connecting rod. Although KE components are weaker than SK components and should not be used for building frames, they may be safely used to apply more compact linkages to SK frames than is possible using SK components. This is due to the reduced height of the KE clamp compared to the SK clamp.

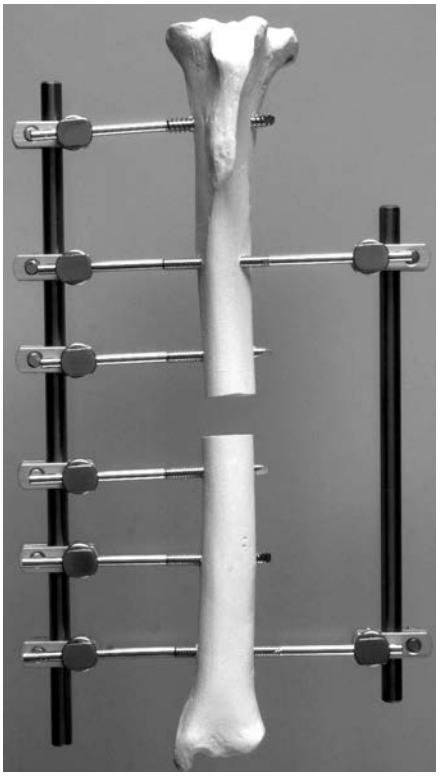

Figure 53-36. Cranial view of a small SK minimal Type II construct on the tibia. The proximal and distal full-pins were placed first and were connected with 6.3 mm carbon fiber composite connecting rods. The proximal-most half-pin was placed next and it should be noted that this is a cancellous thread pin due to the soft bone found in the metaphysis. The half-pins immediately above and below the fracture were placed next, followed by the remaining half-pin in the distal segment. Full-pins could have been safely used at every location except the most proximal pin site if additional frame stiffness was desired.

applying the required number of additional fixation pins from the medial side of the tibia. Half-pins or full-pins or a combination of these may be used to complete the fixator, however, a full-pin at the most proximal location on the tibia tends to cause higher postoperative morbidity than a medially placed half-pin at this position. This is due to the pin traversing a thick layer of soft tissue on the lateral aspect of the leg in a high motion area near the stifle joint.

Staged Disassembly of SK External Fixators

Rigid constructs benefit revascularization of the injured bone and other early fracture healing events, but high fixator stiffness may actually delay the later stages of bone healing and remodeling. Strategic reduction of external fixator rigidity to benefit the later stages of healing is accomplished by a process called staged disassembly. This can be done in several ways: 1) simplifying the frame configuration (e.g. conversion of a Type I-b to a Type I-a); 2) downsizing the frame by replacement of the connecting rods and clamps with smaller components (Table 53-7 and Figure 53-37); and 3) by removal of fixation pins from the central portion of a frame (strategy used for Type I-a fixators).

In skeletally mature patients, staged disassembly should be initiated at approximately 6 weeks after surgery. In adolescent patients, this process can often be started at 3 to 4 weeks

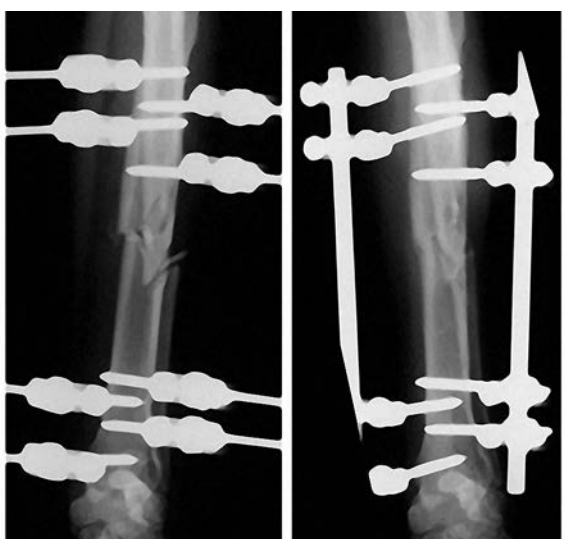

Figure 53-37. Staged disassembly of an external fixator shown in cranial-caudal radiographic projections of a comminuted fracture of the radius and ulna in 22 kg dog initially repaired with a Type I-b construct. The immediate post-operative radiograph (left picture) shows that large SK components were used (note the radiolucent 9.5 mm carbon fiber composite connecting rods). At 7 weeks after surgery (right picture) the large SK clamps and rods have been replaced with small SK clamps and 6.3 mm titanium connecting rods. Downsizing of the components of the fixator has reduced its frame stiffness by approximately four-fold.

Table 53-7. Staged Disassembly Strategies for SK Fixators Relative to the Size of Pins Used to Build the Fixator

Large SK constructs can be staged down to **Small SK constructs** as part of the disassembly strategy

4.3 mm DF
4.8 mm DF

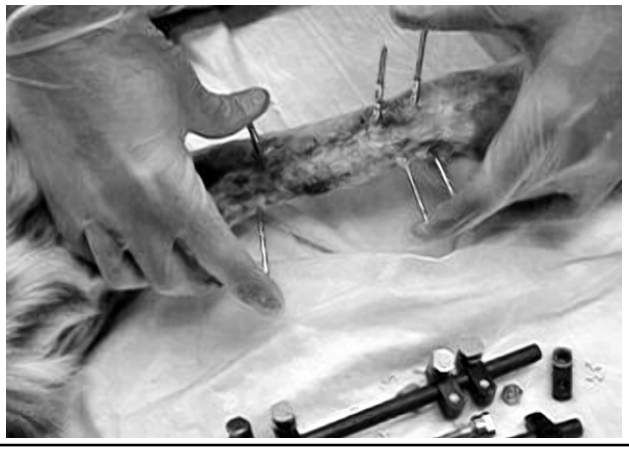

Figure 53-38. Staged disassembly of an external fixator. A Type I-b construct has been temporarily removed from this sedated patient. The surgeon is using the fixation pins to gently manipulate the fracture region to detect evidence of callus deposition. If callus is present, a frame with reduced stiffness will be applied to the fixation pins. If callus is not detected, the original frame will be rebuilt.

post-op. Staged disassembly can usually be done with the dog or cat under heavy sedation, but some patients may require brief duration general anesthesia with propofol. The fixation frame(s) should be temporarily removed to enable critical palpation of the fracture for evidence of callus formation (Figure 53-38). If the fracture feels "sticky" due to the presence of soft callus, it is appropriate to begin staged disassembly. If any of the fixation pins are causing morbidity, strongly consider removal of these fixation elements as part of the staged disassembly strategy. An example of this would be a Type I-b fixator applied to the radius in which fixation pins have been applied craniomedially and craniolaterally. Fixation pins of the craniomedial frame generally traverse less soft tissue than those of the craniolateral frame. On examination at 6 weeks after surgery, the pin tracts of the craniolateral frame might appear to be slightly inflamed compared to those of the craniomedial frame. If this was the case and the surgeon planned to convert the Type I-b frame to a Type I-a frame as part of the staged disassembly strategy, it would be logical to remove the craniolateral frame and its fixation pins.

Circular External Skeletal Fixation

Daniel D. Lewis and James P. Farese

Since the writing of the topic, methodology and nomenclature adopted from Dror Paley's Principles of Deformity Correction have been adapted and become accepted as the convention in small animal orthopedics.

Introduction

Circular external skeletal fixation (CESF) was pioneered by the Russian physician, Gavriil Ilizarov. These are modular systems which can be assembled in numerous configurations to stabilize fractures and arthrodeses, perform bone lengthening and transport as well as correct angular, translational and rotational deformities and are being used with increased frequency in dogs and cats. Circular fixator (CF) frames consist of a series of complete and/or incomplete external rings that are interconnected by multiple threaded rods. Rings are secured in position along these rods by placing nuts on opposing surfaces of each ring. Circular fixators are uniquely designed, allowing the frame to be elongated or shortened during or following surgery. Elongation of the frame during the convalescent period allows for distraction osteogenesis in which regenerate bone is formed within the osteotomy gap resulting from gradual separation of the secured bone segments.

Components, Implants and Instrumentation

The IMEX™ CESF System (IMEX™ Veterinary, Inc., Longview, TX) is the CF system used most commonly by North American veterinarians. This system was developed in conjunction with the Comparative Orthopedics Research Laboratory of the Texas Scottish Rite Hospital for Children in Dallas, Texas and is modeled after a device utilized in human patients. This system has several evolutionary advances which simplify frame construction, improve precision and decrease patient morbidity. The utilization of lighter metals and engineered plastics facilitated this process. Several new components have been developed which substantially decrease the total number of parts necessary for frame assembly, thereby reducing pre-operative frame preparation time.

Traditional CF constructs consist of supporting elements (complete rings, partial rings and arches), connecting elements (threaded rods, linear and angular motors and hinge assemblies), fixation elements (small diameter wires) and assembly elements (cannulated and/or slotted bolts, nuts, washers, plates and posts). The following section describes components of the IMEX™ CESF System.

Supporting Elements

Rings in this system are manufactured from a high-strength tempered aluminum alloy which imparts strength to the supporting elements while keeping the fixators weight-appropriate for use in dogs and cats (Figure 53-39). The rings have holes located about their circumference in which connecting and assembly elements are secured. Ring components are available in 50 mm, 66 mm, 84 mm and 118 mm internal diameters. While it is biomechanically preferable to utilize complete rings, anatomic constraints prohibit their use proximal to the elbow and stifle and often adjacent to other joints. Traditional CFs are mainly applicable for managing conditions involving or distal to the elbow or stifle, while hybrid linear-CF constructs (see section on Hybrid Constructs, Chapter 55) are typically used to manage injuries and abnormalities involving the humerus or femur. Five-eighths partial rings are often used to secure the proximal radius and distal tibia, while stretch ring arches have been developed which facilitate CF application to the proximal tibia and ulna. Stretch ring arches also simplify construction of CFs for transarticular stabilization of the hock and stifle regions. One-third partial ring arches are also available.

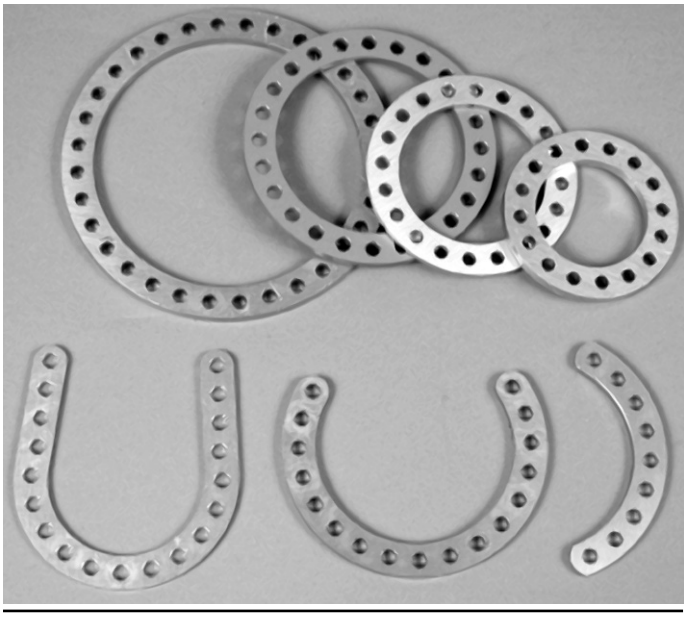

Figure 53-39. Supporting elements: complete rings (top row) are available in 118 mm, 84 mm, 66 mm and 50 mm internal diameter. Stretch and five-eighths partial rings and one-third ring arches (bottom row) are also available.

Connecting Elements

Threaded rods (6 mm thread diameter x 1 mm thread pitch) are the most commonly used connecting elements. Threaded rods are available in 60 mm, 80 mm, 100 mm 150 mm and 225 lengths with a 3 mm hex drive fitting at their ends to accommodate a 3 mm angled or straight hex driver. This hex broach fitting allows rapid replacement or exchange of rods if necessary.

A unique design feature of the IMEX™ CESF System is its zero tolerance, zero motion connecting elements (Figure 53-40). Adjustable components used for angular and linear distraction have nylon drive bushings or inserts between metal parts which prevent binding, allowing adjustments to be made without loosening and retightening nuts. This makes the distraction process simple and precise by eliminating frame instability which causes patient discomfort. Distraction or compression is performed simply with a wrench, facilitating client compliance and negating the need for prolonged hospitalizations.

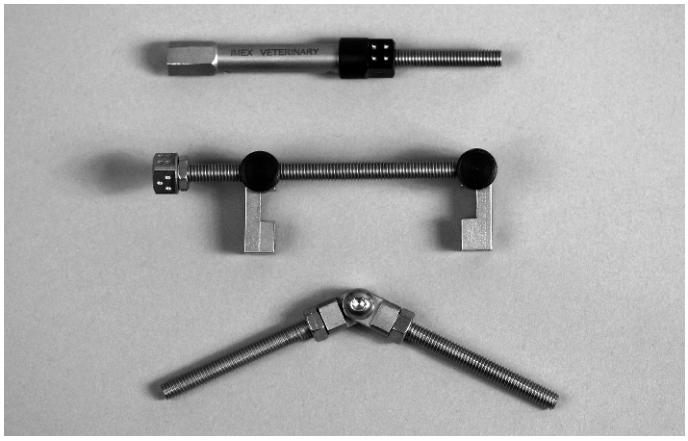

Figure 53-40. Connecting elements (from top to bottom): linear motor, angular motor and hinge assembly secured to short connecting rods with lock nuts.

Linear motors, available in 50 mm, 70 mm and 100 mm lengths are composed of a threaded rod encased in stainless steel housing and are used to perform linear distraction or compression. A nylon drive bushing is positioned between the stainless steel housing and threaded rod (6 mm diameter x 1 mm thread pitch). During distraction or compression, the drive bushing allows distraction or compression without loosening and retightening nuts, eliminating frame instability and thereby minimizing patient discomfort. Distraction or compression is performed simply by turning the clearly marked drive bushing with a 10 mm wrench. One complete revolution of the drive bushing produces 1 mm of linear movement.

Threaded rods can also be used for linear distraction/compression if 10 mm (6 mm thread diameter) paired nylon nuts are used to secure a ring to the rod. Simultaneous rotation of the paired nylon nuts with a double jawed 10 mm wrench which can engage nuts positioned on both sides of a ring will accomplish linear distraction/compression. The use of paired nylon nuts instead of linear motors to achieve linear distraction is most beneficial when adjacent rings are in close proximity. One complete revolution of the paired nylon nuts results in 1 mm of linear movement of the secured ring.

Connecting elements used for angular correction include hinge assemblies and angular motor assemblies. Hinge assemblies are used in pairs to provide pivot points between two rings. Angular motor assemblies provide asymmetric distraction of two rings articulated using paired hinge assemblies. Both elements have nylon inserts which confer zero tolerance, zero motion properties. Like the linear motor units, the angular motor assembly is clearly marked to aid in daily distractions during the convalescent period. Hinges and angular motor assemblies have a hex drive fastener which can be tightened once distraction is complete to lock the fixator in place. It should be noted that the hex drive fastener elements should be loosened prior to steam sterilization to prevent damage to the component as a result of expansion of the nylon insert.

Fixation Elements

Unlike linear fixator systems, traditional CFs use small diameter (1.0 or 1.6 mm) wires, rather than larger diameter pins, as fixation elements. Two wires are generally placed on each ring with the wires secured to opposing surfaces of the ring. The fixation wires are typically tensioned to improve their stiffness characteristics. Although standard Kirschner wires can be used as fixation wires, use of wires with an efficient single lip cutting point is recommended. Fixation wires are also available with olives (or stoppers) to increase stability of the construct and/or to manipulate and secure bone segments. Olive (or stopper) wires have a raised bead (olive) fixed along their length. This olive is brought into contact with the cortex of the bone. The olive can also be used to pull a bone segment into alignment and prevents translation of a secured bone segment along the wire. Inexpensive calibrated tensioning devices are now available to tension wires. Although not a part of Ilizarov's traditional armamentarium, positive and negative profile partially threaded (end threaded) half-pins and positive profile partially threaded (centrally threaded) full-pins can also be used as fixation elements.

Assembly Elements

All assembly elements have 10 mm wrench flats or 3 mm hexagonal recesses, thus keeping instrumentation to a minimum (Figure 53-41). Ten mm (6 mm thread diameter) stainless steel nuts are also used to secure connecting and assembly elements. Fixation wires are secured to the rings with 6 mm wire fixation bolts which are both slotted (for capture of wires that cross rings between holes) and cannulated (for capture of wires that cross rings over a hole). Slotted 6 mm washers are available to capture wires at sites occupied by connecting elements and 6 mm flat washers are available to be used as a spacer for capturing wires that are not inserted immediately adjacent to a ring. Pin fixation bolts are also available which allow the utilization of half-pins and full-pins. The pin fixation bolts accommodate fixation pins ranging from 2.3 mm to 5 mm in diameter and are similar in design to the pin-gripping bolt of IMEX™ SK™ fixation clamp.

Hemi-spherical washers and hemi-spherical nuts are also available. When used in combination the hemi-spherical washers and hemi-spherical nuts allow for angulation of connecting rods. Thus, rings can be secured to each other

Figure 53-41. Assembly elements (from left to right): top row: stainless steel nuts, nylon nuts, wire fixation bolts, pin fixation bolts. Middle row: hemi-spherical washers and nuts, stainless steel washers, slotted washers, and two-hole plates. Bottom row: one- and two-hole posts.

without being in exact parallel alignment. This permits minor adjustments in reduction of fracture segments and fine adjustments in correcting angular deformities. When utilized with two-hole plates, the hemi-spherical washers and hemi-spherical nuts can be used to connect adjacent rings without utilizing corresponding holes and are particularly useful in constructing complex or transarticular frames.

Two-hole plates are available to allow the use of different diameter rings within the same fixator frame. The plate is bolted to the ring extending away from its center. A connecting rod or motor can then be attached to the plate and linked directly to the next larger diameter ring. One- and two-hole posts are utilized to secure fixation wires and pins elevated remote to the surface of a ring, to create hinge assemblies and to secure connecting elements that are not positioned perpendicular to the surface of a ring. Plates and posts are extremely useful when constructing transarticular or other complex frames.

Biomechanics

Circular fixators possess biomechanical characteristics which purportedly enhance fracture healing as well as allow for distraction osteogenesis. The biomechanics of CFs differ primarily from linear fixators in that the tensioned wires stabilizing the bone segments adequately resist bending, shear, and torsional forces while maintaining some degree of axial elasticity. Load/deformation curves of CF constructs undergoing axial compression have a characteristic initial exponential increase in stiffness which is ascribed to tensioning of the wires when subjected to loading. Construct stiffness increases until the slope of the load/deformation curve becomes linear with continued loading, protecting the osteotomy or fracture gap from excessive strain during ambulation. The "axial micromotion" occurring at physiological loads purportedly creates a mechanical environment conducive to bone formation.

Numerous extrinsic (apparatus-related) factors have been shown to affect the stability of the fixation including the number, type, angle of intersection, applied tension and diameter of the fixation wires, as well as the number, conformation, diameter and position of the rings and connecting elements. Intrinsic factors which theoretically contribute to stability of the bone-fixator construct include the area of contact and nature of the interlock between bone segments, the modulus of elasticity of tissue between bone segments, and the tension of the regional soft tissues.

The number of levels of fixation influences the mechanical properties of any fixator construct. Ilizarov found that four-ring CFs (two rings per bone segment) were more stable than two-ring CFs (one ring per bone segment). Additional studies have shown that if a four-ring construct is used to stabilize a fracture, the stability of the CF is increased if the central two rings are positioned in close proximity to the fracture or osteotomy and the proximal and distal rings are positioned adjacent to the joints at the end of the each major bone segment. This distributes the weight-bearing forces evenly over the involved limb segment in a "far-near-near-far" arrangement.

Ring diameter is the single most important parameter influencing the biomechanical profile of any CF constructs. While ring diameter affects stability in all modes of loading, ring diameter has its greatest effect on axial stability. Ring diameter is selected based on anatomic constraints: the smallest diameter rings which can be accommodated should be selected; however, a minimum 1 to 2 cm of clearance should be maintained between the ring and the circumference of the limb to allow for soft tissue swelling and daily management of the wire-skin interfaces.

Since the diameter of rings used in dogs and cats is much smaller than those used in human patients, even children, the biomechanics of CFs used in dogs and cats are markedly different from those used in human patients. Several biomechanical studies have been done evaluating IMEX™ CF constructs and it appears that there is little need to tension wires when using the 50 mm and possibly the 66 mm rings (although wires are usually tensioned to 30 kg when using 66 mm rings). Tensioning of wires on larger diameter rings is warranted with the recommendation to apply 60 kg of tension when using 84 mm rings and 90 kg of tension when using 118 mm rings. Some surgeons advocate simultaneously tensioning wires secured to the same ring (Figure 53-42) and wires secured to partial rings or posts should not be tensioned beyond 30 kg to avoid deformation of the ring or posts.

Olive wires can enhance the stability of fixation. Placing two opposed olive wires to secure a bone segment can significantly improve bending stiffness and stability by minimizing translation of the secured bone segment along the wire. This is particularly important when wires are placed on the same ring with little divergency. Opposing interfragmentary olive wires can also be used to compress anatomically reduced long oblique or spiral fractures.

CF constructs utilizing tensioned wires in combination with half-pins or full-pins are being used with increasing frequency. The use of half-pins has been advocated in locations where divergent fixation wires would pass through prominent muscle

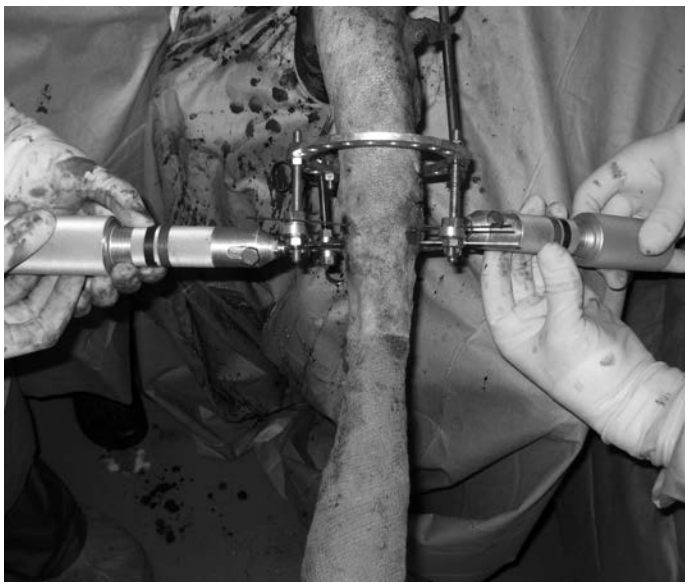

Figure 53-42. Simultaneous tensioning of fixation wires using calibrated tensioning devices.

masses, such as the proximal tibia, or near vital soft tissue structures. These constructs have been shown to have biomechanical characteristics intermediate between those of conventional linear fixators and traditional CFs. The combination of wire and half-pin fixation can be problematic. When used in combination with wires, a single or an inadequate number of half-pins may be subjected to excessive loading as the wires initially deform when subjected to loading. Thus, if the number of half-pins utilized is not sufficient, excessive stress occurs at the pin-bone interface. The use of three (or preferably more) evenly distributed, divergent half-pins per bone segment (depending on concurrent wire utilization) is advocated in these configurations to avoid problems associated with premature pin loosening and pin tract drainage.

Distraction Osteogenesis

Distraction osteogenesis describes the mechanical induction of new bone formation in the gap produced by the gradual separation of two bone segments. Much of what is known regarding the biology of distraction osteogenesis was elucidated by Ilizarov and his colleagues; however, recent investigations have focused on the cellular and molecular events of bone formation in both fracture healing and distraction osteogenesis. Distraction osteogenesis shares many morphologic and biomechanical similarities with early fracture healing. Bone retains the inherent capacity to remodel and repair and these processes are influenced by the local mechanical environment. The new bone which forms in the distraction gap during distraction osteogenesis is referred to as "regenerate" bone (Figure 53-43).

Cyclic axial loading is necessary for remodeling and maintaining bone mass and numerous experimental and clinical studies suggest that axial dynamization accelerates fracture healing. Traditional CFs allow some degree of axial micro-motion, while providing adequate bending and torsional resistance. Clinical studies evaluating the use of CFs to manage fractures in dogs and cats support the contention that CFs promote rapid fracture healing.

Ilizarov advocated performing a corticotomy, which preserved both periosteal and endosteal tissues, for optimal regenerate bone formation during distraction osteogenesis. Recent clinical and experimental studies, however, have shown that preservation of the periosteum has the most significant influence on regenerate bone formation: the method utilized to perform the osteotomy (Gigli wire, bone saw, drill holes-osteotome) has a nominal effect on regenerate formation as long as the periosteal envelope is preserved and most small animal surgeons perform subperiosteal osteotomies using a pneumatic oscillating saw.

Latency or delay refers to the time period following osteotomy before beginning distraction. The latency period used in human patients is typically 4 to 7 days. Several factors will influence the prescribed latency period: the patient's age, the bone involved, the location of the osteotomy, soft tissue trauma present prior to or incurred during surgery, and the primary condition necessitating treatment. Metaphyseal lengthenings produce higher

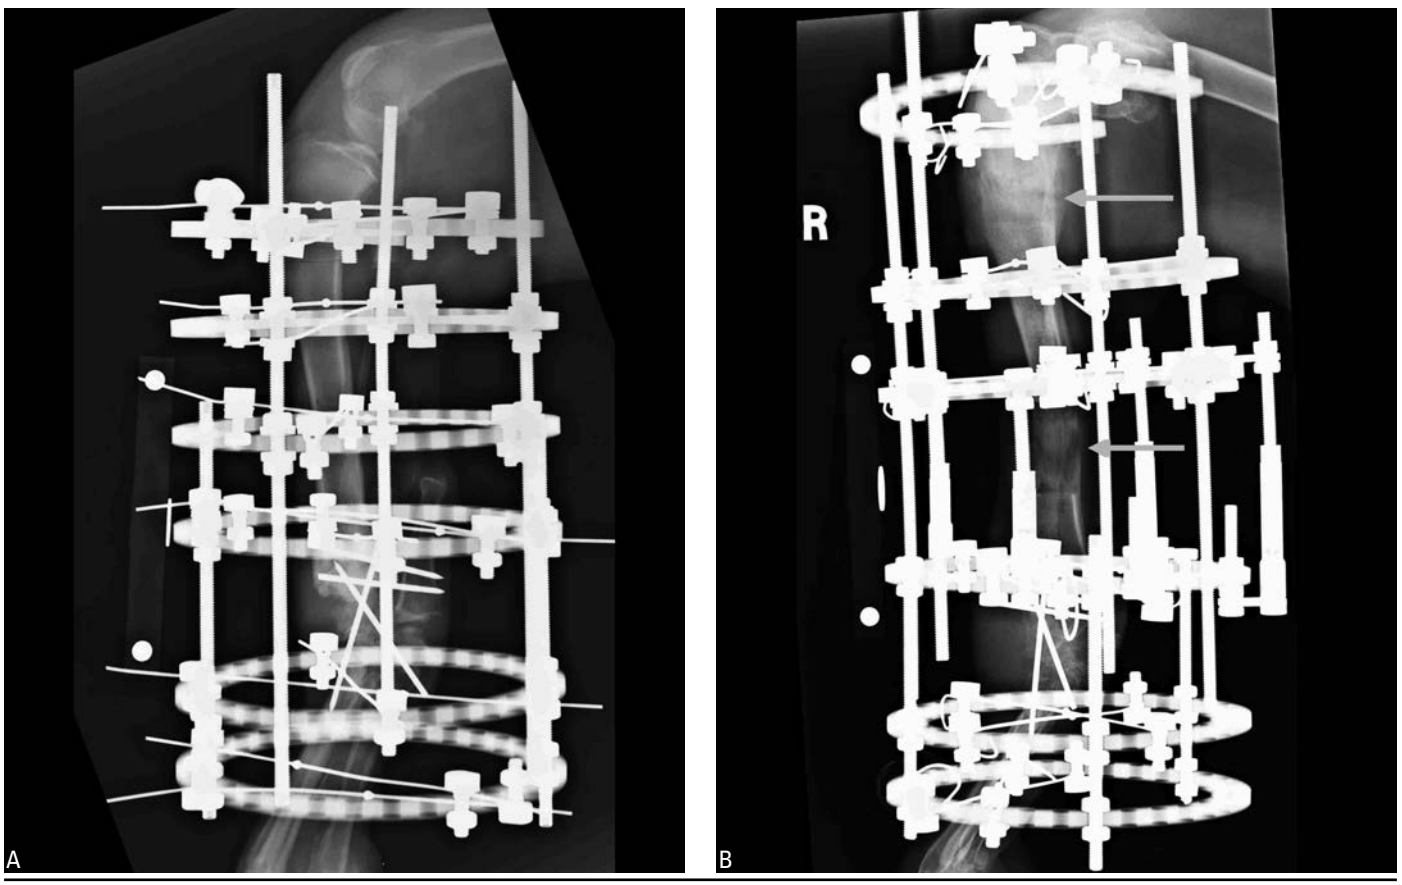

Figure 53-43. A. Pre- and **B.** post-distraction radiographs demonstrating regenerate bone formation (gray arrows in **B.**) in a dog undergoing bi-level distraction for lengthening of the crus.

quality regenerate bone than diaphyseal lengthenings. The metaphyseal region has a greater blood supply and bone surface area in comparison to diaphyseal bone. Proximally located osteotomies produce higher quality regenerate bone than more distally located osteotomies. The latency period allows early vascularization and soft callus formation before lengthening commences. Poor regenerate formation and non-union can occur if distraction is initiated too early. Premature consolidation can occur if the latency period is too prolonged, particularly in young or skeletally immature animals.

The recommended latency period prior to initiating distraction is typically short in dogs undergoing lengthening or angular correction. In young dogs in which the periosteal sleeve was well preserved, a delay period may be unnecessary. Most small animal surgeons generally initiate distraction 1 to 3 days following surgery in dogs in this age group. It is prudent to observe a 3 to 5 day delay before initiating distraction with animals that are 3 to 8 years of age. Longer delay periods may be advisable in older dogs or if the periosteum had been damaged substantially prior to or during surgery.

Rate refers to the amount of distraction that will be performed over a 24 hour period. Experimental and clinical studies indicate that the amount of lengthening performed should be in the range of 0.5 to 2.0 mm/day to promote viable regenerate bone formation. The formation of regenerate bone can be monitored radiographically and the rate adjusted accordingly. Rates for skeletally immature patients undergoing metaphyseal osteotomies may be near the higher limit as these animals have a greater osteogenic potential.

Rhythm describes the frequency (number of fractionations) at which the distractions are performed during a 24 hour time period. Ilizarov had reported that increasing the rhythm from 1 or 2 times per day up to 60 times per day significantly increased regenerate formation and decreased consolidation times; however, studies evaluating rhythms of 1, 4, and 720 times per day in a caprine lengthening model found no significant effects of rhythm on radiographic, mechanical, or histomorphologic regenerate parameters. Increased rhythms, however, allow for superior accommodation of the regional soft tissues, decreasing morbidity during the distraction period. In our clinic we generally perform distractions at a rate of 1.0 to 1.5 mm/day using a rhythm of three or four distractions/day.

Clinical Applications in Dogs and Cats

Circular fixators have been used to manage a number of developmental and traumatic orthopedic conditions in dogs and cats. The most notable of these being limb deformity correction, most frequently antebrachial limb deformity correction. Pre-operative assessment and planning, a thorough knowledge of the instrumentation and its application and conscientious post-operative patient care are essential for a successful outcome. Traditional CFs have also been used to perform deformity corrections and lengthenings of the crus and pes. These systems are also useful for stabilizing complex fractures of the antebrachium and crus, as well as transarticular stabilization, particularly in performing arthrodeses. Frames utilizing hinges allow the surgeon the latitude to adjust the angle of arthrodesis during the early convalescent period and the use of these devices facilitates the removal of all implants following fusion. Finally, CFs can be used to perform bone transport to resolve large traumatic segmental bone defects and oncologic surgeons are now utilizing bone transport in limb salvage procedures in dogs with appendicular bone tumors (see section on Distraction Osteogenesis as an Alternative to Bone Grafting in Chapter 56).

Fracture Management

Circular external skeletal fixation has been utilized extensively for fracture management in human patients and there are recent reports describing the use of CFs for fracture management in dogs and cats. Traditional CFs are most applicable for the stabilization of non-articular antebrachial and crural fractures. Circular fixators are particularly useful for stabilizing fractures with short juxta-articular fracture segments as the divergent placement of small diameter wires provides multiplanar stability. With experience, a surgeon can achieve accurate closed reductions of both simple and complex fractures with relatively short operative times.

Frames are constructed prior to surgery based on preoperative radiographs of the fractured and contralateral intact (if applicable) limb segment. When constructing the fixator, complete rings are generally used to secure the middle and distal portions of the limb segment. Partial rings are used proximally to avoid soft tissue impingement or compromised joint mobility. Stretch rings are useful for securing the proximal ulna and tibia, while 5/8th rings can be used to secure the proximal radius or if the most distal ring interferes with carpal or hock motion. The smallest diameter rings that can be comfortably placed about the circumference of the limb, allowing for post-operative swelling without soft tissue impingement, should be selected. Pre-construction of a frame greatly reduces surgical time. Minor adjustment of the frame should be anticipated and performed as necessary at the time of surgery.

A standard frame configuration consists of three or four rings. A single ring or pair of rings that engage a fracture segment and which are secured together by connecting elements constitute a functional unit referred to as a ring block. While it is preferable to use two or more rings to construct a ring block, there may only be sufficient room to accommodate a single ring in fractures with a short proximal or distal segment. A typical CF construct that would be used to stabilize a crural fracture is composed of two independent ring blocks articulated by linear motors or threaded connecting rods which are secured only to the rings positioned adjacent to the fracture site. This arrangement allows simple adjustment of the distance between the two ring blocks, allowing the major fracture segments to be distracted or compressed. Thus, the frame can be used intra-operatively to distract the fractured limb segment to its normal length which greatly facilitates reduction.

When constructing a CF that will be used to distract a crural fracture out to length, the two ring blocks are constructed based on the length of the major fracture segments. Appropriate length

of each ring block is confirmed by measuring each ring block against the fracture segment it will be used to stabilize on the lateral view radiograph. The articulating intermediate linear motors or connecting rods are then placed between the two ring blocks and the construct is placed over a lateral view radiograph of the contralateral intact limb segment (if available) to assess appropriate frame length (Figure 53-44A). The most proximal and distal rings should be placed at or near their respective metaphyses. The CF is then positioned so that the lateral radiographic image of the intact tibia is appropriately situated within the frame and each ring should be marked, both medially and laterally, along the tibia's central longitudinal axis with a permanent marker. Thus reasonable reduction can be achieved at surgery by placing fixation wires through the tibia in a medial-to-lateral plane and attaching each wire to its corresponding ring at the marked location, if the limb segment has been distracted out to normal length. The frame is then placed over the lateral view radiograph of the fractured limb segment and the intermediate linear motors or connecting rods are compressed to account for shortening of the limb segment as the result of the fracture. The frame is then sterilized in preparation for surgery.

When applying the fixator at surgery, the dog is positioned in dorsal recumbency and the CF construct is slid over the limb and a wire is placed in each metaphysis, parallel to both the proximal and distal joint surfaces. These wires should be placed in the medial-to-lateral plane. The use of intra-operative fluoroscopy, if available, facilitates proper wire placement. These initial two wires are then attached to the abaxial surface of the most proximal and distal rings at the predetermined locations as marked on the frame prior to surgery (Figure 53-44B). The wires are tensioned if indicated depending on ring diameter. If the fracture is over-ridden, the distance between the proximal and distal ring blocks, which are now secured to the bones via the fixation wires, can be increased by turning the intermediate linear motors or the nuts securing the intermediate connecting rods to bring the limb segment out to length. Distraction will create tension in the regional soft tissues which will help reduce the fracture (Figure 53-43C). An attempt should be made to "over-distract" the fracture by a couple of millimeters. Alignment of the fracture can be assessed by palpation, or by fluoroscopy if available.

The next two wires should be placed in the medial-to-lateral plane through the longitudinal axis of the tibia adjacent to the intermediate rings (Figure 53-44D). Attaching (and, if necessary, tensioning) these wires at the predetermined locations as marked on the frame prior to surgery, should result in reasonable craniocaudal alignment of the fracture (Figure 53-44E). If one or both fracture segments need(s) to be transposed in a medial or lateral direction, the segment(s) can be translated along the initial fixation wire(s) by simply applying digital pressure to the bone segment(s) (Figures 53-44F and G). Alternatively, olive wires can be used to translate bone segments. An olive wire is placed on the appropriate, intermediate ring in the medial-to-lateral plane with the olive positioned adjacent to the cortex on the side of the bone which is to be pulled into place. By using the tensioner, which is placed on the exposed end of the wire opposite the olive, the olive wire along with the bone segment can be translated toward the tensioning device.

If a bone segment needs to be translated cranial or caudal, again an olive wire can be used, but this can cause unnecessary impingement of the regional soft tissues. Alternatively, reattaching one or potentially both of the wires on the intermediate ring at holes immediately cranial or caudal (direction opposite of the displacement) to its original position will result in bowing of the wire as it is reattached to the ring with fixation bolts. As the wire is retensioned, the bow in the wire will be eliminated and the bone segment will be translated in the desired direction.

If the fracture was slightly over-distracted, the distance between the ring blocks should be decreased, restoring normal length to the limb segment. Once reduction is acceptable, the remaining fixation wires are placed to complete the construct. Two additional wires should be placed on each ring. These wires should be oriented at 45° to 90°, to each other and olive wires should be used to minimize translation of bone segments. Fixation wires should be placed parallel to the surface of the rings. Wires that are not in immediate contact with the surface of the ring should be secured with flat washers placed subjacent to the wire when it is secured with a fixation bolt. If the wire is bowed as it is attached to the ring, displacement of the bone segment will occur. Proper tensioning of wires will also maximize stability. It is prudent not to cut the fixation wires too short or to bend the wires over until the fracture reduction is evaluated radiographically. This makes any necessary post-operative adjustments simpler to perform.

Isolated double ring block constructs are generally not used to stabilize radius and ulnar fractures as suspension of the limb can be used to facilitate reduction of antebrachial fractures. A typical CF construct that would be used to stabilize an antebrachial fracture consists of three or four rings, all of which are interconnected by long threaded connecting rods which span the entire length of the frame. The construct is assembled and laid on the lateral radiographic view of the contralateral intact limb segment (if available) to assess that the frame length is appropriate with the most proximal and distal rings positioned at or near their respective metaphyses. Position of the intermediate ring is confirmed by comparing its distance from the corresponding proximal or distal ring to the length of the fracture segment those two rings will secure. The frame is then repositioned over the lateral radiographic image of the intact antebrachium such that the radius is appropriately situated within the frame and each ring should be marked, both medially and laterally, along the radius' central longitudinal axis with a permanent marker. Again reasonable reduction should be achieved at surgery by placing fixation wires through the radius in a medial-to-lateral plane and attaching each wire to its corresponding ring at the marked location, but in this case suspension of the limb will be used to distract the limb segment out to normal length. The frame is then sterilized in preparation for surgery.

The dog is positioned in dorsal recumbency for surgery and the CF construct is slid over the limb. The limb is then suspended from the ceiling to distract the limb segment out to length. Tension in the regional soft tissues should again help reduce the fracture (Figure 53-45A). Wires are placed in each metaphysis, parallel to both the proximal and distal joint surfaces. These wires should

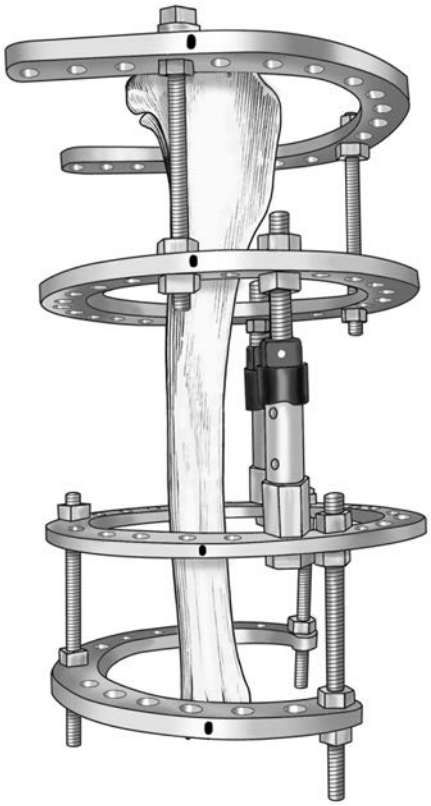

Figure 53-44A. Construction of CF for stabilization of a crural fracture. The individual ring blocks are constructed according to the lengths of the major fracture segments. Overall frame length is based on the length of the intact tibia. The frame is placed over the lateral view radiograph of the intact tibia and the optimal position of each of the medial-to-lateral fixation wires are marked on the frame.

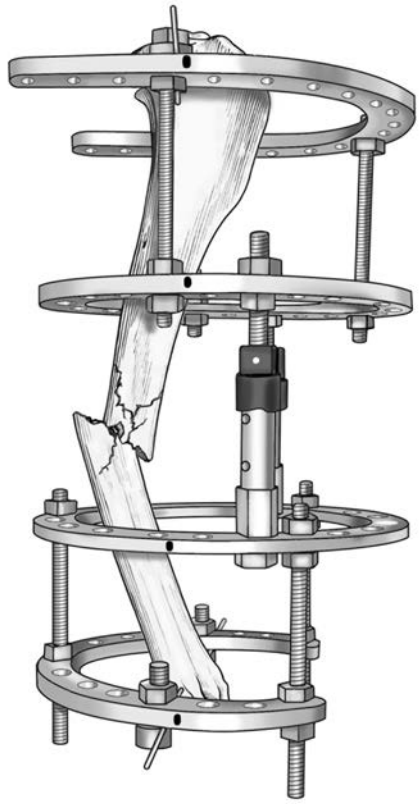

Figure 53-44B. Application of the CF. Medial-to-lateral fixation wires are placed proximally and distal and attached to the frame at the marked positions. The linear motors (that were previously collapsed) positioned between ring blocks will be used to distract the fracture out to length.

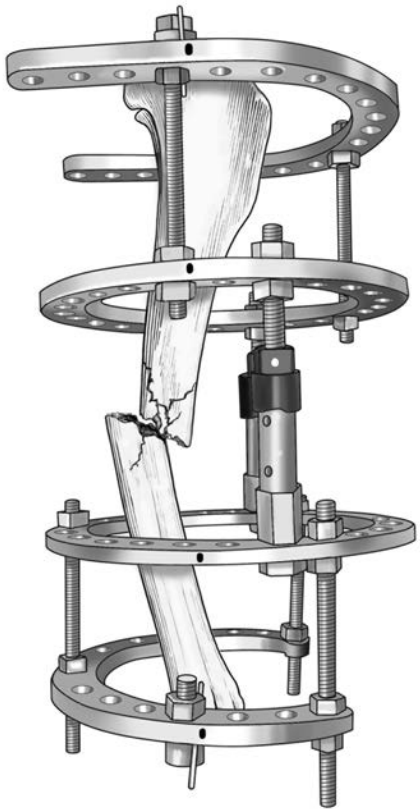

Figure 53-44C. Distraction of the linear motors has brought the fracture out to length and improved craniocaudal alignment.

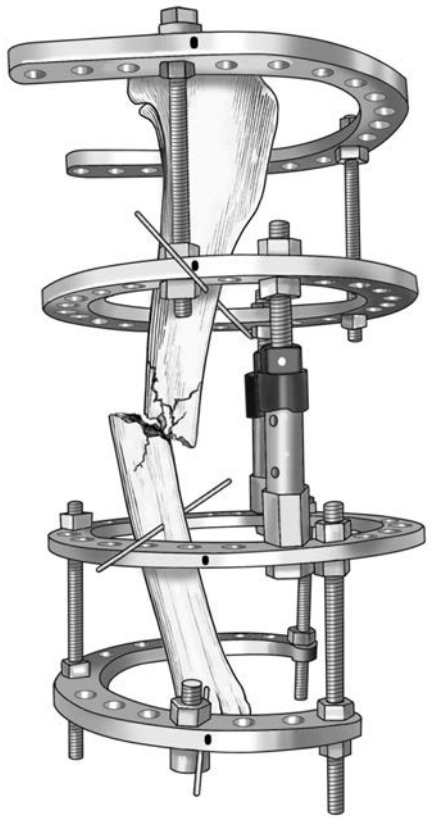

Figure 53-44D. Medial-to-lateral fixation wires have been placed adjacent to the central two rings.

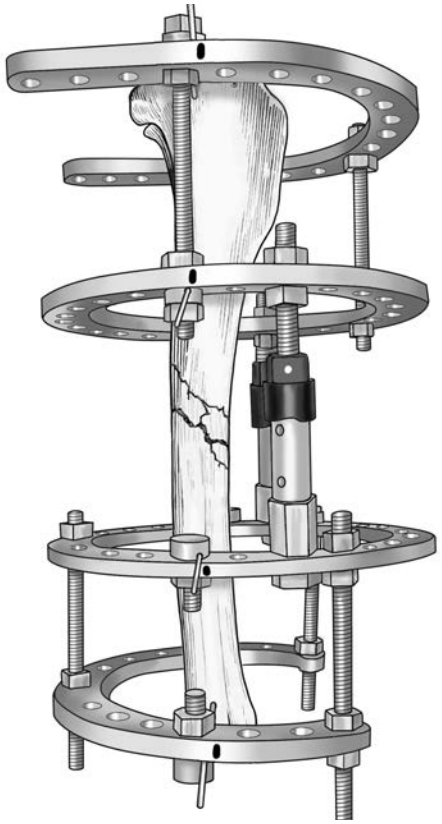

Figure 53-44E. Attachment of these wires at the perviously marked locations results in good craniocaudal alignment of the fracture.

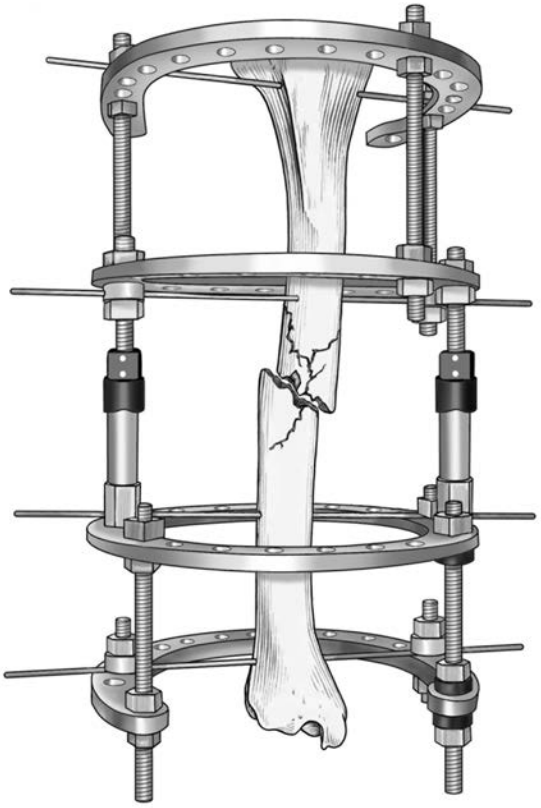

Figure 53-44F. Mediolateral reduction can be improved by translation of the fracture segments (in this case medial translation of the distal segment along the fixation wires).

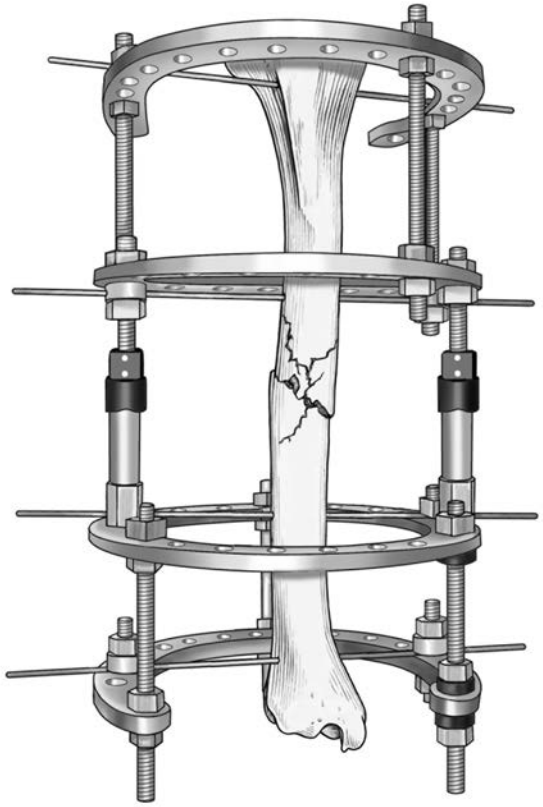

Figure 53-44G. After the final reduction, additional fixation (preferably olive) wires would be placed on each ring.

be placed in the medial-to-lateral plane (Figure 53-45B). The use of intra-operative fluoroscopy, if available, facilitates proper wire placement. These initial two wires are then attached to the abaxial surface of the most proximal and distal rings at the predetermined locations as marked on the frame prior to surgery. The wires are tensioned if indicated depending on ring diameter. If the distraction created by suspending the limb is not sufficient to produce an acceptable reduction, the distance between the proximal and distal rings, which are now secured to the bones via the fixation wires, can be increased by turning the nuts securing one of these rings. An attempt should be made to "over-distract" the fracture by a couple of millimeters. If fluoroscopy is available, alignment of the fracture can be visually assessed. If fluoroscopy is not available, alignment is assessed by palpation. The remainder of the process is similar to that described for reduction and stabilization of crural fractures (Figure 53-45C).

Limb Deformity Corrections

The most common limb deformity occurring in dogs results from premature closure of the distal ulnar physis. Premature distal ulnar physeal closure typically produces valgus and caudal angular deviation with external rotation and procurvatum of the distal radius. Concurrent proximal subluxation of radial head is often present in these dogs which can result in failure of the anconeal process to unite with the remainder of the ulna. Eccentric or complete closure of the distal radial physis can also be a sequella to premature distal ulnar physeal closure. Premature distal radial physeal closure is the second, but less common, limb deformity

occurring in dogs. Affected dogs have a shortened radius, and often shortening of the entire antebrachium, with distal subluxation of the radial head. Angular and rotational deformities can be present in more severely affected dogs. Premature proximal radial physeal closure occurs infrequently, but will produce distal subluxation of the radial head.

Acute correction of limb deformities with bone plates or *linear* external fixators may be limited by tension in the regional soft tissues. The use of CFs and the methods of Ilizarov allow for acute or progressive correction of angular, rotational and translational deformity as well as length discrepancies. Circular fixators also allow the surgeon to make precise adjustments following surgery and throughout the convalescent period.

Limb Lengthening

Limb lengthening is warranted when length discrepancies produce a gait abnormality that impairs limb function. Lengthening may be done as an isolated procedure or in conjunction with angular, translational and/or rotational corrections. Since the radius and/or ulna are the bones which are most frequently lengthened, this discussion will focus on longitudinal antebrachial lengthenings. Craniocaudal and mediolateral view radiographs of both antebrachii, including the manus, should be obtained prior to surgery and length discrepancies between limbs measured. Premature closure of the distal radial physis can require lengthening of the entire antebrachium and is generally done using a three ring construct (Figure 53-46). The proximal ring is positioned near the radial head, the central ring is positioned over the mid-antebrachium and the distal ring at the distal metaphysis. If the radial head is subluxated distally (as an isolated abnormality or in conjunction with abnormalities of the distal antebrachium), a subperiosteal osteotomy is made at the proximal metaphyseal-diaphyseal junction (distal to the position of the proximal ring) and the fixation wires on the proximal ring should only engage the radius. It is helpful to isolate the proximal radius and initiate, but not complete the osteotomy before placing the fixator on the limb. This limits the amount of surgery that must be performed within the frame, but allows the fixation wires to be placed into a stable bone segment. Once the frame and fixation wires are placed and the bone segments are stable, the osteotomy is completed. The proximal ring should be articulated with the central ring using linear motors or threaded rods secured with nylon nuts. This will allow distraction of the proximal radius to correct the existing elbow incongruency. To lengthen the entire distal antebrachium the wires attached to the distal ring should engage both the distal radius and ulna. Subperiosteal osteotomies are made at the distal radial and ulnar metaphyseal junction, proximal to the position of the distal ring. Performing the distal ulnar osteotomy and approaching and initiating the distal radial osteotomy prior to placing the frame over the limb, again simplifies the procedure. The distal ring should be articulated to the central ring using linear motors or threaded rods secured with nylon nuts. When applying the frame, the connecting elements should be positioned parallel to the longitudinal axis of the radius and ulna to produce the most functional lengthening.

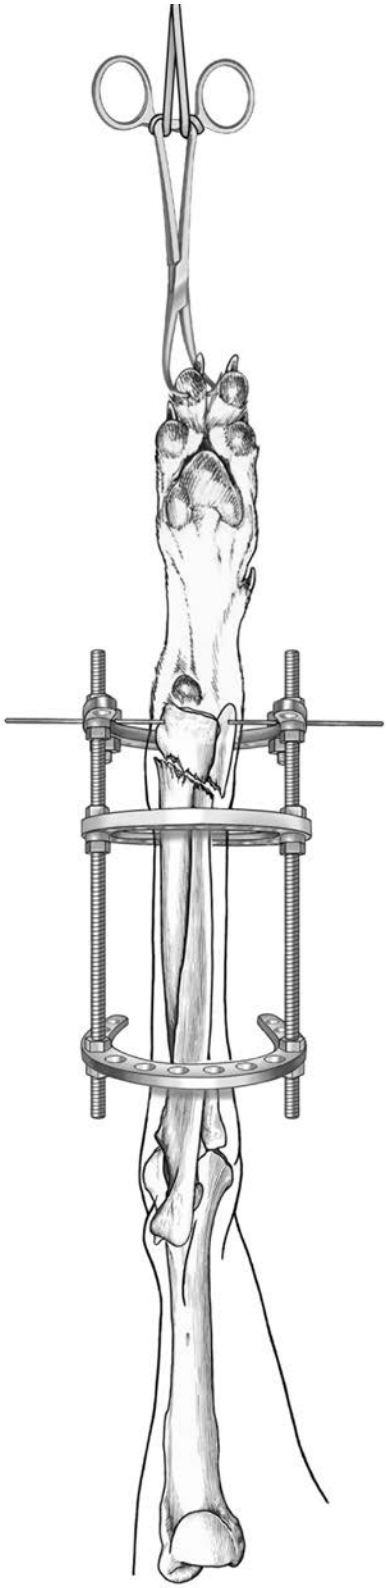

Figure 53-45A. Reduction and stabilization of an antebrachial fracture by suspending the limb. Reduction is nearly anatomic as the result of the traction applied and the initial fixation wire is placed perpendicular to the longitudinal axis of the radius. The frame is attached to the initial fixation wire such that the connecting elements are in alignment parallel with the radius.

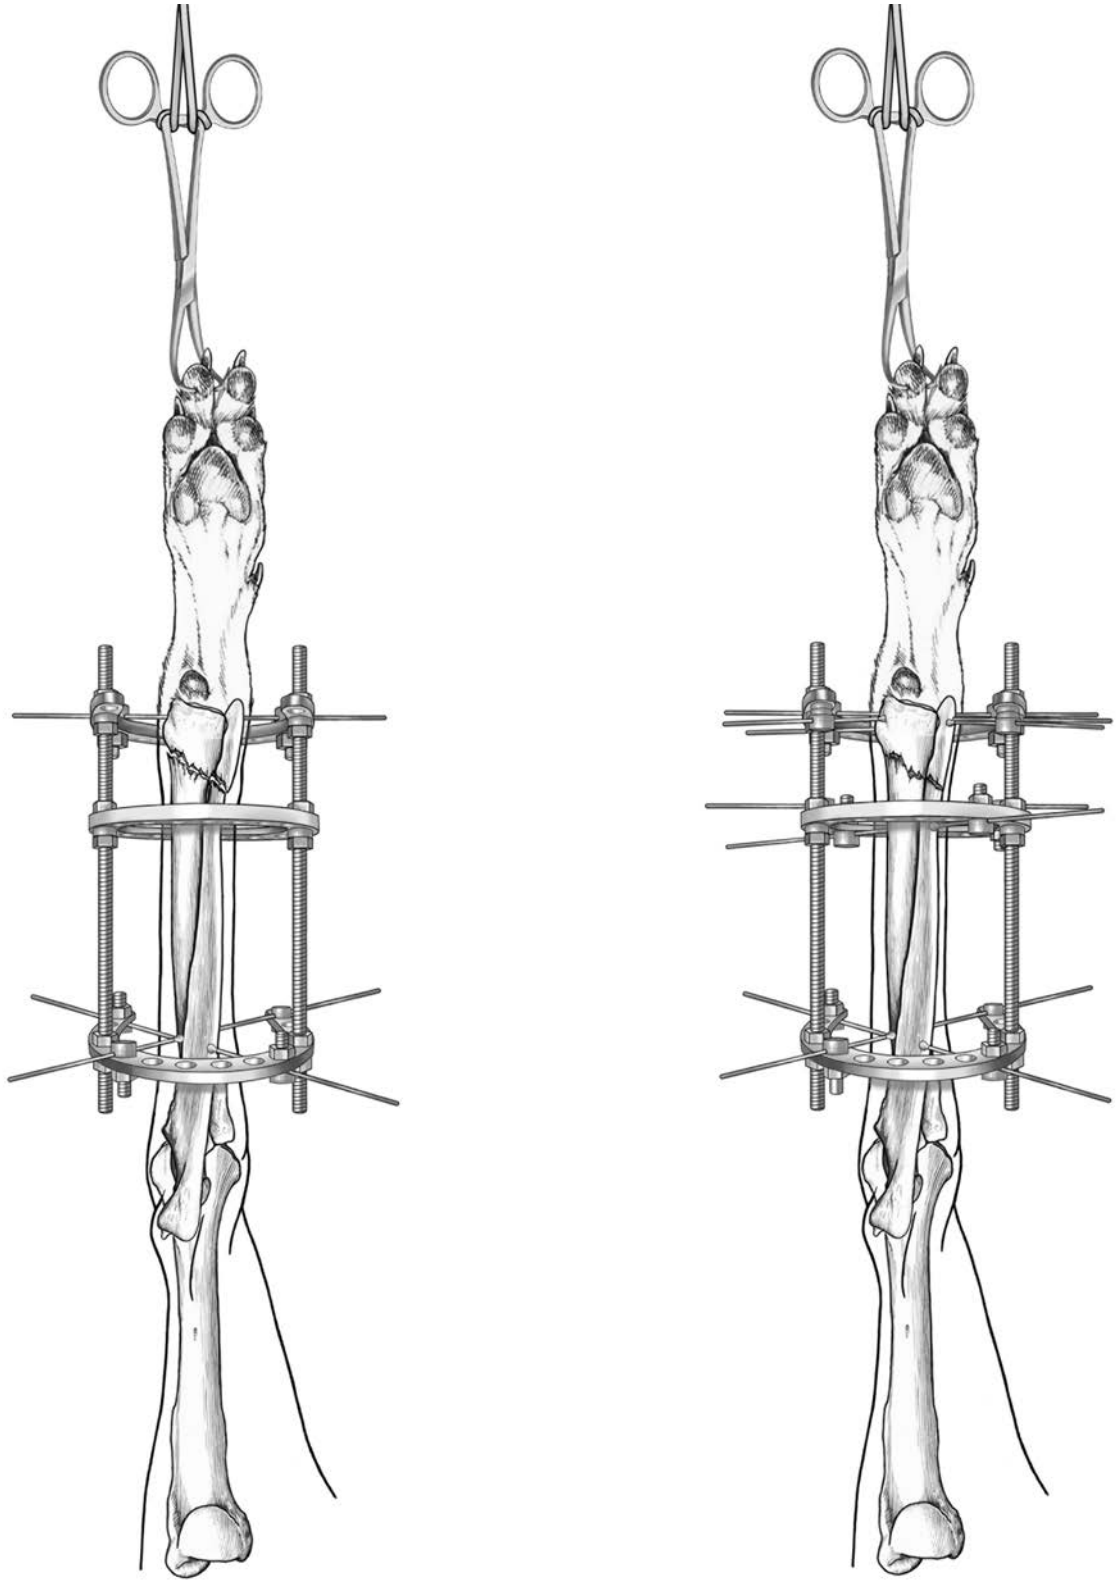

Figure 53-45. B and **C.** The construction is completed with paired divergent olive wires at each level..

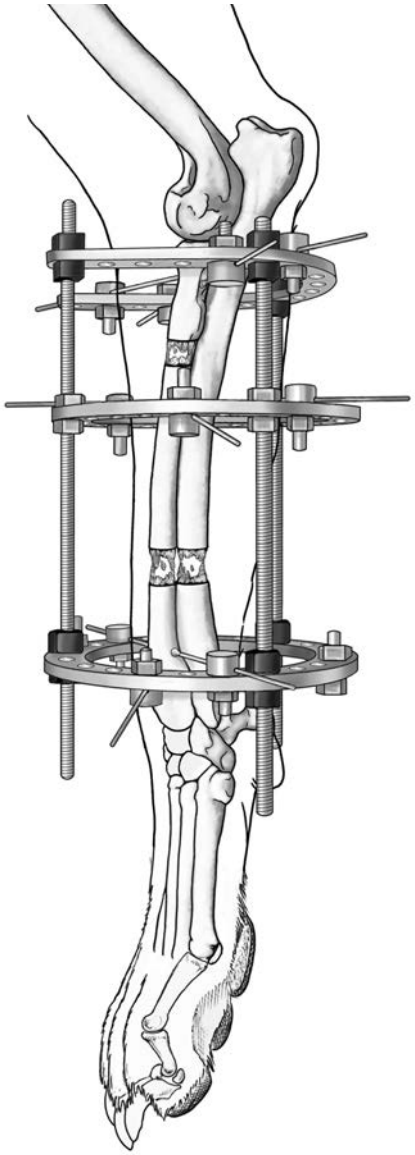

Figure 53-46. Lengthening of the distal antebrachium with concurrent correction of distal subluxation of the radial head. Proximal and distal radial osteotomies and a distal ulnar osteotomy have been done. The proximal radius will be lengthened to restore elbow congruency and the distal radius and ulna distracted to lengthen the antebrachium. Note that nylon nuts have been used to secure both the proximal and distal rings to facilitate distraction.

Angular and Rotational Correction

The discussion will focus on correction of an antebrachial deformity resulting from premature closure of the distal ulnar physis as this abnormality constitutes the most common deformity correction performed in dogs. Pre-operative planning is critical to obtaining optimal results. Although trigonometric preoperative planning methods have been described, a simplified graphic method is preferred to define both the apex and plane of the angular deformity (Figure 53-47). Craniocaudal and mediolateral view radiographs of the entire limb including and distal to the elbow are obtained and tracings of these radiographs should be made in order to plan the procedure. Although the antebrachium is a paired bone system, the radius is the principle weight-bearing bone and the deformity is characterized according to conformational abnormalities of the radius. Straight lines are drawn through the axial plane of the proximal and distal radial segment. These lines are centered through the metaphysis and perpendicular to the adjacent articular surface. The intersection of these two lines denotes the apex of the deformity. It should be noted that in some animals, the apex of the deformity may not be isotopic in orthogonal planes.

To define the plane of the deformity, the mediolateral and craniocaudal components of the deformity, which are vectors and thus have both direction and magnitude, must be calculated. A line is drawn connecting the center of the proximal and distal articular surface of the radius on the tracings of both the craniocaudal and mediolateral radiographs: these lines represent the mechanical axis of the radius. Another line is drawn from the previously defined apex of the deformity perpendicular to the mechanical axis on the tracing on each radiographic projection. The measured length of the line on the craniocaudal radiograph constitutes the medial (varus) or lateral (valgus) component of

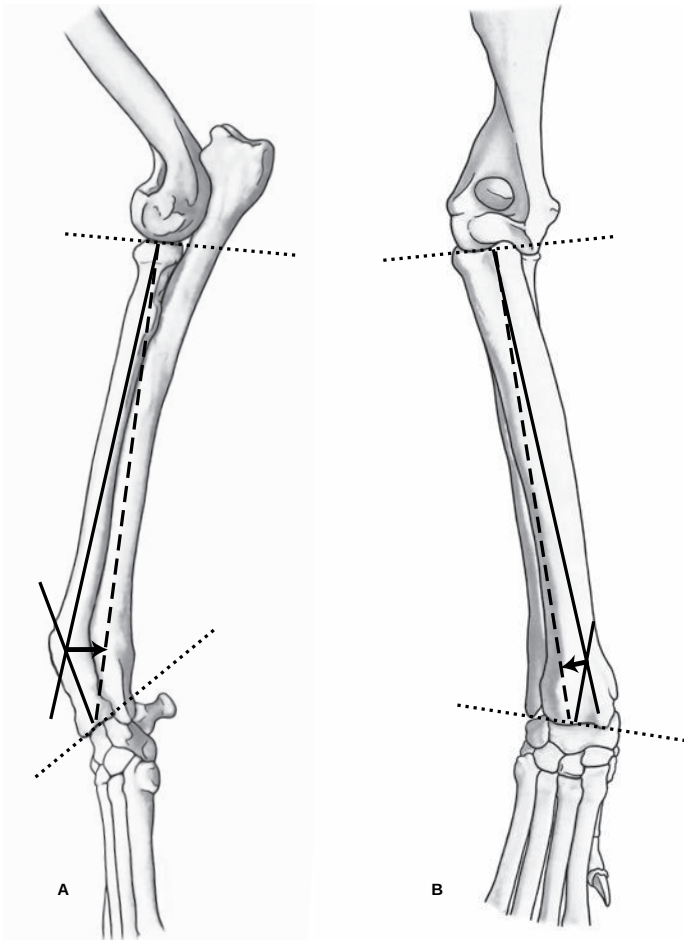

Figure 53-47. Graphic method for defining deformity parameters. Tracing made from radiographs of the right antebrachium. The lines longitudinal axis of the proximal and distal radial segments. The intersection of these two lines denotes the apex of deformity. The dotted line connecting the centers of the articular surfaces of the radius represents the bone's mechanical axis. Vectors (arrows) are drawn from the apex of the deformity back toward the mechanical axis. The vector measured on the mediolateral view radiograph constitutes the craniocaudal component of the deformity, while the vector measured on the craniocaudal view radiograph constitutes the mediolateral component of the deformity.

the deformity. The measured length of the line on the mediolateral radiograph constitutes the cranial or caudal component of the deformity. These same measurements are obtained from line drawings developed from tracings of radiographs of the contralateral normal limb, and the component vectors measured on the normal limb are subtracted from those obtained from the abnormal limb. A tracing (or photocopy) of an appropriate diameter ring (Figure 53-48) which will be used to construct the fixator is made. An X (mediolateral)/Y (craniocaudal) grid is constructed with its origin centered in the ring. This drawing represents the proximal surface of the rings of the proximal ring blocks and should be marked correctly with respect to medial, lateral, cranial and caudal for the limb (left or right) that is being corrected. The plane of deformity is determined by plotting the two adjusted (abnormal minus normal) vector components of the deformity on the X/Y grid. The resultant vector defines the plane of deformity.

A drawing representing an outline of a transverse section of the radius, based on measurements of the craniocaudal and mediolateral dimensions of the radius obtained at the level of the apex of deformity on the pre-operative radiographs, is centered over the X-Y intersection. The circumferential position of the hinges can now be determined. A line drawn between the centers of the paired hinges constitutes the hinge axis. The plane of deformity is located along the concave surface of the radius and the hinges need to be located on the opposite side (convex surface) of the radius in order to correct the deformity. Thus the hinge axis should be positioned roughly perpendicular to the plane of the deformity and tangent to the outline of the radius opposite the plane of the deformity. The tangential location of the hinge axis will result in angular correction without additional lengthening. The two holes on the ring that are intersected by the hinge axis mark the position at which the hinges should be placed. A single angular motor is placed opposite the hinge axis, approximately equal distant from two hinges, which will be located on the concave surface of the deformity.

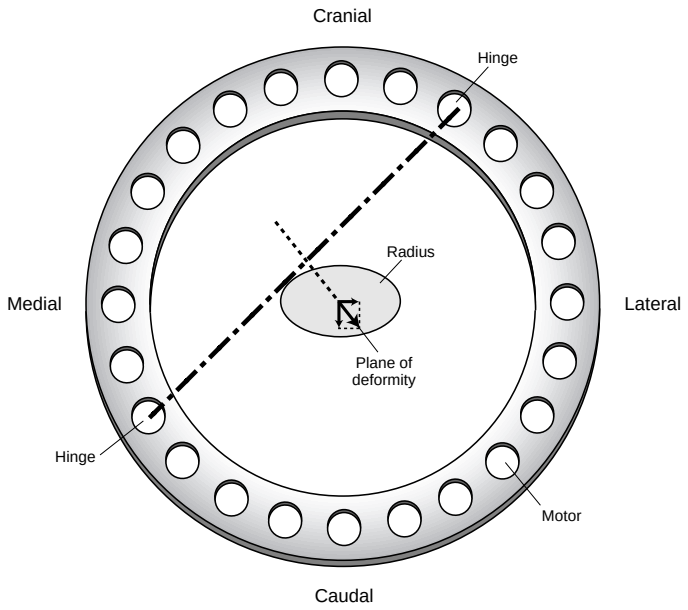

Figure 53-48. Drawing of the radius (based on dimensions obtained at the apex of deformity) centered within a tracing of the proximal surface of an appropriate diameter ring. The smaller arrows radiating along the X and Y axis out from the origin represent the adjusted (abnormal minus normal) mediolateral and craniocaudal vector components of the deformity. The larger arrow represents the resultant vector and the plane of the deformity. The hinge axis (dotted-dashed line) is positioned roughly tangential to the convex surface of the radius (roughly perpendicular and opposite the plane of the deformity), to determine the circumferential location of the hinges.

The fixator is assembled prior to surgery. A three ring construct is used in most dogs with two rings used to secure the proximal radial segment and a single ring used to secure the distal radial segment (Figure 53-49). It is advisable to mark the medial, lateral, cranial and caudal positions of the proximal surface of each ring appropriately for the limb that is to be corrected. The paired

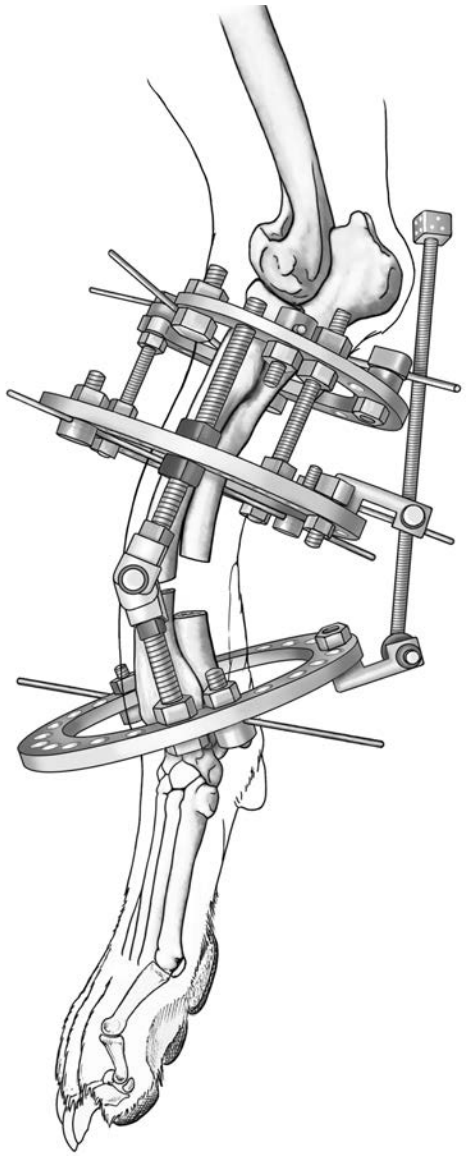

Figure 53-49. Application of a three ring construct for correction of an antebrachial angular deformity. The hinge axis (the two hinges are superimposed in this picture) is located at the apex of the deformity, roughly perpendicular to the plane of deformity and tangential to the convex cortex of the radius. The rings of the proximal ring block have been secured by multiple divergent wires. The distal radial segment is secured with a single wire which will simplify rotational correction.

angular hinges and an angular motor are placed between the ring blocks at the appropriate holes as determined on the pre-operative drawing. The hinges can be bolted directly to the distal ring if the apex of deformity is located at or near the distal epiphysis, but the hinges are usually secured to both rings using short threaded rods at the holes as determined on the pre-operative drawing. Paired nylon nuts can be used to secure the rods to one of the rings if lengthening is anticipated. The longitudinal position of the hinges is located at the apex of the deformity. Construct dimensions, ring position and hinge position are determined by laying the frame directly over the lateral view radiograph of the deformed antebrachium. Frame angulation can be adjusted to conform to the deformity by adjusting the angular motor.

At surgery the entire forelimb is clipped and prepared for aseptic surgery and the dog is positioned in dorsal recumbency. A 2 to 4 cm subperiosteal segmental ostectomy of the distal ulna is performed at the level of the apex of the deformity. Following closure of the ulnar approach, subperiosteal isolation of the distal radius is performed exposing the location of the apex of the deformity. An osteotomy is initiated, but not completed, perpendicular to the longitudinal axis of the distal radial segment and parallel to the plane of the deformity. The longitudinal location of the radial osteotomy will influence the impact acute rotational correction will have on the plane of deformity. The plane of deformity should not be changed appreciably by acute rotational correction if the radial osteotomy is performed at or preferably slightly distal to the apex of the deformity. Performing the radial osteotomy proximal to the apex of the deformity is not advised if acute rotational correction is to be done, as the plane of deformity will be altered by rotational correction.

The frame is then placed on the limb and a fixation wire is placed in the proximal radius in the medial-to-lateral plane, perpendicular to the longitudinal axis of the radius. This wire is secured to the proximal surface of the proximal ring of the fixator and the longitudinal position of this wire should place the hinge axis at the apex of the deformity. Consideration should be given to placing this wire the day prior to surgery and then radiographing the limb, as constructing the fixator based on tracings of radiographs obtained with the first wire already in place simplifies placement of the hinge axis precisely at the apex of the deformity at surgery. The wire can then be bent over against the antebrachium and the limb coapted until surgery. At surgery the wire can be straightened out and tensioned or carefully replaced by inserting a new wire through the same hole in the radius. The connecting elements of the frame should be aligned parallel to the longitudinal axis of the radius and the hinges positioned at the apex of the deformity. The frame is rotated about the antebrachium until the hinge axis is positioned perpendicular to the plane of deformity and tangential to the convex cortex of the radius. It is important to center the radius, rather than the antebrachium, within the frame. A fixation wire is then placed parallel to the distal surface of the distal ring. This wire should be placed in the "true" mediolateral plane (from styloid process to styloid process) which will not be co-planar with the wire in the proximal radius if rotational deformity is present. Two divergent olive wires should then be placed on each of the rings of the proximal ring block to stabilize the proximal radial segment and the radial osteotomy is then completed.

Rotational deformity, if present, should be corrected before additional fixation wires are placed in the distal radial segment (Figure 53-50). Rotational deformity is estimated by comparing the planes of flexion and extension of the ipsilateral elbow and antebrachiocarpal joint. The plane of extension of the elbow (which is caudal) is marked on the distal surface of the distal ring. The antebrachiaocarpal joint is then flexed so that the paw

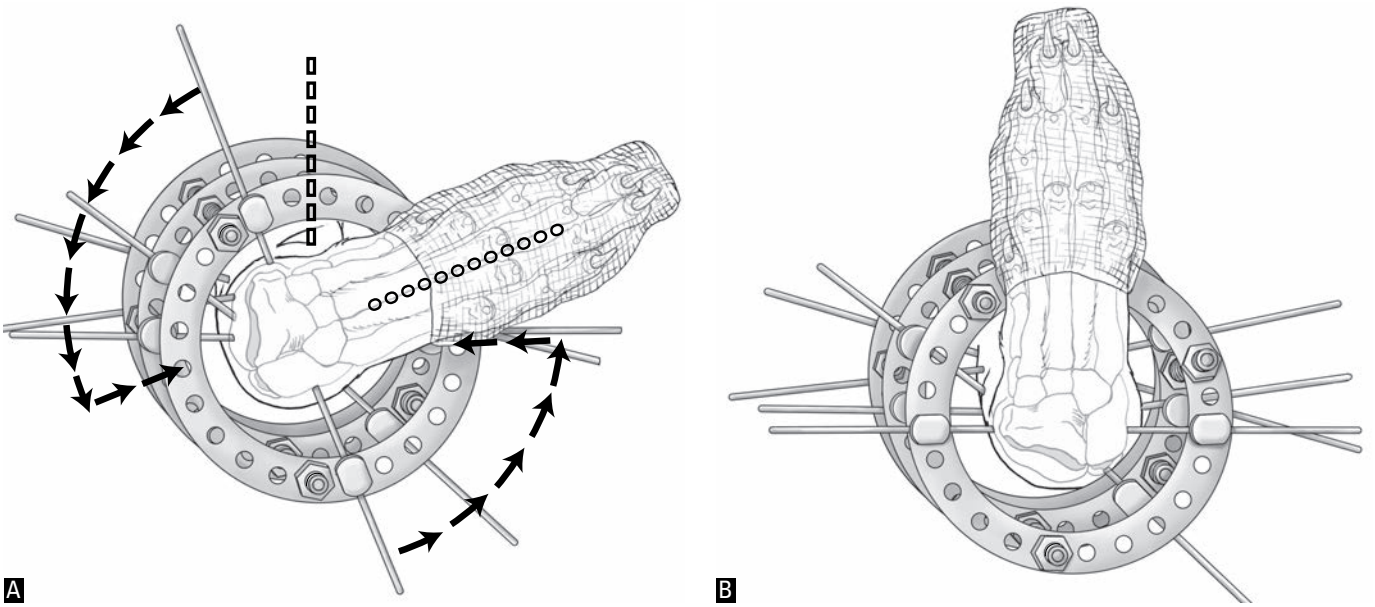

Figure 53-50. Acute correction of rotational deformity. **A.** This dog is positioned in dorsal recumbency and has approximately 60° of external rotation. The line of small open circles represents the plane of flexion and extension of the carpus. The line of small rectangles represents plane of flexion and extension of the elbow. There is nearly a five hole discrepancy (on the surface of the distal ring) between these the two planes of flexion and extension. The wire stabilizing the distal radial segment needs to be repositioned five holes in a counter clock-wise direction to resolve the rotational deformity as indicated by the heavy arrows. **B.** The wire has been rotated to correct the rotational deformity.

is positioned parallel with the distal surface of the distal ring. The location of the division between metacarpal bones III and IV is marked on the distal surface of the distal ring. The number of holes between these two marks is counted and this represents the amount of rotation the wire securing the distal radial segment must be rotated about the surface of the distal ring to have the elbow and antebrachiocarpal joint flex and extend through the same plane. It is highly advisable to mark this wires' position, and the position where the wire will be resecured at on the ring, before loosening and moving the fixation bolts.

Once rotational correction has been performed and the wire is secured to the distal ring, flexion and extension of the elbow and antebrachiocarpal joint should be compared. Adjustments can be made if deemed necessary. Two divergent olive wires should be placed to secure the distal radial segment to the distal ring. Following surgery in addition to obtaining standard craniocaudal and mediolateral view radiographs of the antebrachium, a radiograph centered through the hinge axis should also be obtained. The hinges should be superimposed over one another on this view and the entire frame should be visible on the film so that the distraction protocol can be calculated. Distraction is measured along the concave cortex of the radius and a rate of 0.75 to 1.50 mm/day fractionated into three or four incremental distractions is considered acceptable. The amount of distraction of the angular motor that will produce the appropriate amount of distraction at the osteotomy can be calculated using the method of similar triangles (Figure 53-51). Once the distraction period is completed and the deformity is corrected the hex drive fastener elements on the hinge assemblies and the angular motor should be tightened to lock the frame in position.

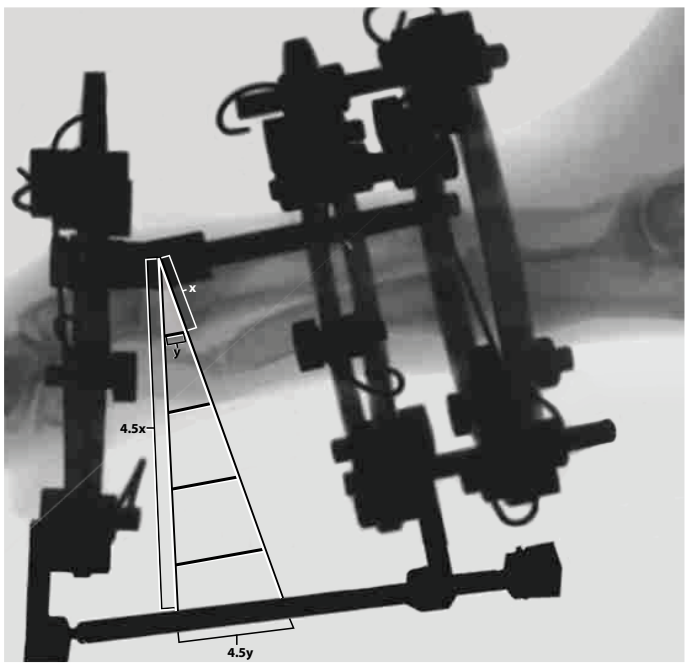

Figure 53-51. Post distraction radiograph demonstrating the method of similar triangles used to determine proper distraction ratio. The distance from the hinge axis to the angular motor is approximately 4.5 times that of the distance from the hinge axis to the surface of the concave cortex of the radius. Thus, the angular motor would need to be distracted 4.5 mm to produce 1 mm of distraction along the concave cortex of the radius.

Bone Transport

Bone transport is a specific application of distraction osteogenesis used to resolve large segmental bone defects. With this technique an intercalary bone transport segment is created by performing a transverse osteotomy in the viable bone segment 1 to 2 cm adjacent to an osseous defect. Regenerate bone is produced in the distraction gap which develops as the transport segment is sequentially moved across the bone defect. Longitudinal bone transport is typically performed using a five ring construct, with two rings securing both the proximal and distal bone segments and the intermediate ring securing the transport segment. The transport ring is secured to the frame using paired nylon nuts which allow the ring to be moved precisely along the threaded rods at a rate of 0.5 to 2.0 mm per day. A delay period of 5 to 7 days may be warranted depending upon the age of the animal, the condition of the regional soft tissues and the location of the osteotomy. Radiographs should be obtained bi-weekly during the distraction process and the rate increased or decreased if necessitated by the appearance of the regenerate bone. Docking refers to the process of the transport segment contacting and eventually obtaining union with the bone at the opposite end of the osseous defect. Obtaining union at the docking site can be facilitated by placing a cancellous bone graft at the site several days prior to docking and constructing the fixator such that the transport ring can be moved several mm beyond the bone defect, thus facilitating in compression of the docking site.

Bone transport has been used in dogs to resolve large segmental defects resulting from highly comminuted fractures, following sequestrectomy in infected fractures and in performing limb salvage procedures in dogs with appendicular bone tumors. These large segmental defects have traditionally been managed with massive bone allo- or autografts or prostheses, which are prone to infection and implant failure. Regenerate bone is highly vascular and resistant to infection and all implants can be removed once the docking site has achieved union and the regenerate bone has consolidated (Figure 53-52).

Postoperative Management and Complications

Management of animals with CFs is similar to that of animals with traditional linear fixators. Following surgery, the CF is wrapped to limit postoperative swelling and to protect any incisions, open wounds and wire/pin insertion wounds. Sterile gauze is placed over any wounds and the insertion sites and the foam portion of recycled disposable surgical scrub brushes which are impregnated with chlorhexidine are packed between the skin and the frame to limit postoperative swelling. Care must be taken not to pack the sponges too tightly within the frame or edema and swelling of the distal limb may be aggravated. Cast padding and Vetwrap tape is then used to apply a bandage around the entire fixator. The CF is initially unwrapped and the limb and surgical sites assessed for swelling or complications on a daily basis. The wire/pin-skin interfaces are cleaned aggressively with a gauze or cotton tip applicator and diluted chlorhexidine solution. The CF is then re-wrapped. When the acute swelling and edema has subsided and the wire/pin-skin insertion sites heal sufficiently, packing sponges within the frame can be discontinued. The

Figure 53-52. Bone transport being utilized for a limb salvage procedure in a dog with a distal radial osteosarcoma. The distal two-thirds of the radius have been excised and the transport segment has been moved approximately half the distance across the segmental defect with early regenerate bone forming in the distraction gap. (Radiograph courtesy of Dr. Nicole Ehrhart)

owners should be directed to construct a shroud or sleeve that fits securely over the entire fixator, but can be easily removed for daily cleaning of the wire/pin-skin interfaces.

Performing intensive, frequent (a minimum of three times a day) physical therapy is important during lengthening and correction of angular deformities to reduce the development of muscle (especially flexor muscles) contracture. Contracture is less of a problem with higher rhythms (more fractionated distractions). The administration of nonsteroidal anti-inflammatory drugs is also beneficial in encouraging weight-bearing, mitigating contracture during the distraction period.

The most common complication associated with the use of CFs is wire/pin tract drainage and bone lysis surrounding the fixation elements. Inflammation associated with wire/pin tract drainage typically develops several weeks after surgery and generally does not influence the final outcome even when the fixator must be maintained for an extended period of time. Minor wire/pin tract drainage may resolve with broad spectrum antibiotic administration. If drainage is substantial and/or purulent and/or there is substantial bone lysis and proliferation adjacent to a wire/pin, that fixation element should be removed and replaced if necessary. Proper insertion techniques and meticulous, appropriate daily care can greatly decrease the incidence of wire/pin tract complications.

Application of Hybrid Constructs

Robert M. Radasch

Introduction

Hybrid circular external skeletal fixation (HCESF) combines the fixator components, methodology of application, and biomechanics of traditional linear and circular external fixation devices. The benefits of both systems are enhanced when a hybrid circular fixator (HCF) is properly applied in appropriate situations. Hybrid fixators have been used clinically to manage long bone and spinal fractures, as well as bone deformities. The circular components of a HCF allow adequate fixation of small juxta-articular bone segments using two to three narrow (1.0 -1.6 mm) tensioned transfixation wires secured to a ring. The linear components of the frame are then applied to the primary bone segment using traditional positive profile half-pins or full-pins. The basic components of a HCF are the supporting, connecting, fixation and assembly elements (Figure 53-53). All components, except the fixation elements (wires and pins) are

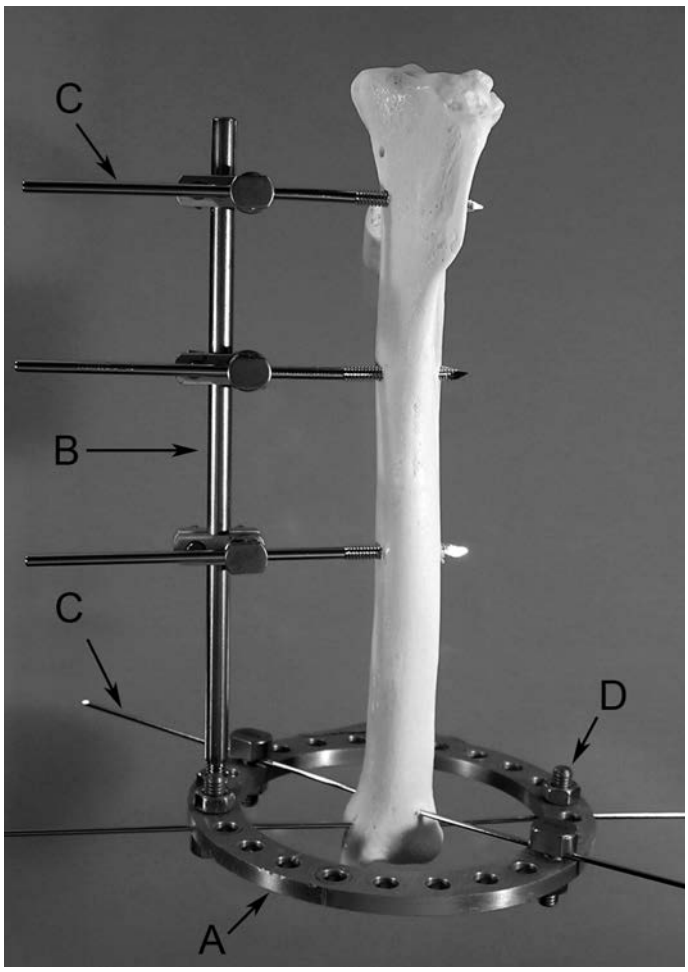

Figure 53-53. A basic HCF allows stabilization of small juxta-articular bone segments with two or three tensioned narrow transfixation wires, while the primary bone segment is stabilized with positive profile half-pins or full-pins. The basic components are the supporting *(A)*, connecting *(B)*, fixation *(C)*, and assembly *(D)* elements.

reusable numerous times, making HCESF economically practical for veterinary practice. The only HCF currently available in veterinary orthopedics is manufactured by the IMEX Company (Longview, Texas). Therefore, this section will concentrate on the application of the IMEX HCESF system utilizing IMEX-SK components, pins, wires and rings.

Indications

Fractures involving the metaphyseal region of all long bones are relatively common in veterinary medicine. These fractures frequently have a short juxta-articular bone segment precluding the use of many implant systems (Figure 53-54), and are often comminuted, making anatomical reduction of the bone fragments impossible and of questionable mechanical benefit. A HCF can be applied using closed, or "mini-approach" techniques utilizing the principles and benefits of biological osteosynthesis, while still allowing manipulation of the main bone segments to achieve adequate fracture reduction or alignment. In addition, adjustments of the frame can be performed during the postoperative period to improve reduction or to stimulate the later stages of bone healing.

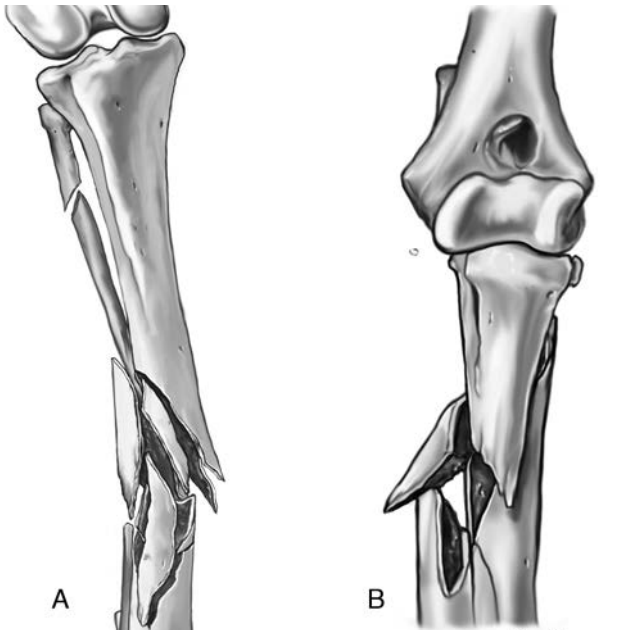

Figure 53-54. Typical fractures with short juxta-articular components involving the distal tibia **A.**, and proximal radius/ulna **B.** that are easily stabilized with a HCF.

Hybrid Circular Fixator Components

The majority of components used to create a HCF frame have been thoroughly described in the proceeding sections. However, there are several unique components used almost exclusively with HCF frames. Successful management of juxta-articular fractures while minimizing complications depends upon a thorough knowledge of how each individual component affects the overall mechanical characteristics of the HCF. In addition, a working understanding of how each component can be used and integrated into the system will allow manipulation of the juxta-articular and primary bone segments to achieve proper fracture reduction or alignment.

Supporting Elements

A full ring is the most commonly used supporting element of a HCF. Partial or stretch rings and arches are often used instead of a full ring to prevent interference with joint motion (Figure 53-55). Partial rings and arches are very useful in managing fractures involving the proximal tibia, proximal radius, spine, distal femur, and humerus. Rings (partial or full) and arches are available with 35, 45, 50, 66, 84, and 118 mm internal diameters. The appropriate ring or arch size chosen will depend upon the animal's weight as well as the diameter of the regional anatomy. The inner ring diameter should be approximately 2.0 cm larger than the regional anatomy at the level where the ring will be positioned. This diameter will allow for typical postoperative soft tissue swelling without the ring compressing or cutting into the underlying soft tissues.

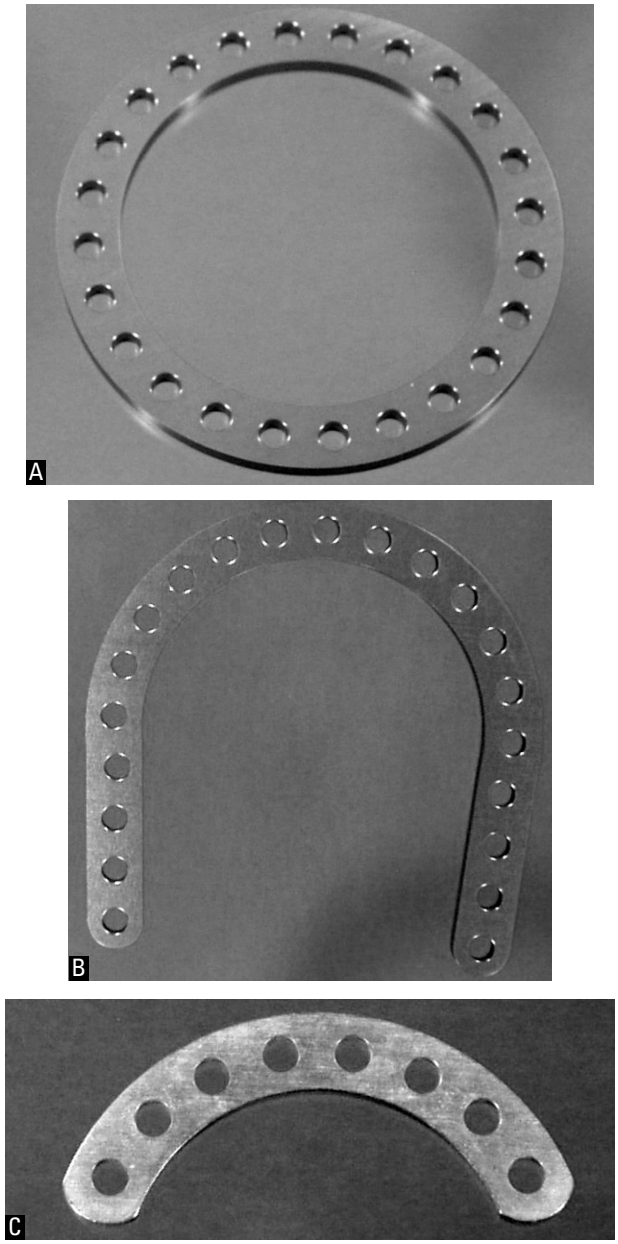

Figure 53-55. Supporting elements of a HCF. Full ring **A.**, partial or stretch ring **B.**, and arch **C.**

Connecting Elements

The standard connecting element of the IMEX HCF is the small 6.3 mm hybrid rod, currently available in 50, 75, 100, 150, 200, and 250 mm lengths (Figure 53-56). Hybrid rods are also available in 9.5 mm diameter (lengths = 50, 75, 100, 150, 200, 250, 300, and 350 mm) and 3.2 mini (length = 125 mm). Large and small hybrid rods are made of titanium, and mini hybrid rods are made of stainless steel. The hybrid rod serves the same function as the connecting rod in a linear external fixator. IMEX-SK clamps attach along the smooth shaft of the hybrid rod to secure fixation pins to the frame. Large, small, and mini SK clamps are used with the large, small and mini hybrid connecting rods, respectively. In the author's experience, the small hybrid rod (6.3 mm diameter) and SK clamps are used most commonly to create a HCF for both dogs and cats. The large hybrid rod and SK clamps would be used for giant breed dogs, while the mini system would be reserved for toy breed dogs and small cats.

One end of the hybrid rod is threaded, allowing it to be secured to the supporting element (ring, arch or partial ring). The large and small hybrid rods have 6.0 mm thread diameter and therefore are secured to the supporting element with two 6.0 mm nuts. The mini hybrid rod has a 4.0 mm thread diameter and is secured using two 4.0 mm nuts. The threaded section of the large and small hybrid rods can be placed into the holes of the 50, 66, 84, and 118 mm rings or arches. The mini hybrid rod can only be used with the mini 35 or 45 mm rings and is placed through either the slots or holes of the mini ring.

The hybrid rods can also be attached to the supporting ring or arch using paired 6.3 mm (used with small and large hybrid rods) HEMI-spherical washers and nuts, which allow the rod to be angulated approximately 7.5° in relationship to the ring surface (Figure 53-57). Advantages of angulating the hybrid rod include: 1) facilitating manipulation of bone segments to achieve fracture reduction; 2) allowing small angular corrections; and 3) enabling biomechanical improvement of frame stiffness by reducing fixation pin working length (distance between the hybrid connecting rod, pin-gripping bolt of the SK clamp, and the near cortex of primary bone segment). The hybrid rod can be positioned anywhere on the supporting ring or arch. However, the hybrid rod should be positioned so that the fixation pins, attached to the rod, will pass through safe soft tissue corridors (as described in previous sections), in order to minimize postoperative pin tract morbidity.

An alternative to a threaded hybrid rod, is the use of a 6.3 mm titanium or radiolucent carbon fiber SK™ linear external fixation connecting rod, connected to the ring element using a Universal SK™ Hybrid Adapter (Figure 53-58). The Universal SK™ Hybrid Adapter allows the connecting rod to be angulated approximately 32.5°, in any direction to the ring surface. The Universal SK™ Hybrid Adapter is secured to the ring element using two 6 mm bolts and nuts. The two 8 mm bolts of the rod-gripping element, when tightened, lock the connecting rod into the desired orientation, by compressing the broach surrounding the

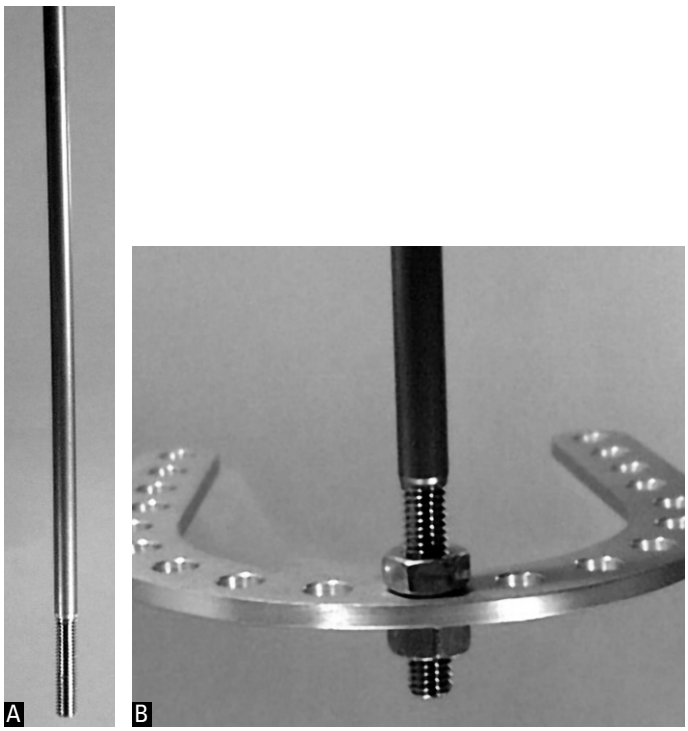

Figure 53-56. Connecting element of a HCF is the hybrid connecting rod **A.** One end of the rod is threaded allowing it to be secured to a ring with two nuts **B.**

connecting rod. The Universal SK™ Hybrid Adapter provides the same benefits of the hemispherical washer and nuts with the additional advantages of: 1) greater range of angulation of the connecting rod in relationship to the ring (32.5° vs. 7.5°) and 2) use of radiolucent carbon fiber connecting rods which can facilitate imaging the fracture. The Universal SK™ Hybrid Adapter can only be used on 50-118 mm ring diameters.

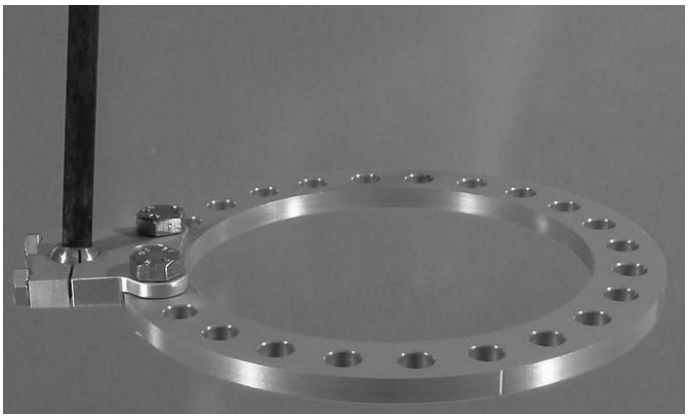

Figure 53-58. Universal SK™ Hybrid Rod Adapter allows up to 32.5° of angulation of a smooth 6.3 mm titanium or carbon fiber connecting rod in relationship to the ring surface.

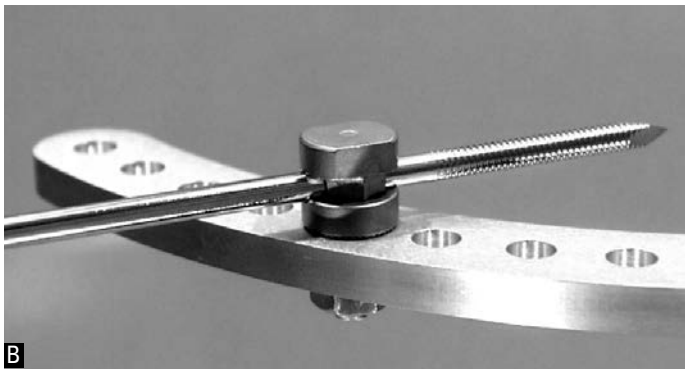

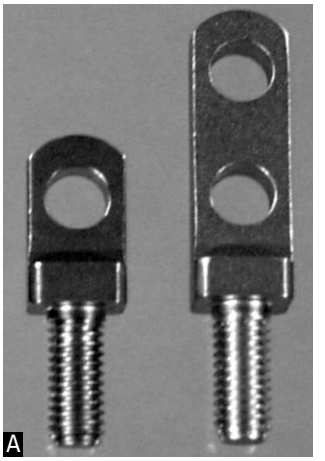

Figure 53-59. A pin fixation bolt **A.** allows half-pins or full-pins to be placed directly onto a ring or arch **B.**

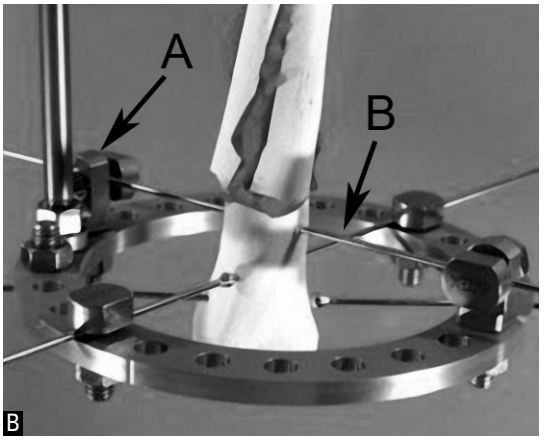
Assembly Elements

Assembly elements unique to an IMEX HCF include pin fixation bolts, one and two hole posts, two hole plates, and threaded SK clamps. Pin fixation bolts allow 3.0 to 4.8 mm half-pin or full-pins to be placed directly on a 50, 60, 84 or 118 mm ring or arch (Figure 53-59). Juxta-articular fractures involving the femur, humerus or spine are best stabilized with half-pins or full-pins instead of divergent narrow wires. Divergent wires in these locations can penetrate large muscle masses, or result in impingement of normal flexion and extension of the associated joint. A pin fixation bolt is secured to a ring or arch with a 6.0 mm nut. The supporting element then serves as a platform for pin insertion into the juxta-articular bone segment. The basic anatomy and mechanics of the pin fixation bolt is identical to that of the pin-gripping bolt/washer assembly of the linear SK clamp. As the 6.0 mm nut attaching the fixation bolt to the ring is tightened, the fixation pin is trapped and secured between the hole in the head of the bolt and the meniscus of the sliding washer. The pin fixation bolt will accept the IMEX drill sleeve, which should be used to minimize soft tissue trauma during pre-drilling of holes prior to pin insertion.

One and two hole posts serve several important functions (Figure 53-60). The threaded portion of the post allows it to be secured to the ring using a nut. The hole(s) in the post will accept the threaded portion of a wire fixation bolt, a pin fixation bolt, or a hybrid rod. These components are secured to the post with appropriate size nuts. Two posts, on opposite sides of the ring, can be used to place an additional wire above or below the ring to improve fracture stability. The wire is secured to the post using wire fixation bolts and nuts. A wire attached to a post is referred to as a "drop wire". Fixation pins can also be placed above or below a ring using a single post and a pin fixation bolt. However, there should never be a combination of



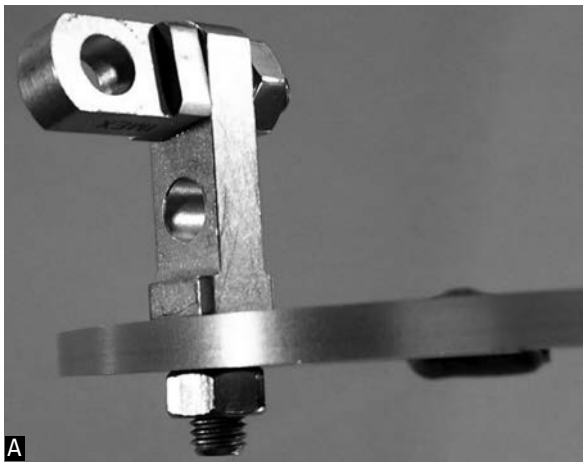


Figure 53-60. One or two hole posts **A.** allow fixation elements (pins or wires) to be placed above or below the ring surface for additional support. A wire placed above or below the ring is called a "drop wire "**B.**

wires and pins secured to the same bone segment. Axial micromotion occurs with bone segments secured to a ring with two or more narrow wires during weight bearing. Fixation pins rigidly secure bone segments and do not allow for micromotion in any plane. Therefore if a juxta-articular bone segment is secured to a ring with wires and a single fixation pin, the axial micromotion provided by the wires will result in cyclic bending forces at the fixation pin-bone interface. This may result in premature loosening of the fixation pin with subsequent pin tract drainage, sepsis and patient discomfort.

Two posts can also be connected to each other with a nut to create an adjustable articulation (Figure 53-61). Alternatively, a hybrid rod can be connected to a ring or arch with an angular hinge assembly to also create an adjustable articulation (Figure 53-62). Articulations will allow diagonal struts to be constructed using small or large hybrid rods. Diagonal struts improve the stiffness of a HCF frame allowing the use of a simple type I-a frame when appropriate. Furthermore, a diagonal can be removed 6 to 8 weeks after surgery to destabilize the frame and stimulate the later stages of bone healing. To construct a diagonal, the threaded end of a hybrid rod is placed through a hole in one of the posts of the articulation, and secured using two nuts. The threaded end of the other post is secured to the ring or arch with a nut. The smooth shaft of the hybrid diagonal rod can be secured utilizing the "stacked clamp" technique (as described in the previous section: Basic Principles for the Application of External Fixators) to a fixation pin using a SK single clamp. Alternatively, the diagonal strut can be attached to the hybrid connecting rod of the HCF frame using a SK double clamp.

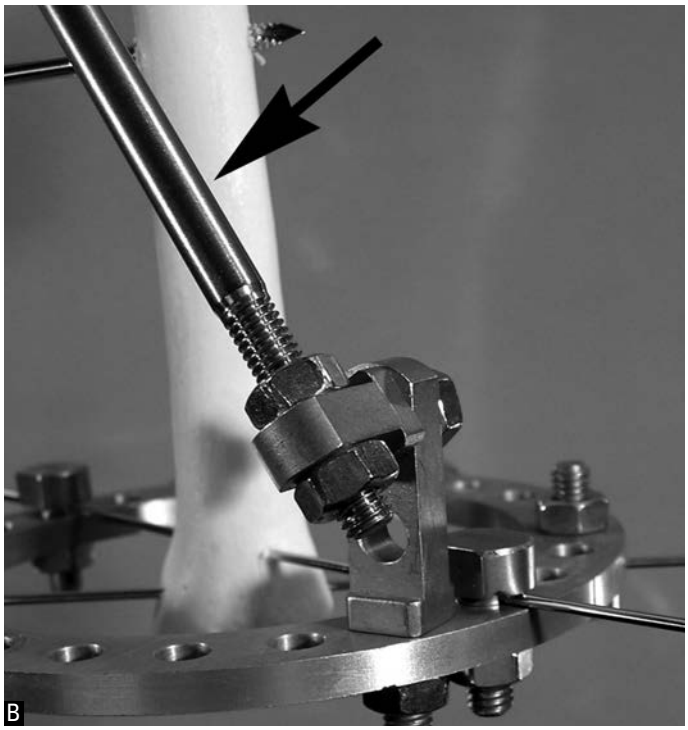

Figure 53-61. An articulation **A.** can be constructed from two posts. Articulations allow placement of a diagonal strut *(arrow)* to improve frame stiffness **B.**

Figure 53-62. An angular hinge used to create an articulation(photo courtesy of Dr Alan Cross). The threaded end of a hybrid connecting rod is screwed into one end of the angular hinge and secured with a single nut. The hinge is attached to a 50-118 mm ring with a single 6mm bolt.

A two-hole plate can be used to offset a small or large hybrid connecting rod from the ring (Figure 53-63). This may be necessary if the hybrid connecting rod and associated SK clamps are too close to the limb and could potentially result in pressure necrosis of the underlying soft tissues. One hole of the plate is attached to the ring using a 6.0 mm bolt and nut. The threaded portion of a large or small hybrid connecting rod is secured to the second hole in the plate using two 6.0 mm nuts. Alternatively, the hybrid rod can be attached to the plate using paired 6.0 mm spherical nuts and washers, to allow angulation of the rod up to 15° away from perpendicular relative to the plane of the ring. The design of the spherical nuts and washers allows for angulation of the rod in any direction that is desired.

A modified threaded small SK single clamp is available for placement of half pins from all-thread connecting rod elements (Figure 53-64). This 6 mm clamp is identical to the linear SK clamp, except that the portion secured to the connecting element is threaded instead of smooth. The thread pitch and size of the threaded SK clamp correlates to the 6.0 mm thread on the all-thread connecting rod. The threaded SK clamp is extremely useful when creating a hybrid spinal frame. Threaded SK clamps can be positioned anywhere along the all-thread connecting rod of a spinal frame. Half-pins can be angulated proximal,

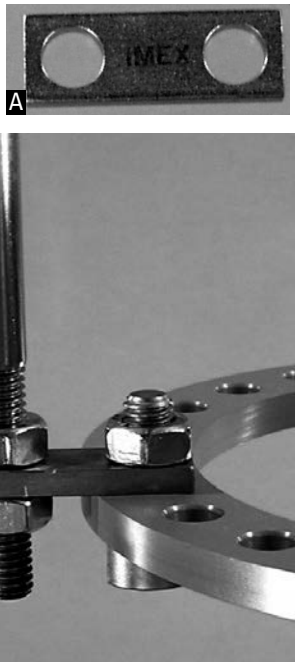

Figure 53-63. Two hole plates **A.** allow hybrid rods to be offset from the ring **B.**

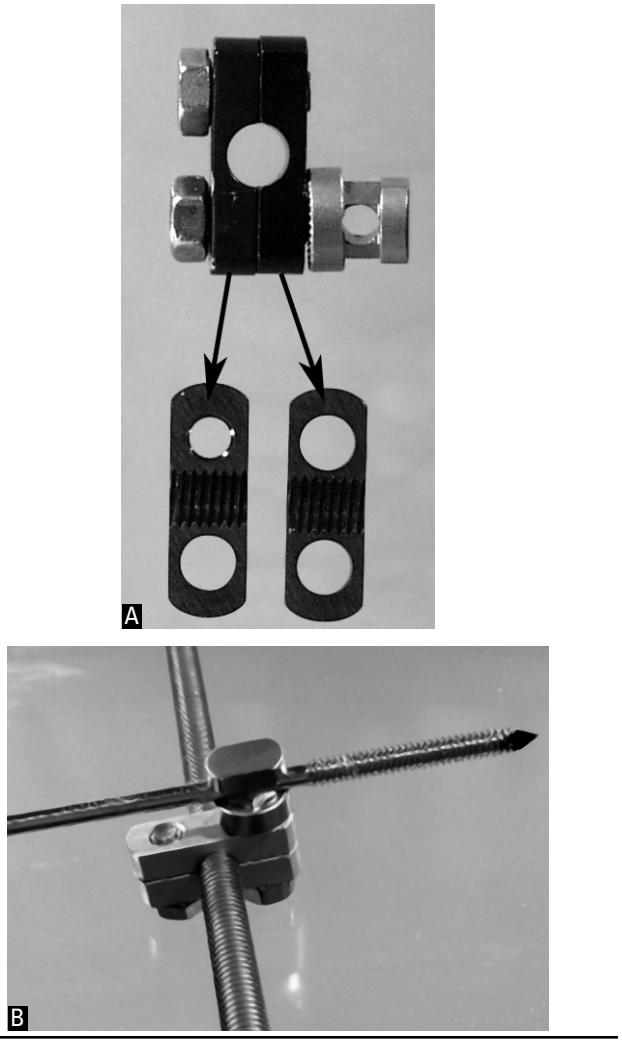

Figure 53-64. Modified threaded SK clamps **A.** allow half pins to be placed along all-threaded connecting rods **B.**

distal, dorsal, and ventral; in addition, the clamp can be moved forwards or backwards to facilitate placement of half pins into vertebral bodies.

Hybrid Circular Fixator Frame Design

The same nomenclature used to describe linear external fixator frames has been adopted for description of HCF frames. HCF frames can be uniplaner (type I-a, or type II); biplaner or modified multiplaner (type I-b) (Figure 53-65). The number and position of hybrid rod(s) utilized in fixator construction are the principle differences between the frames. Insertion of the fixation pins should always be through safe soft tissue corridors, thus dictating the possible positions of the hybrid rod(s) and the frame configurations available for a particular bone.

The most basic frame is the unilateral-uniplaner type I-a frame. This frame is most commonly used to manage fractures or simple bone deformities involving the radius/ulna or tibia in small to medium sized patients. Additional frame stiffness should be created by the addition of a diagnol strut to all type I-A frames, improving bending, torsional and axial stiffness. A type I-b frame utilizes two hybrid rods placed 60 to 90° apart. Hybrid I-b frames are often used to manage comminuted fractures of the radius/ulna or tibia, especially in large and giant breeds. A type I-b frame can easily be converted to a type I-a frame, by removing a hybrid connecting rod, and the associated SK clamps and fixation pins. This is referred to as staged disassembly or destabilization of the frame, and may stimulate the later stages of bone healing.

Type II HCF frames can be used to manage fractures of the tibia. **However application of type II frames to the radius is not recomended** because full pins passed through the bone may result in iatrogenic pin tract fractures. Furthermore, full-pins passed in the proximal half of the antebrachium penetrate large muscle masses and generally cause substantial pin tract morbidity and patient discomfort. If a type II hybrid frame is necessary for the management of a fractured tibia, half-pins should be placed in the proximal-medial aspect of the bone and the full-pin(s) placed in the distal two-thirds of the bone. This pin orientation will help reduce pin tract morbidly by keeping fixation pins out of the large proximal-lateral musculature of the tibia. **Therefore, to minimize pin tract complications without jeopardizing stability, hybrid 1-b frames are usually preferred over hybrid II frames for tibial fractures.** The hybrid type I-b frame offers mechanical characteristics similar to a type II frame. Additionally, the type I-b frame allows more freedom of placement of the two hybrid connecting rod, so that half pins can be placed through safe soft tissue corridors with minimal soft tissue penetration.

Multiplaner type I-b frames can be applied to metaphyseal fractures of the femur and humerus. However, full rings cannot be used to create a HCF for fractures involving these bones due to the extensive musculature surrounding the elbow, shoulder, stifle, and hip joint. Arches and partial rings are easily positioned near these joints without impinging joint function or encroaching upon regional soft tissues. Articulations and diagonal struts are generally incorporated to create multiplaner type I-b frames in the humerus and femur, in order to improve frame stiffness.

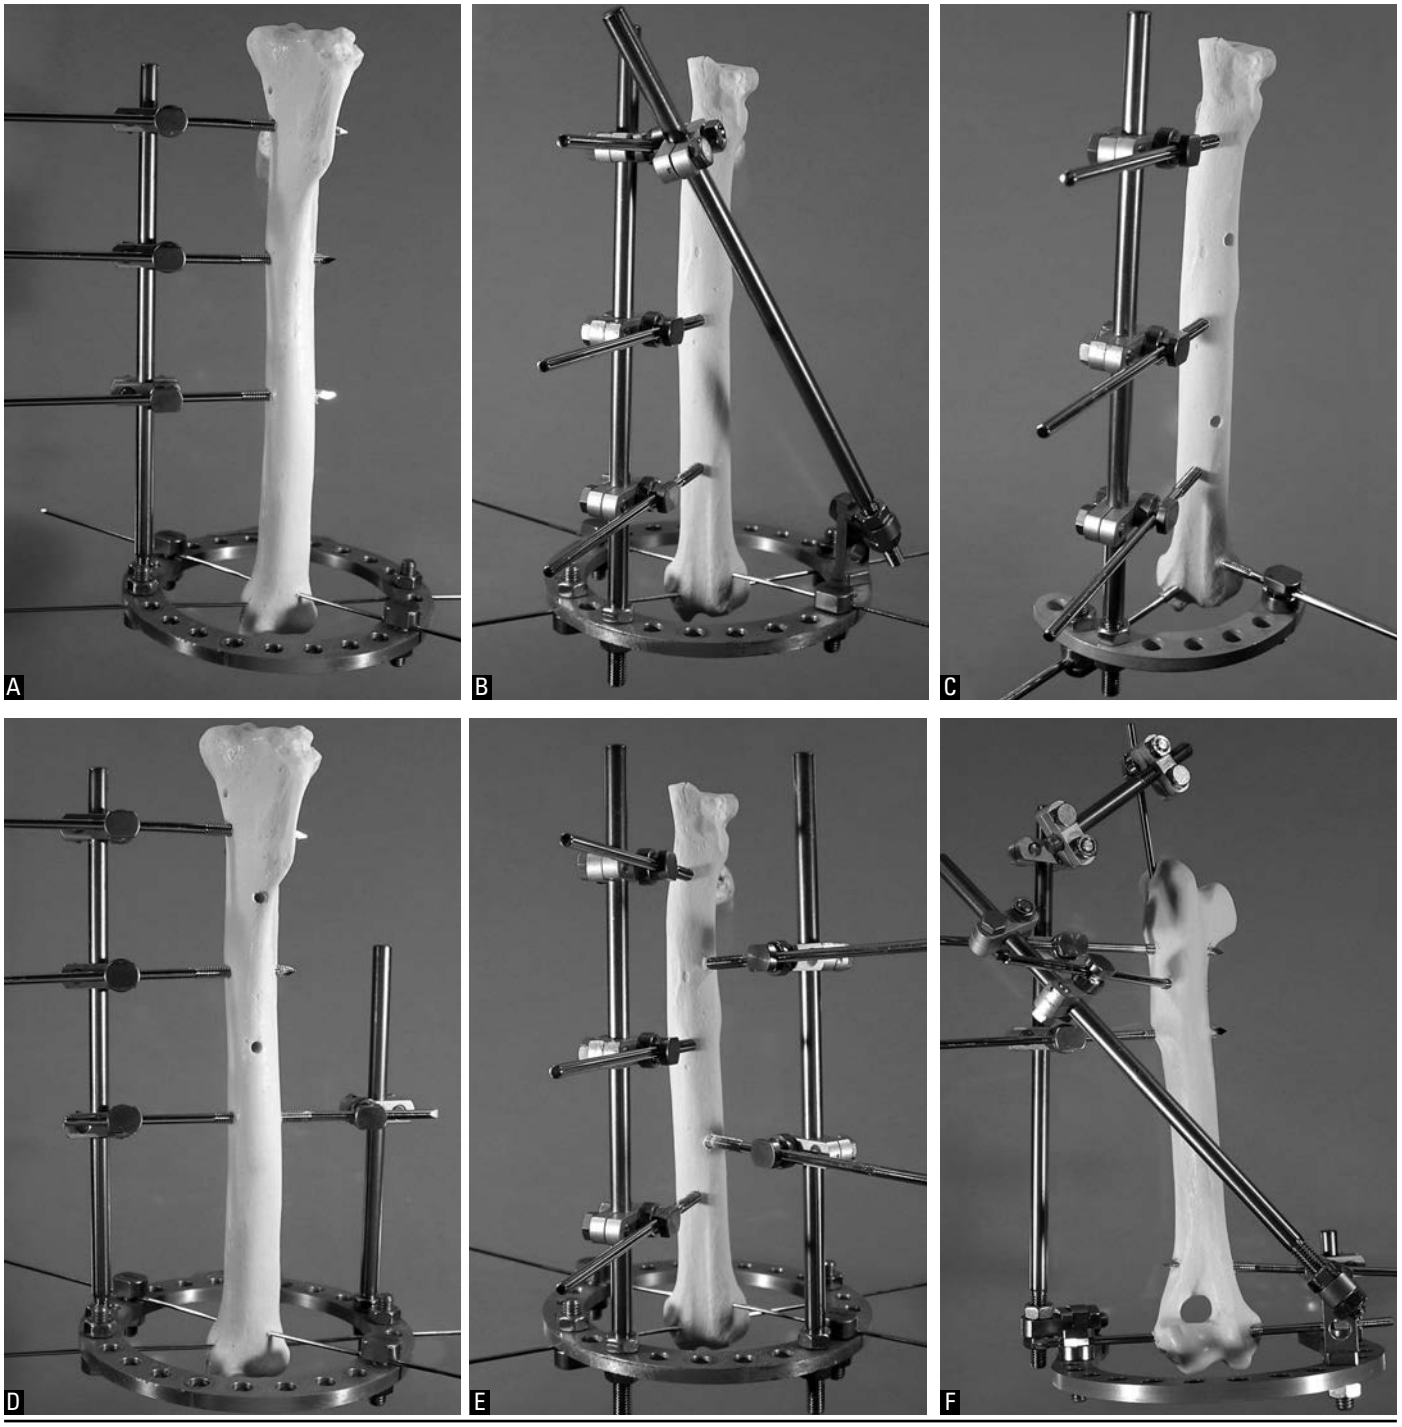

Figure 53-65. Common HCF frame designs. Type I-a frame **A.** Type I-a frame with diagonal strut **B.** Type I-a frame using arch and half-pins **C.** minimal Type II frame **D.** Type I-b frame **E.** and multiplaner Type I-b frame **F.**

Parabolic shaped arches with 140 and 220 mm internal diameters are available to create spinal HCF frames (Figure 53-66). Two to four spinal arches can be connected with three or four sections of 6.0 mm all-thread connecting rod. Half pins can then be placed into the vertebral bodies and secured to the arches using half pin fixation bolts. Modified threaded small SK clamps are positioned along the all-thread connecting rods of the frame. Half pins can be placed into vertebral bodies from the threaded SK clamps, as well as from the spinal arches using pin fixation bolts. In the author's experience a simpler two arch spinal frame used in conjunction with threaded SK clamps is easier to position on the spine, and place fixation pins into vertebral bodies, than the multi arch frame.

Application of a HCF

The application of a HCF is relatively easy; however, close adherence to basic linear and circular fixator application principles should be followed to improve clinical results and reduce postoperative complications. One primary advantage of any external fixation device, is that it can be applied using the principles of biological osteosynthesis. Whenever possible, the HCF should be applied using a closed technique. If necessary, to adequately reduce or align the major bone segments, a mini-approach can be used. However, the local fracture hematoma should not be disrupted. If a mini-approach is used, addition of an autogenous

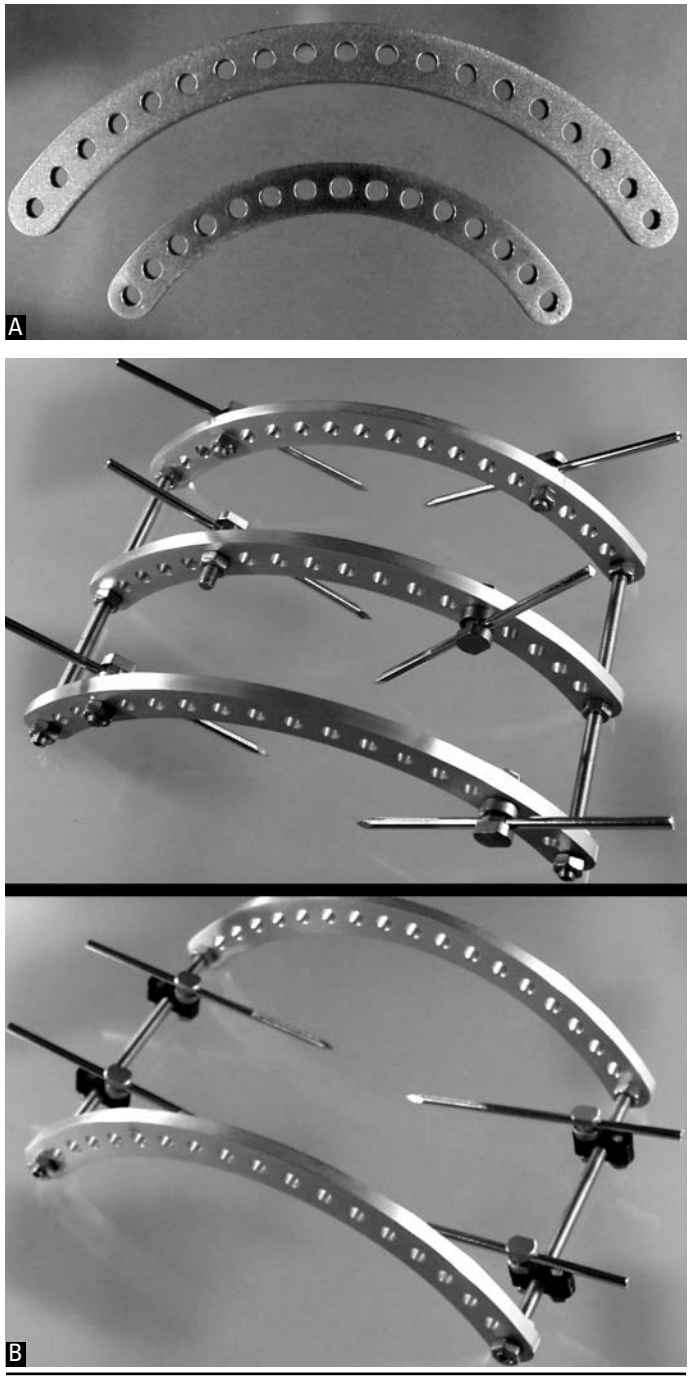

Figure 53-66. Parabolic arches **A.** with 140 and 220 mm internal diameters are used to create spinal frames **B.**

cancellous bone graft at the fracture site is recommended. Fixation pins should always be placed into appropriately sized pre-drilled holes using low speed insertion to avoid mechanical and thermal bone damage. Fixation pins should either be positive profile or tapered Thread-Run-Out (TRO) and inserted perpendicular to the diaphysis. Cortical thread pin design is used in all locations except the proximal tibia, distal femur, and proximal humerus. A cancellous thread profile is preferred in these locations where the cortex is thin and the bone is relatively soft. The threaded diameter of the fixation pin should not exceed twenty-five percent of bone diameter. Pins should be placed a distance of at least 1-bone diameter from the fracture region or fissures. A minimum of three positive profile fixation pins should be inserted into the primary bone segment.

Fixation wires are inserted into the small juxta-articular bone segment at divergent angles. The wires should be placed through the juxta-articular bone segment in regions with minimal overlying soft tissues. Care should be taken to prevent placement of wires through extensor and flexor tendons and major muscles. One wire should be placed on each surface of the ring. If possible, a third "drop wire" should be integrated into the short bone segment to improve resistance to bending and torsional forces. The use of counter-opposed stopper wires (described in the section: Application of Ring Fixators) will also improve fracture stability by minimizing bone translation along the wires. Special 1.0 to 1.6 mm transfixation wires with a free cutting point that easily penetrates cortical bone are recommended instead of trocar pointed K-wires. Wires placed on 66, 84, and 118 mm rings should be tensioned to approximately 90 Kg. "Drop wires" and wires placed on 50 mm rings should not be tensioned. Full rings should be used whenever possible to improve fracture stability. Several lengths of sterile hybrid rods should always be available for intra-operative frame construction and modification if necessary. The hybrid rod should be at least the same length as the fractured bone once axial reduction is achieved. Slightly longer hybrid rods may be needed if diagonal struts will be created. Release incisions in the skin should always be created around each fixation wire and pin. The skin release incision should be 1 to 2 cm long for fixation pins and 0.5 cm for fixation wires. The skin release incisions should be deepened down to the level of the bone by blunt dissection using a hemostat.

The overall goal of fracture reduction and stabilization using a HCF is to, 1) restore the bone to its normal axial length, 2) position the proximal and distal joint surfaces in normal anatomical alignment to each other, and 3) prevent any translational malalignment of the primary and juxta-articular bone segments. Orthogonal radiographs of the normal limb can help determine the correct angular alignment of the proximal and distal joint surfaces, as well as the normal axial length expected of the fractured bone once reduction is complete. Intra-operative fluoroscopy, if available, can assist with wire and pin placement as well as for assessment of fracture reduction and joint alignment. If fluoroscopy is not available, joint surfaces can be "mapped-out" by inserting several 22 to 24 gauge needles into the corresponding joints in several different planes. The "hanging leg prep," (as described in the Basic Principles for the Application of External Fixators), is very useful to reduce fractures involving the radius and ulna when applying a HCF. If a full ring is used to construct the frame, it must be placed over the limb prior to hanging the limb. **The "hanging leg prep" in the author's experience, often makes reduction of juxta-articular tibial fractures difficult and therefore is not recommended.**

Application of a HCF to a Tibial Fracture

The following description applies to the placement of a type I-a or a type I-b HCF frame to a fractured tibia with a short juxta-articular component. Several factors need to be considered to determine if a hybrid type I-a or a type I-b frame should be used to manage the fracture. These factors include: 1) the fracture configuration (two or three piece fracture with load sharing versus a commi-

nuted fracture with no load sharing); 2) patient weight; and 3) patient age. As a general rule, a type I-a HCF frame is applied to fractures with some degree of load sharing by the primary and juxta-articular bone segments, immature or young patients, and fractures in small to medium sized patients. To minimize bending forces acting on the fracture and frame components, a diagnol articulation ("strut") is always recommended when using a type I-a HCF frame. A type I-b HCF frame is usually reserved for large and giant breeds, or comminuted juxta-articular, non-load sharing fractures configurations. If a type I-a HCF frame is applied to the tibia, the hybrid rod should be positioned over the medial aspect of the limb. If a type I-b HCF frame is used, hybrid rods are placed over the medial and anterior regions of the limb.

General Application Steps for a Fractured Tibia

1) The patient is positioned in dorsal recumbency, at the end of the table to facilitate traction on the tibia in order to achieve fracture reduction. If a full ring is used for frame construction, it should be placed over the limb prior to any wire or pin insertion. The hybrid rod does not need to be attached to the ring if it will interfere with reduction or initial wire placement.

2) A 1.0 to 1.6 mm transfixation wire, preferably with a stopper (olive wire), is passed through the juxta-articular bone segment. The wire should be parallel to the corresponding joint surface, perpendicular to the longitudinal axis of the tibia, and placed in the true medial-lateral plane of the juxta-articular bone segment (Figure 53-67). **Positioning of this first wire is critical.** The wire should be placed 5 to 10 mm from the joint surface.

3) The juxta-articular bone segment is centered within the ring. The wire is secured to the outside ring surface with two wire fixation bolts or a bolt and slotted washer. The wire should be tensioned. If a hybrid rod has not already been attached to the ring it should be positioned on the medial aspect of the ring and secured with paired nuts or spherical nuts and washers (Figure 53-68).

4) A pilot hole is pre-drilled into the primary bone segment after creating a release incision in the regional soft tissues, approximately 1 to 2 cm from the associated joint surface. A drill sleeve should be used while pre-drilling to protect the surrounding soft tissues. The pilot hole should be created parallel to the corresponding joint surface, perpendicular to the tibial diaphysis and placed in the true medial-lateral plane of the primary bone segment (Figure 53-69). **Proper positioning of the pre-drilled pilot hole is critical.**

5) A positive profile or a tapered Thread-Run-Out (TRO) half-pin is inserted, using low speed into the pilot hole until several threads penetrate the far cortex. **Note: at this stage, a half-pin should be positioned in the primary bone segment, and a wire placed through the short juxta-articular segment. The pin and wire should be parallel to their corresponding joint surfaces, perpendicular to the longitudinal axis of the tibia and in the true medial-lateral plane of their corresponding bone segments (Figure 53-70).**

6) Axial reduction is achieved by placing traction on the ring (Figure 53-71A). Rotational and angular corrections are accomplished by rotating and manipulating the ring until the wire and half pin are parallel and in the same sagittal plane to each other (Figure 53-71B). If necessary, a mini-approach to the fracture can

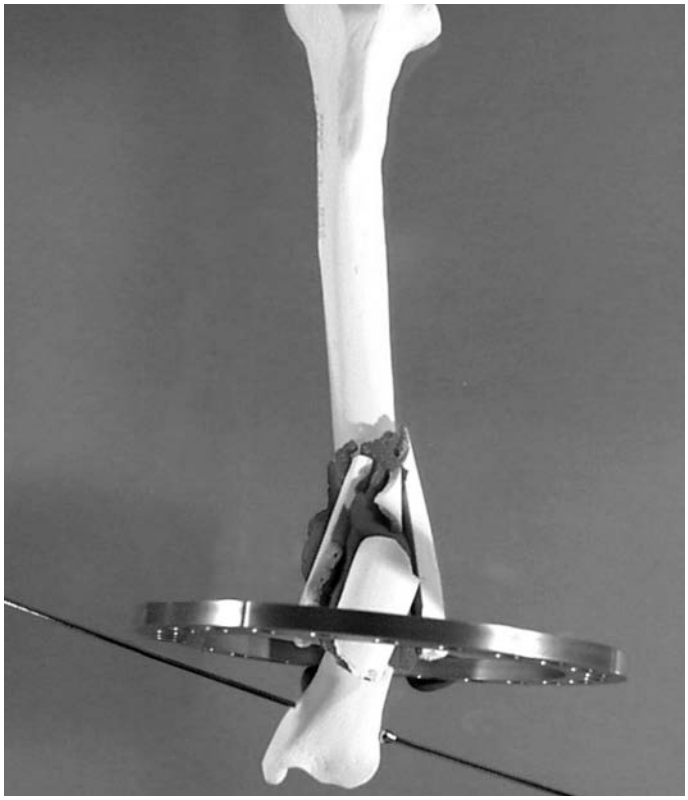

Figure 53-67. The initial transfixation wire is placed through the juxta-articular bone segment. The wire is placed 5-10 mm above and parallel to the joint surface. In addition, the wire is inserted in the true medial-lateral plane and perpendicular to the longitudinal axis of the bone segment.

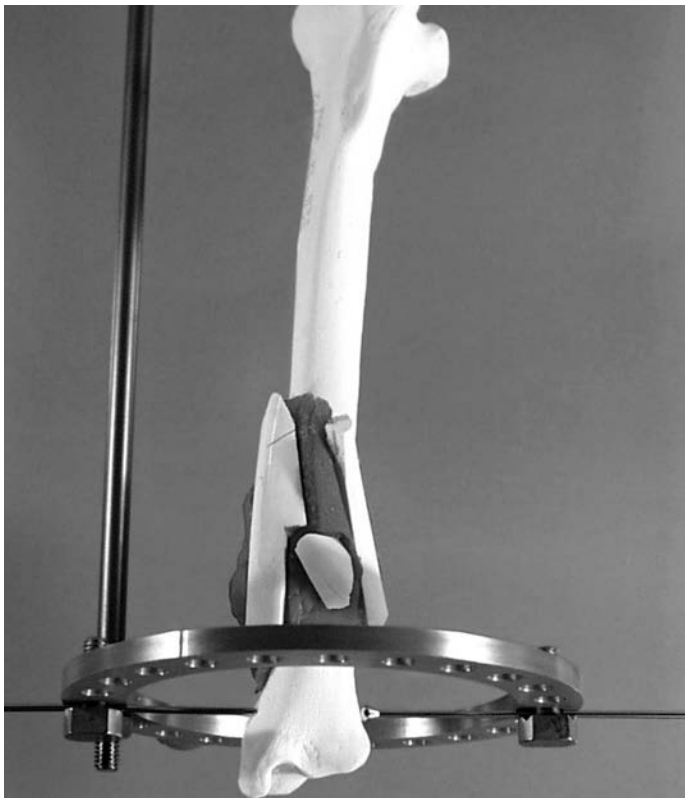

Figure 53-68. The juxta-articular bone segment is centered within the ring and secured with two wire fixation bolts. The hybrid connecting rod is placed on the medial aspect of the ring using two nuts.

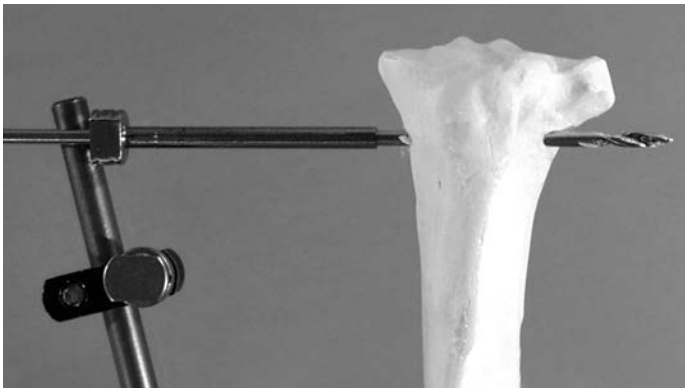

Figure 53-69. A pre-drilled pilot hole is created in the primary bone segment parallel to the corresponding joint surface. The hole is orientated perpendicular to the tibial diaphysis and in the true medial-lateral plane of the bone segment.

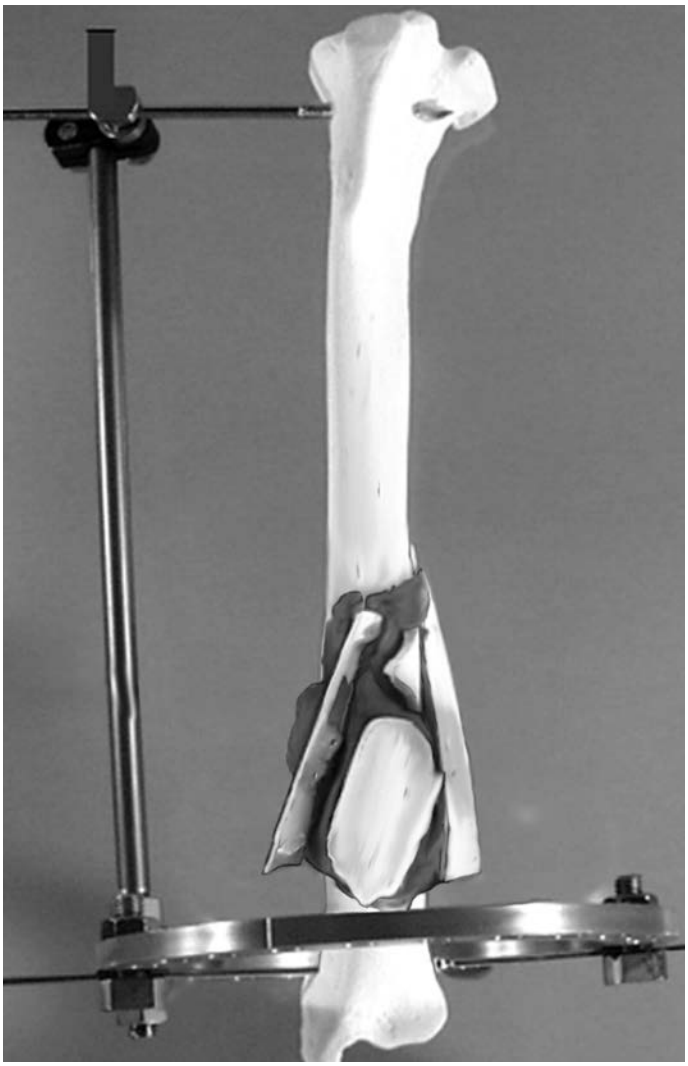

Figure 53-70. The correct position of the trasfixation wire and the positive profile half-pin. Each fixation element is parallel to the corresponding joint surface, perpendicular to the longitudinal axis of the tibia, and in the true medial-lateral plane of the bone segments.

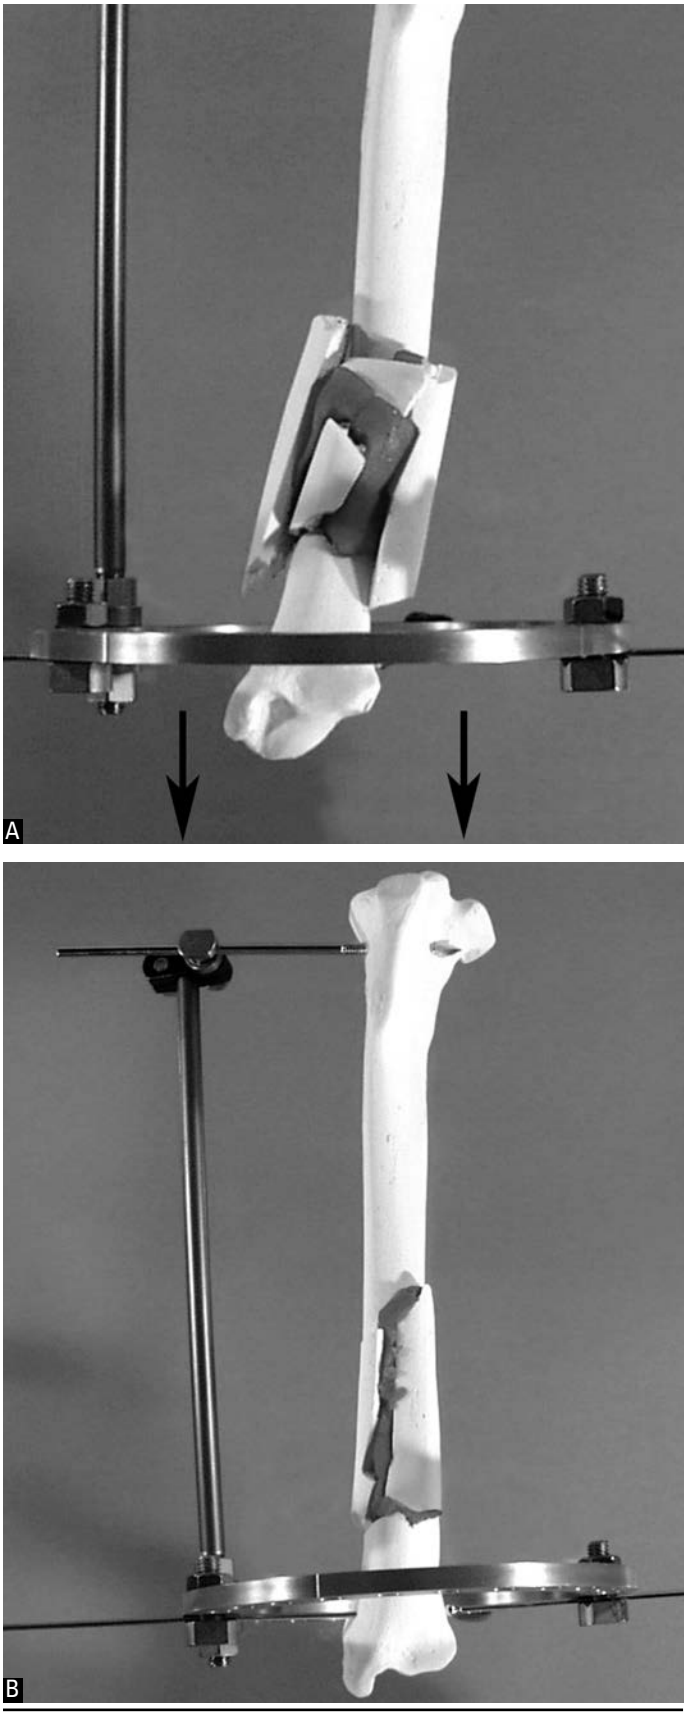

Figure 53-71. Digital traction placed on the ring **A.** with the SK clamp loosely attached to the hybrid connecting rod and fixation pin will result in axial reduction of the fracture **B.** Once reduction is accomplished the SK clamp is re-tightened to the connecting rod.

be made to facilitate reduction.

7) The half-pin is attached to the hybrid connecting rod, using an SK clamp while maintaining axial, rotational and angular alignment. If necessary, the position of the hybrid rod can be changed on the ring to improve reduction or to allow subsequent fixation pins to be passed through safe soft tissue corridors. If spherical washers and nuts or a universal hybrid rod adapter were used in frame construction, the hybrid rod can be angulated to improve reduction. However, the orientation of the pin and wire to each other should not be altered, assuming they were correctly positioned initially.

8) If substantial medial-lateral translational malalignment of the juxta-articular and primary bone segment exist, the SK clamp can be loosened and the half pin translated medial or lateral, as needed to improve reduction (Figure 53-72). Likewise, the wire fixation bolts can be loosened and the juxta-articular bone segment translated medial or lateral. However, the orientation of the pin and wire to each other should not be altered. **Note: at this stage: 1) the proximal and distal joint surfaces should be parallel; 2) the primary bone segment and the short juxta-articular segment aligned in the medial-lateral and anterior-posterior planes; 3) anatomical axial length re-established; and 4) rotational malalignment corrected.**

9) A second wire, preferably with a stopper, is passed through the juxta-articular bone segment. This wire should be orientated approximately 40-60° to the first wire, parallel and flush to the inner ring surface. Before placing the second wire, it is imperative that the juxta-articular bone segment is not tilted in an anterior-posterior direction. Digital pressure placed on the malaligned bone segment will improve reduction. The wire should be passed through regions with minimal soft tissue coverage over the bone. Using counter-opposed stopper wires will help prevent translation of the short juxta-articular bone segment. The wire is then secured to the ring with wire fixation bolts and tensioned (Figure 53-73).

10) Place two or three additional SK clamps on the hybrid connecting rod. Position a clamp over the primary bone segment near the fracture site. Digitally correct any anterior-posterior tilting of the primary bone segment at the fracture site. Insert a positive profile half-pin into the primary bone segment at a distance of at least one times the diameter of the bone at the fracture, after creating a pre-drilled pilot hole. The SK clamp can be used as a drill guide with the aid of a drill sleeve. Secure the SK clamp and pin to the hybrid connecting rod. Place additional half-pins into the medial aspect of the primary bone segment. The half-pins should be equally spaced along the medial shaft of the tibia (Figure 53-74). Typically three to four positive profile fixation pins should be placed into the primary bone segment.

11) Add a "drop wire" to the ring using two posts if sufficient bone is available. Do not tension this wire. If possible, the drop wire should be placed in a different plane than the previous two wires placed on the ring, to improve bending and torsional stability.

12) A diagonal strut can be created if additional frame stiffness is necessary.

13) A type I-b HCF frame can be created, if necessary, by attaching a second hybrid rod to the anterior surface of the ring using two nuts. Position two to four SK clamps along its shaft and insert half-pins into the anterior surface of the tibia, as previously described. These pins should be passed between the half pins inserted from the medial hybrid rod (Figure 53-75).

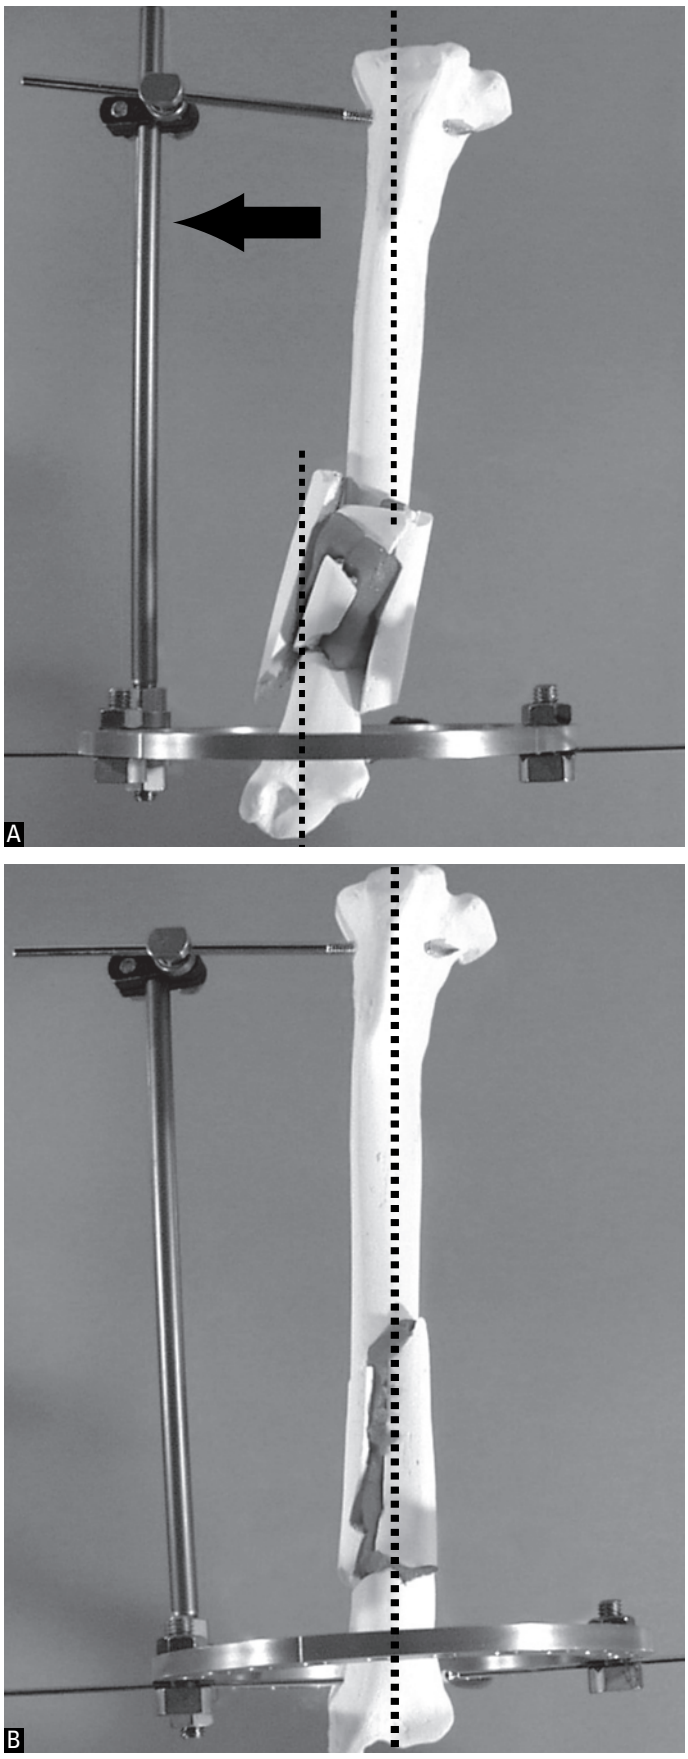

Figure 53-72. Medial-lateral translational malalignment **A.** is corrected by loosening the SK clamp and moving the half pin and primary bone segment in the appropriate direction to improve alignment **B.** Once alignment is achieved, the SK clamp is re-tightened.

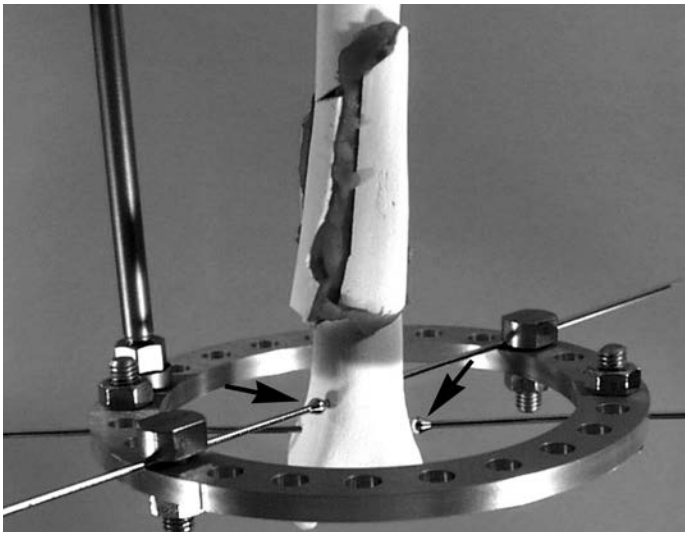

Figure 53-73. A second transfixation wire is passed through the short juxta-articular bone segment and secured to the ring. Counter-opposed olive wires *(arrows)* will help prevent translation of the bone segment, improving resistance to bending and torsional forces.

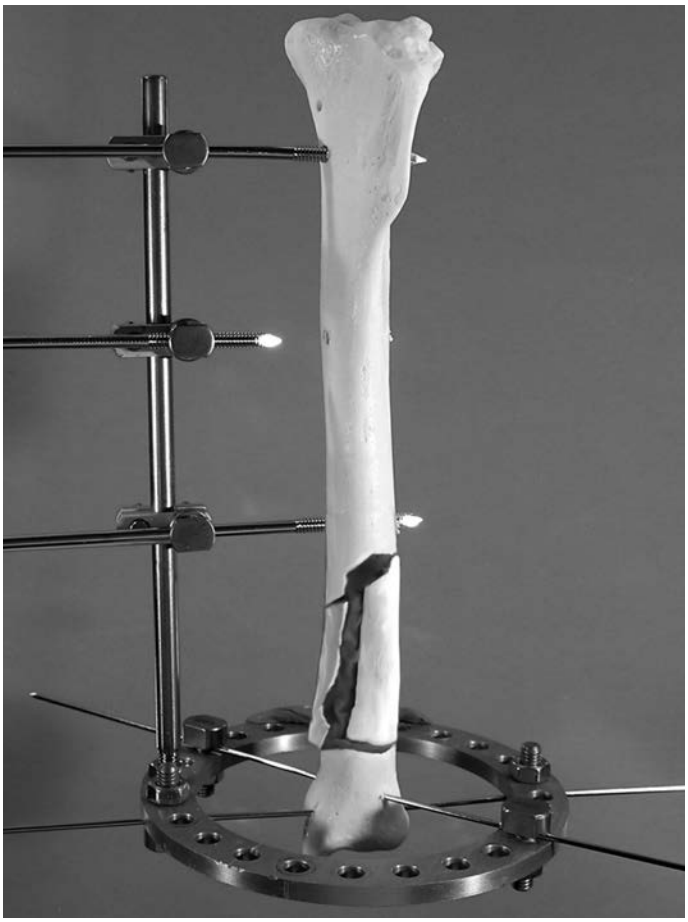

Figure 53-74. Additional SK clamps are equally spaced along the hybrid connecting rod and additional half pins are placed into the primary bone segment after pre-drilling pilot holes.

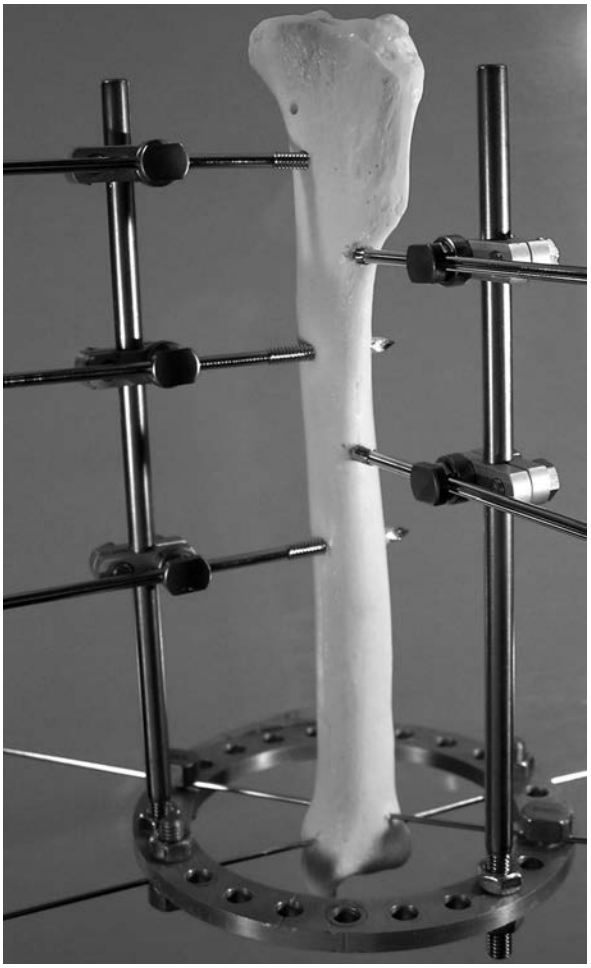

Figure 53-75. A hybrid Type I-b frame can be created by adding a second hybrid connecting rod, SK clamps and half-pins to the anterior aspect of the ring.

Application of a HCF to a Radius/Ulna Fracture

A "hanging leg prep" will often facilitate re-establishment of axial limb length of radial/ulnar fractures. If a full ring is used, it must be placed over the antebrachium prior to hanging the limb. A more detailed description of the "hanging leg prep" can be found in the Basic Principles for Application of External Fixators section. The basic steps used to apply a HCF to the tibia can be followed for the radius with only several modifications. **One primary difference is that the position of the hybrid connecting rod(s) in relationship to the limb will be altered to allow placement of half pins through safe soft tissue corridors.** Due to the flat ovoid shape of the radius it is difficult to pass fixation pins in the medial-lateral plane. However, the bone is a relatively easy target to insert half pins in the cranial-medial and cranial-lateral planes. Fixation pins placed in these locations will pass through safe soft tissue corridors. Similar to the tibia, the decision to use a type I-a frame (with or without a diagonal), or a type I-b frame will be dependent upon the fracture configuration (load or non-load sharing), patient's age and weight. **Hybrid type II frames are not recommended on the radius.** To place a hybrid type I-a frame on the radius, the hybrid connecting rod should be positioned over the cranial-medial aspect of the antebrachium. If a hybrid type I-b frame is used, hybrid connecting rods are

positioned over the cranial-medial and cranial-lateral aspect of the antibrachium, approximately 60° to each other.

General Application Steps for a Fractured Radius/Ulna

1) With the leg suspended, and axial length re-established, the carpus and elbow should be flexed and extended to determine if any rotational or angular joint malalignment exists. Any malalignment should be corrected as described for application of a linear fixator. The ring or partial ring is positioned over the juxta-articular bone segment and secured to the bone with a stopper wire. The wire should be positioned parallel to the joint, perpendicular to the longitudinal axis of the bone, and in the medial-lateral plane of the juxta-articular bone segment.
2) A half-pin is inserted into the primary bone segment through a release incision and a pre-drilled hole placed over the cranial-medial aspect of the antebrachium. This pin should be placed 1 to 2 cm from the corresponding joint surface. The half-pin should be positioned parallel to the joint surface and perpendicular to the longitudinal axis of the bone.
3) The half-pin is connected to the cranial-medial hybrid connecting rod using an SK clamp. The elbow and carpus should again be flexed and extended to evaluate and correct any rotational or angular malalignment, if present.
4) An additional wire is passed through the juxta-articular bone segment approximately 60° to the first wire and on the opposite flat surface of the ring. This wire is secured to the ring using wire fixation bolts and nuts. Both wires connected to the ring should be tensioned. A "drop wire" should be placed if the length of the short bone segment will allow.
5) Two or three additional SK clamps are placed on the hybrid connecting rod and half-pins inserted into the cranial-medial aspect of the radius to complete the frame.
6) Additional frame stiffness should be created by the addition of a diagnol strut.
7) A hybrid type I-b frame can be created by positioning a second hybrid connecting rod, approximately 60° from the first rod, over the cranial-lateral aspect of the antibrachium. The rod is connected to the ring. Additional SK clamps are added to the rod and half-pins are inserted into the cranial-lateral aspect of the radius through release incisions and pre-drilled pilot holes. These half-pins should be placed between the half- pins placed from the cranial-medial hybrid rod (Figure 53-76).

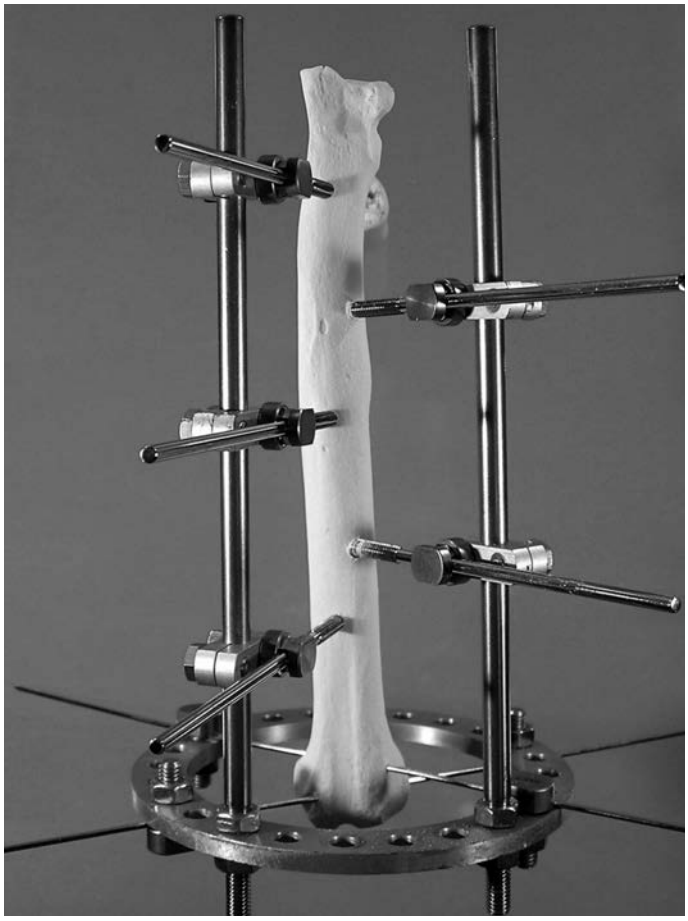

Figure 53-76. Hybrid Type I-b construct used to stabilize a distal radial fracture.

Application of a Multiplaner 1-B HCF to a Distal Humeral or Femur Fracture

Due to the extensive soft tissues surrounding the stifle and elbow joint, a full ring cannot be positioned over the distal humerus or femur without impingement of joint motion. Partial or stretch rings are used instead. Furthermore, placement of divergent wires from a ring in these locations causes substantial penetration of the flexor and extensor muscle groups. In the author's experience, this often results in **significant permanent** loss of joint motion. However, if fixation elements are only placed in the medial-lateral plane of the juxta-articular bone segment, joint motion is preserved in both the elbow and stifle joints. In addition, fixation pins should only be placed into the proximal-lateral and cranial-lateral regions of the humerus and femur to minimize penetration of major muscles near the hip and shoulder joint. Safe soft tissue corridors have been described for the humerus and femur in the linear external fixation section.

General Application Steps for a Distal Humeral or Femur Fracture

1) A pilot hole is pre-drilled through the condyle in the true medial-lateral plane of the distal juxta-articular bone segment. A **positive profile full-pin** with cortical (humerus) or cancellous (femur) thread profile is inserted through the condyle using low speed.
2) The full-pin is attached to the medial and lateral aspect of a stretch ring using two pin fixation bolts and 6.0 mm nuts. The open surface of the ring can be directed cranial or caudally to allow normal motion of the joint. The author preferes to direct the open surface of the ring caudaully in order to provide an anterior platform available for additional connecting elements (Figure 53-77). Alternatively, the open end of the ring can be orientated cranial.
3) An intramedullary pin is inserted in a normograde manner from the proximal aspect of the bone the intramedullary pin can be retrograded from the fracture site, through a mini-approach. The pin is inserted into the center of the femoral condyle or into the medial half of the humeral condyle. If necessary, a mini-approach can be used to facilitate placement of the intramedullary pin into the condyle. The pin is advanced until the axial length of the bone

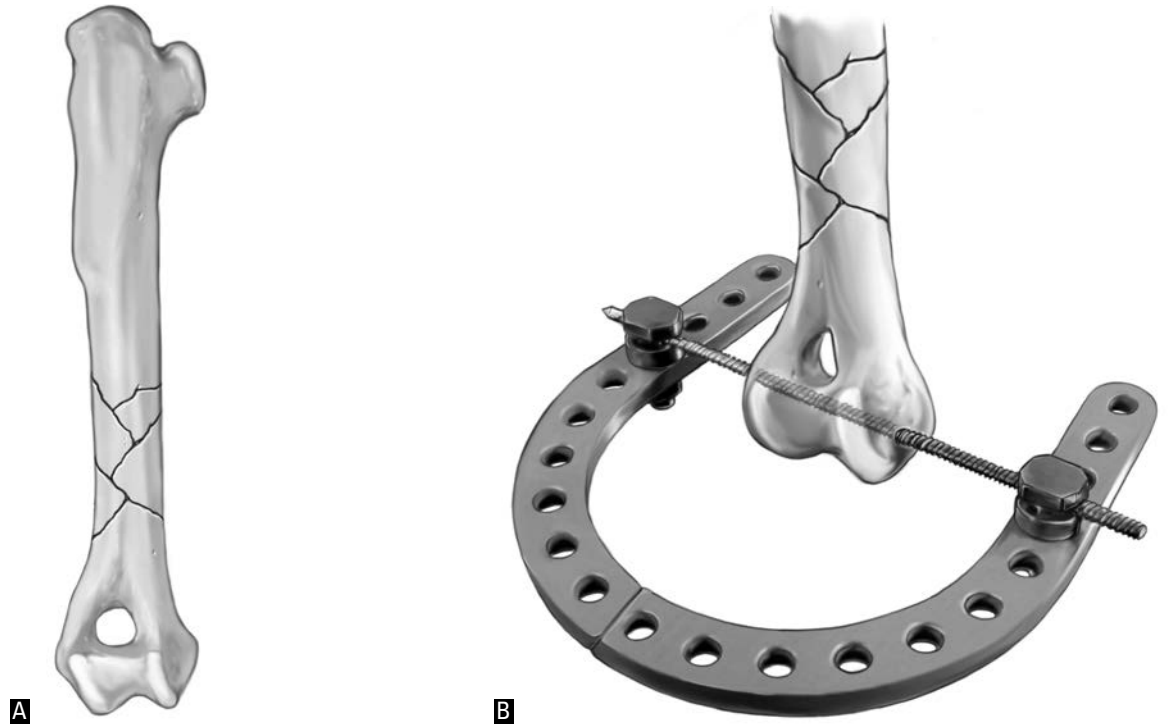

Figure 53-77. Application of a multiplaner Type I-b hybrid construct to a distal humeral fracture **A.** A transcondylar positive profile center threaded full-pin is secured to a stretch ring using two half-pin fixation bolts **B.** The open end of the ring has been directed caudally to prevent impingement of joint function, and allow an anterior platform for other connecting elements.

is re-established. The pin also prevents translational malalignment of the condyle and the primary bone segment. Once the fracture is aligned, the pin is then passed distally into the condyle.

4) The stretch ring is manipulated to correct rotational and angular malalignment of the condylar bone segment. A hybrid connecting rod is secured to the lateral aspect of the stretch ring using two 6.0 mm nuts. To allow proper angulation of the hybrid rod, it may be necessary to attach the hybrid rod to the ring using either paired spherical nuts and washers, or by creating an articulation using two posts.

5) The proximal end of the hybrid rod is attached to the proximal aspect of the primary bone segment using two - three positive profile half-pins and SK clamps. The hybrid rod can be tied into the intramedullary pin using an articulation. Alternatively the IM pin can be contoured and directly attached to the hybrid rod with an SK clamp (Figure 53-78).

6) To provide additional support of the condyle, a positive profile half-pin is inserted into the condylar or supracondylar region, distal to the fracture. The pin can be inserted into either the medial or lateral aspect of the condyle. The author has found that a medially placed half-pin is clinically well tolerated, penetrates less soft tissue and results in less restriction of joint motion than a laterally placed pin. The half-pin is placed from either a post or a short hybrid connecting rod (Figure 53-79).

7) One or two diagonal struts can be created using articulations secured to the anterior region of the stretch ring to improve frame stiffness. Additional half-pins can be placed into the proximal cranial-lateral aspect of the humerus or femur from SK clamps positioned along the diagonal strut (Figure 53-80).

8) The frame can easily be destabilized to enhance fracture healing postoperatively by: a) removal of the intramedullary pin; b) removal of diagonal struts; or c) by converting the HCF into a lateral 1-a linear external fixator by removing the ring, diagonals, medial half-pin, and cutting the medial aspect of the full pin.

Postoperative Care of the HCF

Postoperative care of a HCF is similar to the care previously described for circular and linear fixators. If destabilization of the frame is desired, it is generally performed 6 to 8 weeks after surgery. Staged disassembly is usually not necessary if fixation wires have been used in the short bone segment. If a wire or pin causes significant drainage or becomes loose it should be removed, or replaced if necessary. Orthogonal radiographs should be performed every 6 to 8 weeks until fracture healing is complete and the frame removed. The supporting, connecting and assembly elements of the HCF can be cleaned and reused numerous times.
