Figure 53-80. A diagonal strut is created on the anterior or anterior-medial aspect of the ring using an articulation. The strut is connected to a proximal half-pin using a "stack clamp" technique. Additional half-pins can be placed into the proximal-lateral aspect of the humerus from an SK clamp positioned on the diagonal strut.

Chapter 54

Bone Grafts and Implants

Harvesting and Application of Cancellous Bone Autografts

James P. Toombs

Introduction

Application of a freshly harvested cancellous bone autograft is considered to be the "gold standard" treatment for promoting the healing of bony defects. In spite of this, cancellous bone grafting is one of the most underutilized procedures in veterinary orthopedics.

Cancellous bone grafts benefit healing by three different mechanisms: 1) the matrix of cancellous bone contains bone morphogenetic proteins that stimulate uncommitted mesenchymal cells to differentiate into bone forming cells at the injury site (osteoinduction); 2) the trabecular surfaces of the cancellous bone graft allow invasion of the graft by newly formed blood vessels and provide a surface or scaffold upon which new bone can be deposited (osteoconduction); and 3) bone forming cells in the graft which survive transplantation may participate directly in early formation of bony callus (osteogenesis). The delicate trabecular structure of cancellous bone does not enable it to bear weight or support fixation devices (structural support function).

Clinical Indications for Cancellous Bone Grafting

Specific clinical indications for cancellous bone grafting fall into two major categories: 1) conditions where bone healing requires enhancement (nonunions, potential nonunions, highly comminuted fractures, and osteotomy procedures that depend upon rapid new bone formation for a successful outcome – e.g. triple pelvic osteotomy); and 2) treatment of bone loss secondary to trauma (high energy open fractures), disease (osteomyelitis and bone cysts), or surgical resection (arthrodeses, empty holes in bone after bone plate removal, and limb salvage procedures in patients with bone neoplasia).

Nonunions

Most nonunion fractures seen in dogs and cats are hypertrophic and are attributable to inadequate stabilization. Application of appropriate internal or external fixation improves the mechanical environment such that many of these fractures will heal successfully without bone grafting. Avascular nonunions, however, do require bone grafting. The sclerotic ends of such fractures are debrided back to bleeding bone using either a bone curette or rongeurs, and a Steinmenn pin, K-wire, or drill bit is used to reopen the medullary cavity. Fibrous tissue at the fracture site should also be resected. A liberal amount of freshly harvested cancellous autograft should be packed into the resulting defect to enhance bone healing.

Potential Nonunions

Decreased vascular density in the distal radius of small breed dogs has been implicated in the higher frequency of nonunion seen in these patients. Treatment usually involves open reduction, fixation with a bone plate and screws, and application of canellous bone autograft to the fracture region.

Comminuted Fractures

Highly comminuted fractures have avascular fragments that have a tendency to be resorbed. Additionally, fixation devices applied to such fractures must function in buttress mode, thus provision of optimal stability can be challenging. Vigorous early production of bridging callus stimulated by liberal application of cancellous autograft over the fracture region is often critical to a successful outcome in these cases.

Osteotomy Procedures

Rapid formation of bridging callus is critical to a successful outcome in canine patients that have undergone triple pelvic osteotomy (TPO). As most TPO patients are young dogs with relatively soft bone, pullout of fixation screws and loss of reduction can occur with repetitive loading. Liberal application of cancellous bone graft at the ilial osteotomy site facilitates rapid production of bridging callus thus promoting successful healing before implant loosening can occur. Corticocancellous bone removed from the pubis and the triangular piece of bone removed from the dorsal aspect of the caudal ilial bone segment can be cut into small pieces and mixed with the graft as a cancellous bone extender.

High Energy Open Fractures

Bone loss is a common feature of high energy open fractures, especially those accompanied by significant soft tissue shearing injuries. Initial treatment includes wound debridement and stabilization of the fracture. Cancellous bone grafting is often delayed for about 14 days to allow the surrounding soft tissue to recover sufficient vascularity to be supportive of the bone graft. If the graft cannot be covered with skin or muscle, it can be protected with a sterile nonadherent dressing followed by a bandage. If the cancellous bone graft fails, it is generally resorbed or expelled through the wound. Cancellous bone is the only type of bone graft that can be safely applied to contaminated or infected fractures, as grafts containing cortical elements will generally sequestrate.

Osteomyelitis

Chronic bone infection is characterized by large areas of avascular bone and dense scar tissue, which can be impenetrable barriers to parenterally administered antibiotics. When avascular bone and scar tissue are removed by debridement, this results in a large bony defect that is slow to heal and is prone to reinfection. Packing such a defect with freshly harvested cancellous bone is helpful in resolving infection and promoting

bone healing. Rigid stabilization and appropriate antibiotic therapy are required in addition to the graft in order to obtain a successful outcome.

When cancellous autograft is applied to a contaminated or infected host bed, care must be taken to avoid contamination of the donor site. In this situation, the following procurement and application procedure is recommended: 1) perform the host site surgical procedure and any necessary debridement, lavage, obtain a sample for culture, and then cover the repair site with moist sponges; 2) change gloves and use a separate set of surgical instruments to harvest the cancellous bone graft; 3) close the donor site; 4) apply the cancellous graft to the recipient site; and 5) close the repair site.

Bone Cysts

Bone cysts are benign fluid-filled lesions of unknown etiology that may be monostotic (involving a single bone) or polyostotic (involving more than one bone). Clinical signs include pain and swelling, but cystic bone lesions can be asymptomatic until they reach a fairly large size or until a pathologic fracture occurs. Treatment involves curettage of the walls of the cyst, filling of the resulting defect with cancellous bone graft, and stabilization of the bone until healing occurs.

Arthrodesis

When arthrodesis is performed, stable bony union of multiple, often complex joint surfaces must be achieved as quickly as possible. A successful outcome depends upon adherence to the following principles: 1) removal of all cartilage from the surfaces that must undergo bony healing; 2) liberal application of cancellous bone graft to fill defects and to promote early callus formation; 3) rigid fixation; and 4) healing of the joint in a functional anatomic position.

Bone Plate Removal

Implant removal is performed in some patients that have undergone longbone fracture repairs with bone plates and screws. Implant removal results in a variable number of empty holes that can act as stress concentration points until healing occurs. Some surgeons advocate packing the empty bone holes with cancellous autograft bone to speed the healing of these defects.

Limb Salvage

Animals with a neoplastic lesion involving the distal radius are the best candidates for limb salvage. Wide resection of the neoplastic portion of the bone produces a defect that is too massive to be filled with cancellous bone alone. Typically, an allogeneic cortical bone segment is cut to fit the defect. Rigid stabilization is accomplished with bone plate and screw fixation that extends from the proximal radial host segment to the distal portion of the 3rd metacarpal bone. To promote rapid healing at the alloimplant-host bone junctions, freshly harvested cancellous autograft is packed into the medullary cavity at the proximal and distal ends of the alloimplant (composite grafting). Cancellous bone is also liberally applied over the proximal and distal interfaces of the alloimplant segment. Further discussion of this technique can be found in the section "Harvesting, Storage, and Application of Cortical Allografts" in a later section of this chapter. Distraction osteogenesis provides an alternative solution for dealing with large bony defects in limb salvage patients and this technique is covered in the last section of this Chapter.

Donor Sites for Cancellous Bone Grafts

In young adult animals, the metaphyseal regions of most major longbones can provide graft material with high osteogenic potential. With progressing age, bone marrow at some of these sites undergoes a slow transformation from hematopoietic marrow to fatty marrow. Cancellous bone obtained from areas where the bone marrow is still hematopoietic provides the highest level of osteogenic function. In this regard, the best sites for obtaining cancellous autografts in mature dogs are the proximal humerus, proximal femur, distal femur, and the wing of the ilium. Cancellous bone taken from these sites has a rich, deep reddish brown appearance. In contrast, cancellous bone taken from the proximal metaphysis of the tibia, a site where marrow becomes fatty, has more of a yellowish or tan appearance (Figure 54-1).

The 3 most commonly used sites for obtaining cancellous bone grafts in dogs are the craniolateral aspect of the proximal metaphysis of the humerus, the dorsal aspect the wing of the ilium, and the caudomedial aspect of the proximal metaphysis of the tibia. In terms of both the quality and the quantity of graft material that can be obtained, the proximal humerus is the best of these three alternatives. The proximal humerus is also an easily accessible site. The quality of cancellous bone from the wing of the ilium is quite good, but the volume of material that can be obtained is significantly less than for the humerus, and it is not as easily accessible. Although the proximal tibia is easily accessible, cancellous autograft from this site tends to provide less volume and lower quality material compared to the other two sites. If additional graft material is needed from the same donor site at a later date, restoration of cancellous bone is more rapid and complete in the proximal humerus compared to the proximal tibia. The recommended waiting time before returning to a site for a second graft harvest is 2 months.

Figure 54-1. Split sections of the humerus and tibia from a 5 year old mixed breed dog. Abundant cancellous bone with a dark reddish-brown appearance is present in the proximal humerus. Much less cancellous bone is seen in the proximal tibia and it has a yellowish-tan appearance due to the absence of hematiopoietic bone marrow.

The femur offers two additional donor sites for obtaining cancellous bone. A greater quantity can be obtained from the condylar region of the distal femur compared to the greater trochanteric region of the proximal femur. Graft quality is good at both locations. Access to these sites requires more dissection than is needed for access to the proximal humerus and proximal tibia. The distal femur offers a convenient location for harvesting cancellous bone graft to be used for a triple pelvic osteotomy procedure.

Obtaining a large amount of cancellous bone graft material is problematic in cats. The proximal metaphyseal region of the humerus is the preferred donor site, similar to dogs. Rib grafts can provide a larger volume of material and these can be harvested and cut into small chips with rongeurs. This cortico-cancellous graft material can be mixed with cancellous bone to fill large bony defects in feline patients.

Surgical Approaches to Donor Sites

Proximal Humerus

A 2 to 3 cm long skin incision is made over the craniolateral aspect of the greater tubercle, just cranial to the palpable acromial head of the deltoideus muscle. Subcutaneous tissue is separated by sharp dissection to reveal the periosteal surface of the bone. Exposure is maintained by insertion of a small Gelpi self-retaining retractor. An access hole is made with a Steinmann pin or drill bit through the thin outer layer of cortical bone in the proximal metaphyseal region of the humerus (Figure 54-2). It is important to maintain a safe distance from the growth plate in skeletally immature animals. It is also important to make the access hole in the metaphysis rather than in the hard cortical bone of the diaphysis. An access hole in this later location increases the risk of a postoperative iatrogenic fracture of the donor bone.

Figure 54-2. Craniolateral access hole in the proximal humerus.

Proximal Femur

A 2 to 3 cm long skin incision is made directly over the lateral aspect of the greater trochanter. The subcutaneous tissues and the superficial gluteal muscle are sharply incised to reveal the surface of the bone. Exposure is maintained with a Gelpi retractor. An access hole is made with a Steinmann pin or drill bit.

Distal Femur

A 2 cm long incision is made over the bone halfway between the fabella and the proximal patella, parallel to the margin of the patella. The incision is made from the skin to the bone on either the medial or the lateral aspect of the femoral condyle. A Gelpi retractor is applied to maintain exposure, which reveals the stifle at the caudal margin of the reflection of the joint capsule. An access hole is made through the cortex of the condyle with a Steinmann pin or drill bit at the location shown in Figure 54-3.

Figure 54-3. Lateral access hole in the distal femur. Medial access to the distal metaphysis of the femur is an acceptable technique as well.

Proximal Tibia

A medial skin incision 2 to 3 cm in length is made starting approximately 2 cm distal to the tibial plateau, midway between the tibial tubercle and the medial collateral ligament. Subcutaneous tissues and underlying muscle (insertions of sartorius and gracilis muscles) are separated with sharp and blunt dissection to reveal the proximal tibial metaphysis. The cross-sectional shape of the proximal tibia is triangular, with the base of the triangle located caudally. In light of this, the access hole in the metaphysis should be made at a caudomedial location as shown in Figure 54-4.

Figure 54-4. Caudomedial access hole in the proximal tibia.

Iliac Crest

A 4 to 8 cm long skin incision is made directly over the dorsal aspect of the iliac crest. Deep fascia is incised along the entire length of the incision. The middle gluteal muscle is sharply incised from its attachment to the dorsal aspect of the iliac crest and then is subperiosteally elevated from the wing of the ilium to reveal the bone. The dorsomedial aspect of the ilium is exposed by sharp incision of the insertion of the sacrospinalis muscle. Exposure is maintained with Gelpi retractors. An access hole can be made in the dorsal surface of the ilium, or an osteotome or saw can be used to remove a cap of bone from the craniodorsal aspect of the iliac crest as shown in Figure 54-5. If

a large quantity of bone graft is needed, this cap can be cut into multiple pieces with a pair of rongeurs to serve as a cancellous bone extender. The corticocancellous bone chips are then mixed with cancellous bone and applied to the recipient site. The iliac crest may be preferable to the previously mentioned longbone metaphyseal donor sites in young animals with open growth plates because there is less risk of clinically significant growth disturbance as a complication of graft procurement.

Figure 54-5. Lateral aspect of the left ilium with an osteotomy of the craniodorsal portion of the iliac wing.

Instrumentation and Graft Harvesting Procedure

Minimal instrumentation is required for harvesting cancellous bone grafts from the humerus, femur or tibia. Placement of a small Gelpi retractor is useful to maintain exposure at the donor site. A Steinmann pin or drill bit is used to penetrate the thin cortex of the metaphysis. The access hole should not be made through the thicker cortical bone of the diaphysis. In young patients with open physes, it is important to locate the access hole a safe distance away from the growth plate. Growth deformities have been reported secondary to graft harvest in these patients. In very small patients with open physes, cancellous bone graft harvest from the wing of the ilium is a safer procedure than graft procurement from a longbone donor site. An osteotome or a bone saw are helpful for removing the craniodorsal portion of the wing of the ilium for improved access to the cancellous bone available for harvest.

A bone curette is inserted through the access hole to remove cancellous bone. The size of the bone curette can be varied according to the size of the patient, but a 5 mm curette works well in most cases. A rotational scooping movement of the curette is effective for harvesting cancellous chips. It is important to avoid penetration of the far cortex during graft procurement. A large amount of cancellous bone can be harvested through a single access hole, although the volume available is frequently underestimated (See Figure 54-6). If a larger opening is needed, the hole should be lengthened along the longitudinal axis of the bone, keeping the corners rounded. Square corners and extension of the access hole perpendicular to the long axis of the bone cause significant mechanical weakening that may predispose inatrogenic fracture of the bone through the graft site.

Graft Application Techniques

Cancellous bone graft material should be protected from dehydration in order to achieve optimal effect. Individual chips

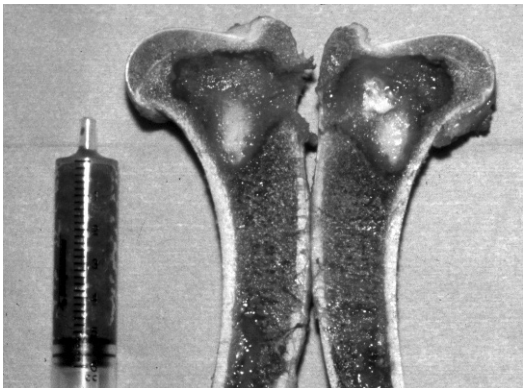

Figure 54-6. Split section of the humerus after collection of a cancellous bone graft from a junior surgery dog. The volume collected is contained within a 6 cc syringe. Note the large amount of cancellous bone that is still available distal to the graft collection site.

can be immersed in patient blood that has been aspirated from the access hole and placed in a small stainless steel cup. Alternatively, graft chips can be placed in a blood soaked sponge until they are applied to the recipient site. Graft chips should never be immersed in saline or disinfectant solutions.

Graft application should be the last thing done prior to soft tissue closure over the repair site. Adequate preparation of the recipient site is very important. The orthopedic repair and all debridement and lavage should be completed prior to graft harvesting and placement. Adequate nutrition to sustain the cancellous graft chips until they are revascularized is most likely to occur when they are applied to viable bone surfaces and immediately covered with viable soft tissues during surgical closure of the wound. When severe soft tissue trauma is present (i.e. shearing wounds), it may be prudent to delay cancellous bone grafting until sufficient wound healing has occurred to provide a supportive environment for the graft.

Graft chips that are about the size of a match head (2 to 3 mm in diameter) provide an ideal surface to volume ratio, thus facilitating nutrition of the graft by diffusion until revascularization takes place. Cancellous bone chips should not be densely packed into a defect as this may impair diffusion. Appropriately applied cancellous autograft chips have been shown to be extensively revascularized by 1 week after implantation.

"Closed" application of cancellous bone graft may be useful when highly comminuted shaft fractures are treated using a non-invasive repair technique such as closed application of an external skeletal fixator. "Closed" cancellous bone grafting involves making a 1 cm long access incision over the middle portion of the fracture region. This will accommodate a modified 3 cc syringe which is used to inject the bone graft material over the area of comminution. The tip of the syringe is cut off, the plunger is pulled back, and chips of cancellous bone graft are loaded into the empty cylinder. The loaded syringe is then inserted through the access incision down to the level of the fracture and graft material is injected. This process can be repeated at different angles to deposit 3 cc aliquots of cancellous bone throughout the area of comminution.

Avoiding Possible Complications of Cancellous Bone Grafting

Complications following cancellous bone grafting in dogs and cats are uncommon. Formation of a seroma or hematoma at the donor site is perhaps the most frequently encountered problem. Both of these events are easily preventable. If persistent hemorrhage is encountered from the access hole, it can be plugged with a piece of absorbable gelatin sponge (Gelfoam). Careful closure of overlying soft tissue layers (especially the deepest layer immediately over the access hole) to obliterate dead space, and proper attention to hemostasis will prevent postoperative seroma formation.

Iatrogenic fracture through the access hole has been reported after cancellous bone graft harvest from the proximal humerus and proximal tibia. Guidelines for avoiding this complication are as follows: 1) Make sure to locate the access hole in the metaphysis rather than in the diaphysis; 2) Make sure to direct the drill bit perpendicular to the cortex rather than obliquely when drilling, so that the access hole will be circular; and 3) If the access hole needs to be enlarged, an increase in its length is less detrimental to bone strength than an increase in width.

Premature closure of open physes and resultant growth deformities have been reported secondary to the harvesting of cancellous bone graft material from longbone metaphyses. In skeletally immature animals (< 13 months old), cancellous bone should be obtained from the wing of the ilium (instead of from the humerus, tibia, or femur) because there is little chance that disturbed growth will result in a major clinical problem at this site.

Infection at the donor site is a potential complication when the surgeon is confronted with an open, contaminated or infected fracture. In this situation, a separate set of sterile, uncontaminated instruments and a new pair of surgical gloves must be used for harvesting the cancellous bone graft. The surgeon must not go back and forth between the donor site and the repair site. The graft material is stored in a cup filled with blood obtained from the access hole or in a blood soaked sponge while the surgeon closes soft tissues over the donor site. The graft is then applied to the fracture region and the repair site is closed.

With proper attention to detail, all of the complications of cancellous bone grafting previously discussed are easily avoidable. In any case in which the use of a cancellous bone graft is anticipated, the surgeon must remember to clip and prepare an appropriate donor site to enable the use of this simple and an extremely valuable technique when needed.

Corticocancellous Bone Graft Harvested from the Wing of the Ilium with an Acetabular Reamer

Colin W. Sereda and Daniel D. Lewis

Introduction

A large volume of corticocancellous bone graft may be readily obtained from the wing of the ilium using a powered acetabular reamer. Although graft incorporation is slower and less uniform when compared to similar volumes of cancellous bone graft, the corticocancellous bone grafting technique is advantageous because it yields a greater volume of graft, offers a more proximate location of the harvest site when performing procedures involving the hind limb, and produces graft with a consistency that is favorable for packing into bone defects, resulting in an intimate association with the recipient bed.

Surgical Procedure

The patient is placed in lateral recumbency. An area extending approximately 5 cm cranial to the wing of the ilium to 3 cm caudal to the greater trochanter, and from dorsal to the wing of the contralateral ilium to 5 cm ventral to the ilial body is clipped, aseptically prepared and draped for surgery.

The skin incision begins craniodorsal to the iliac spine and is continued caudally, paramidline to the level of the middle of the body of the ilium. Subcutaneous tissues and the deep gluteal fascia are incised along the same line as the skin incision, exposing the tuber sacrale. The origin of the middle gluteal muscle on the dorsal ilium is incised, allowing subperiosteal elevation of the middle gluteal muscle. Elevation is continued caudally to the level of the caudal dorsal iliac spine, but should not be continued beyond this point in order to preserve the cranial gluteal vein, artery, and nerve. Elevating the middle gluteal muscle off of the cranial aspect of the wing of the ilium improves exposure. Exposure is maintained by placing one or two Hohmann retractors from dorsal

to ventral to expose the wing of the ilium. Gelpi retractors can also be placed to facilitate esposure.

An acetabular reamer (20 or 23 mm for small dogs, 26 or 29 mm for medium-sized dogs, and 29 or 32 mm for large dogs) attached to a low speed, high torque drill is used for harvesting the graft. Reaming is initiated on the lateral ilium immediately caudal to the iliac crest. It is continued caudally, removing the lateral cortex and cancellous bone while leaving the medial cortex and dorsal edge of the ilium intact. Reaming is carried as far caudally as is feasible, creating an oval-shaped defect (Figure 54-7). When the cup of the reamer is full, it is detached from the extension and the graft is removed to be stored in a sterile receptacle until required. Switching to a smaller diameter reamer generally allows the surgeon to extend reaming down the body of the ilium. Care must be taken to avoid penetrating the medial cortex of the ilium with the reamer. When the reaming is completed, additional exposed cancellous bone along the periphery of the defect can be harvested with a bone curette.

The donor site is thoroughly lavaged with sterile saline. A splash block of local anesthetic may be administered prior to closure to decrease postoperative discomfort. Closure is performed in multiple layers to decrease the risk of postoperative seroma formation. The superficial fascia of the middle gluteal muscle is apposed to its periosteal insertion or to the superficial fasia of the sacrospinalis muscle with a series of horizontal mattress sutures. The gluteal fascia, subcutaneous tissues, and skin are closed routinely.

The harvested graft has a paste-like consistency, which facilitates packing the graft into bone defects and results in intimate contact with the recipient bed.

Postoperative Considerations

The cortiocancellous graft appears more radiodense than a cancellous graft on immediate postoperative radiographs because of the graft's cortical component. Morbidity associated with ilial corticocancellous graft harvest is minimal; however, transient, self-limiting hind limb lameness and seroma formation may occur. Restricted postoperative activity is therefore recommended.

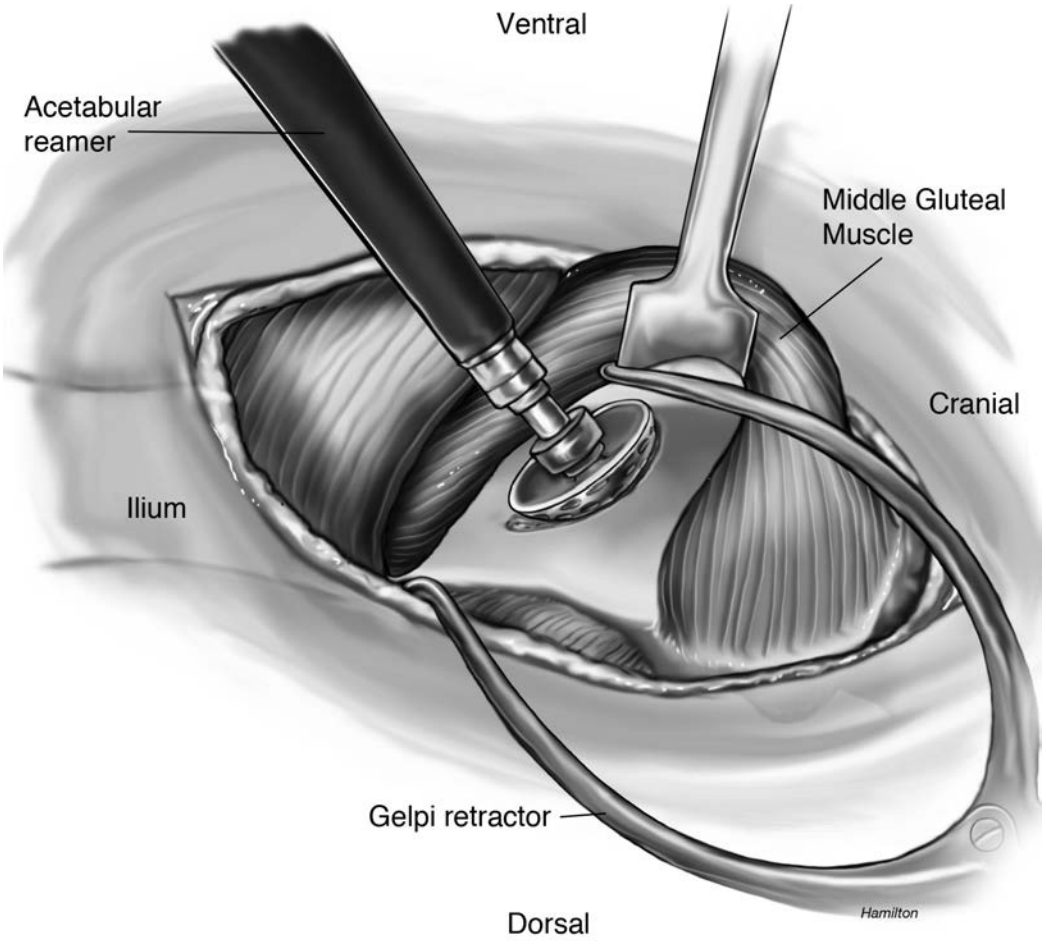

Figure 54-7. Self-retaining retractors are used to increase exposure of the lateral aspect of the wing of the ilium. Reaming begins immediately caudal to the iliac crest and is continued caudally as far as is reasonably possible. The lateral cortical and inner cancellous bone is removed.

Harvesting, Storage and Application of Cortical Allografts

Kenneth R. Sinibaldi

Introduction

Cortical allografts have been used to enhance repair of long bone fractures in veterinary surgery for several decades.[1-4] An allograft is bone transferred from one individual to another individual of the same species. This type of graft elicits an immune response because of foreign cellular antigens of the allograft and the reaction of the host immune system. Fresh-frozen processed cortical allografts are the most commonly used cortical grafts in veterinary orthopedic surgery. Allografts are also considered alloimplants because they are a nonviable material (dead bone), and by definition, the term implant refers to any nonviable material placed in the body.

An autogenous allograft (autograft) is bone transferred from a donor site to a recipient site in the same individual. There are definite disadvantages to this type of graft. Sufficient bone is often not available, morbidity at the donor site is a concern, increased anesthetic and surgery time, and increased risk of infection. Fresh frozen allograft is preferred for convenience of storage, and reduction of disease and immunogenicity.[5-9]

Frozen allografts provide structural (mechanical), osteoconductive, and osteoinductive support to fracture repair.[10] Other methods of processing bone allografts include cryopreservation, freeze-drying (lypholized) and demineralized preparation. The processing of bone grafts by these methods is more involved technically and are not practical for the veterinary surgeon in practice. Inconvience of allograft harvesting, processing, storage, and quality assurance have limited their use.[11]

Harvesting of Allografts

Harvesting of allografts is practical for the veterinary surgeon and requires adherence to strict asepsis, preparation and time. The procurement of cortical allografts begins with proper donor selection. Donors should be mature, healthy animals, preferably between the 1.5 to 8 years of age, with no preexisting neoplastic, metabolic, bacterial, or viral diseases. A complete physical examination and review of history are essential. Current vaccinations and blood screening for transmissible diseases should be performed. Immature donors have bones that may be brittle and less developed than older donors, and this factor may cause problems during implantation with stability (screw purchase).

Allografts can be harvested from dead donors and then sterilized with ethylene oxide. Although ethylene oxide is considered a superior sterilizing agent for surface contamination, but low residual levels may be toxic to recipient tissue and could interfere with healing. It may also affect the mechanical strength and incorporation of cortical allografts.[12,13] Freshly harvested cortical allografts are preferred.

Absolute aseptic surgical technique is required. All donors should be prepared as for any standard surgical orthopedic procedure, with proper aseptic scrubbing and draping. Donors are placed under general anesthesia, and standard approaches to the long bones are used. The bone should be exposed from metaphysis to metaphysis by removing as much soft tissues (muscle and periosteum) as possible. An oscillating bone saw is used to cut the bone. This saw should be cooled with liquid during cutting. After the bone is removed, it is placed in a solution of lactated Ringer's or saline. This is temporary before final preparation of the graft. Once all the donor graft has been harvested, euthanasia is performed on the donor.

The grafts are then stripped of all remaining soft tissue attachments, and the medullary contents are removed. A sharp periosteal elevator or scalpel blade works best for stripping, whereas a bone curette works best for removal of medullary contents. The medullary cavity should be flushed out with sterile lactated Ringer's or saline solution. Once the graft is clean, it can be cut into proximal, middle, and distal thirds, halved or maintained in its full length. The graft's medullary cavity is cultured for aerobic and anaerobic organisms. The graft is placed in a suitable glass jar that has been previously autoclaved. Each jar with the graft should be marked, indicating left or right, with the name of the bone, segment of bone, date of harvesting, and donor identification. The jar and graft are then immediately placed in a household freezer at a temperature of -20° C. Any temperature warmer than this leads to improper freezing and possible autolysis. The American Association of Tissue Banks allows 6 months storage at -20° C and recommends -40° C for longer-term storage (up to 5 years); -70° C is preferred.[11] The colder temperatures inhibit molecular translations that result in degradation. The author has not had any problems safely storing bone grafts at -20° C for 1 year. Only grafts that culture negative are placed in the bone bank.

The most common indication for use of cortical allografts is replacement of bone in patients with highly comminuted fractures. Other indications are correction of nonunions, delayed unions, and mal-unions with or without bone loss, bone lengthening, limb-sparing procedures for bone tumors, and, in selected cases, osteomyelitis with bone loss due to sequestrum formation.[14] This last indication should be considered a salvage procedure if amputation is not an option. In preparation for surgical implantation of an allograft, radiographs of the opposite limb should be made, and bone length measured. An estimate of the graft length needed is made by comparing the intact cortical segments on the lateral projection of the affected limb and subtracting this from the total length of the normal bone. (Figure 54-8). A graft is then selected based on this estimate as well as by visually comparing the width of the host and graft bone. Usually, the femur is used to replace a segment of femur, however the use of other long bones should not be discouraged because the width of other bones may be adequate if a near perfect match cannot be made with similar bones.

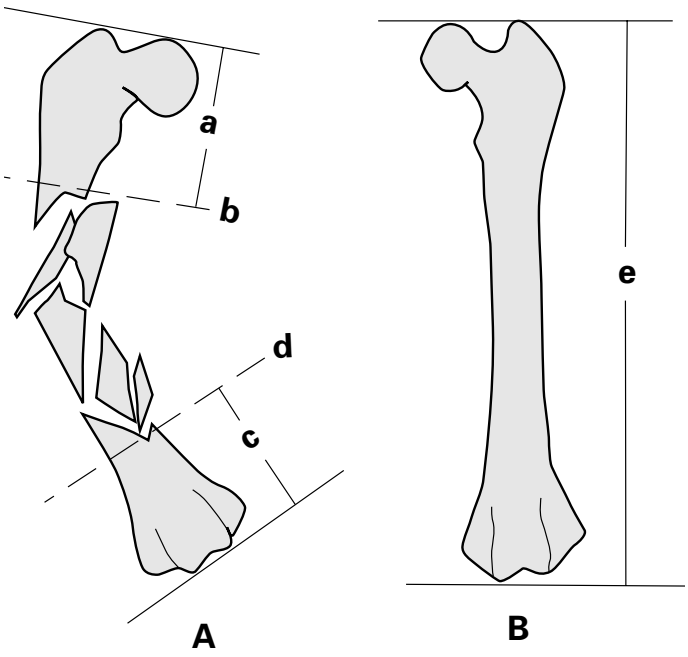

Figure 54-8. Estimate of allograft length is made by measuring the proximal bone segment *(a)* with the planned osteotomy cut *(b)* and the distal bone segment *(c)* with the planned osteotomy cut *(d)* and subtracting the total of these from the length of the normal opposite femur *(e)*. Fractured femur **A.** Opposite normal femur **B.**

Surgical Application

Prior to surgery a proper allograft is selected based on previous radiographic planning, visual observation and comparison of available allografts. It is prudent to select an allograft that is slightly longer then is required should adjustment be needed during surgery. Most importantly, the diameter of the allograft bone should be as close as possible to the host bone. Prophylactic antibiotics are administered at the time of anesthesia, during the operation and postoperatively. An appropriate cancellous bone graft site is prepared. The addition of cancellous bone at the host-graft site increases the success of the procedure.[7] Before the surgical procedure, the cortical allograft is allowed to thaw in a sterile bowl of lactated Ringer's solution or normal saline solution. The patient is aseptically prepped, draped and strict surgical technique followed. If a large number of bone segments are to be removed, the surgeon must have a point of reference proximally and distally to maintain proper alignment with respect to rotation, varus and valgus. This is best done with small Kirshner wires placed parallel to each other, one in the proximal fracture segment and one in the distal segment. The fracture is exposed, and the comminuted fragments are removed. The fractured bone ends, proximally and distally are cut with a bone saw perpendicular to the long axis of the bone in preparation for the cortical allograft. The allograft is cut to the proper size; the surgeon must ensure that it is perpendicular to the long axis of the graft. This cut should allow 360° of cortical contact ideally, and not less than 50% contact at the host-graft interface. In some cases of delayed union, malunion, and nonunion, the callous formation may be larger than the allograft or cut surface. This is not of concern and can serve as a ridge for autogenous cancellous bone to be placed on to augment grafting. A dynamic compression plate is selected to allow for a minimum of five cortices (three screws) above and below the allograft. Standard ASIF plating technique is used. The plate is contoured to both the host bone and allograft. An alternate technique is to contour the plate preoperatively from the radiograph of the normal intact bone and make adjustments at the time of surgery. The plate is first applied to the allograft with a minimum of two screws (four cortices) in a neutral position. The allograft is aligned to the host bone to ensure as close to 360° of cortical contact as possible. This is not always possible, but the closer to 360° the better the stability. Care should be taken to test the reduction at both ends of the allograft before completing screw fixation of the plate. Alignment should be observed and rotation, varus and valgus corrected. The preplaced Kirschner wires and temporary cerclage wires or bone clamps aid in proper positioning. If any correction is needed the plate can be removed and the allograft cut for correction. If the correction causes the total bone length to be shorter, a new allograft should be used. Depending on the bone, most patients can tolerate shortening of 2 to 3 cm in the limb without an impact on function. The screw holes above and below the allograft are placed in the loaded position. This maneuver results in compression at the host-graft interfaces. The remaining screws are placed in a neutral position. The entire surgical site is flushed with lactated Ringer's solution before placing an autogenous cancellous bone graft around the host-graft interfaces. Commercially prepared cancellous bone chips or cancellous bone chips and demineralized powder can also be used (Veterinary Transplant Services, Seattle, WA). The surgical site is cultured for aerobic and anaerobic organisms before routine closure.

Postoperative Care

Postoperative care consists of an appropriate coaptation with a modified Robert Jones dressing or padded bandage, depending on the long bone repaired, for 2 to 3 weeks. Activity should be restricted to leash only walks and cage or kennel confinement during this time period. Antibiotics are administered for 2 weeks postoperatively and are adjusted or discontinued based on the culture results. Radiographs are taken at 3 to 4 week intervals, to follow healing and implant stability for the first 3 months followed by radiographic exam every 6 to 12 months thereafter. Plate removal should only be considered in young patients or in those patients with allografts less than 3cm and only after 2 years post surgery. Plate removal is "staged" with 3 to 6 months between surgeries.

Bone Healing

Cortical allografts heal by proceeding through phases of inflammation, revascularization, osteoinduction, osteoconduction and remodeling. This process takes much longer due to the dense structure of cortical bone.[15] Cortical allograft incorporation differs from autogenous cancellous bone in that initial repair is due to osteoclastic rather than osteoblastic activity.[16] Resorption occurs rapidly shortly after transplantation and gradually declines to normal levels within a year.[16] Resorption of the graft and replacement by host bone begin at the host-graft interface and move toward the center of the graft, with marked proliferation of periosteal and endosteal bone covering

the graft surfaces.[7] This process can take years depending on the length of the graft. Biopsy specimens taken at various levels of long allografts at 45.5 months[7] and 92 months[14] after implantation showed graft bone still present. As this process continues, mechanical strength is added to the graft. Predominately at the center portion of the allograft with live bone present in the external and internal circumferential lamella.14 The presence of dead bone matrix from the graft interspersed with interstitial lamellar and host osteons affords strength to the bone.[16]

Cortical allografts provide osteoconductive, osteoinductive and mechanical support in the repair of long bone fractures. Success has been reported to be over 80%.[7] Outcome is dependent on case selection, degree of trauma, soft tissue damage, coexisting injuries and adherence to strict surgical asepsis and technique. Decreased surgical time, stability of the fracture repair, and rapid return to function are definite benefits. Harvesting of bone, aseptic technique, and bone plating principles may be a limitation, depending on training and surgical experience. The added cost of proper surgical equipment and time spent setting up the bone bank are also possible limitations. As a general rule, infected or open fractures and metaphyseal fractures that do not allow proper screw purchase are not indications for cortical allografts.

Distraction Osteogenesis as an Alternative to Bone Grafting

Nicole Ehrhart

Introduction

Distraction osteogenesis is a technique capable of generating large amounts of bone by gradual distraction of osteotomized bone ends. This method is now widely accepted for the treatment of shortened limbs, bony defects from tumor or trauma and angular limb deformity.[18] The technique is most commonly performed using circular external fixator systems and tensioned fine wires, a method introduced and refined by Ilizarov.[18]

Historical Perspectives

Gavril A. Ilizarov was a physician with no formal orthopedic training who practiced in a small industrial town in Western Siberia after World War II. Antibiotics were scarce and chronic osteomyelitis and non-unions were common post-war injuries among the population of patients he cared for. As a result, he found himself practicing orthopedics in his general practice in an isolated area of the world without access to any of the technological and medical advances that took place during the post-World War II era. He devised an innovative external fixator system comprised of modular rings and trans-osseous wires attached to the rings under tension to stabilize bone fragments. The phenomenon of distraction osteogenesis was discovered incidentally, when Ilizarov applied a fixator designed to create gradual compression of the fracture ends to a patient with an infected non-union. He instructed the patient to adjust specialized nuts on the frame several times daily in order to achieve compression at the fracture site. Instead, the patient mistakenly turned the nuts in the wrong direction, thereby lengthening the frame and creating distraction at the fracture site (Figure 54-9). Ilizarov observed significant new bone formation in the distraction gap and simultaneous resolution of the infection. He applied this technique successfully to some of the most challenging conditions in orthopedic surgery.[16,17] The reconstruction of bones affected by post-traumatic conditions, such as intercalary defects, shortening and deformity was the most common application of his method. In 1984, an Italian

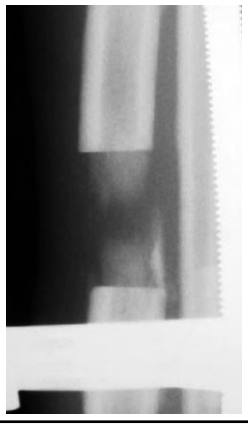

Figure 54-9. Distraction osteogenesis. Note the regenerate bone formation between the two osteotomized bone surfaces.

veterinarian by the name of Dr. Antionio Ferretti, began using the Ilizarov methods in veterinary patients. The use of circular fixation and distraction osteogenesis began to appear in North American veterinary literature in the early 1990s.[24] Currently, IMEX Veterinary (Longview, TX) manufactures a circular external fixator system that has lightweight design elements suitable for veterinary patients (Figure 54-10). Other circular external fixation systems are also available in North America and Europe.

Bone transport osteogenesis is a modification of the original distraction osteogenesis technique, involving the transport of a bone fragment across a bony defect with distraction osteogenesis occurring in the trailing pathway of movement (Figure 54-11). The bone fragment eventually contacts the opposite end of the defect, and is compressed to the adjacent bone in its new position, resulting in union between the bone fragment and the parent bone. The new bone that forms in the distraction pathway rapidly remodels into lamellar bone, thereby filling in the segmental defect. This method was used by Ilizarov to salvage many limbs that otherwise would have been amputated because of non-union, osteomyelitis or extensive segmental bone loss.[18] Bone transport osteogenesis is also used in veterinary patients for limb salvage following segmental bone loss due to trauma or tumor excision.[11,12]

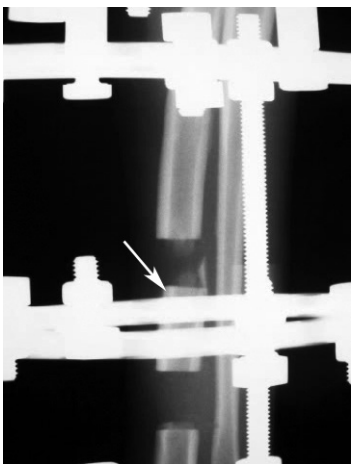

Figure 54-11. Bone transport osteogenesis 14 days following the start of distraction. Note the wisps of new bone forming between the transported bone segment *(arrow)* and the parent bone.

Histomorphology of Distraction Osteogenesis

Distraction osteogenesis requires prolonged and gradual distraction of two freshly osteotomized bone ends (See Figure 54-9). The new bone by distraction osteogenesis or bone transport osteogenesis is termed **regenerate bone**. The process of new bone formation is often called **osteoneogenesis**. The biology of distraction osteogenesis has been extensively studied.[1,4,6-8,10,21] The results of these investigations have greatly expanded the understanding of the histological, biochemical, vascular, radiographic, and mechanical properties of regenerate bone formation. Ilizarov mistakenly assumed that distraction osteogenesis recapitulated endochondral bone formation. This belief was generated by the radiographic observation that a radiolucent zone consistently occurred in the center of the regenerate bone **(radiolucent central zone)** until distraction was completed, similar to a growth plate which remains radiolucent until growth is completed. More recent studies have shown that bone formation during distraction osteogenesis results from both intramembranous and endochondral ossification, with intramembranous bone formation predominating at a ratio of 5:1.[14] The radiolucent central zone is comprised of Type I collagen columns adjacent to a zone of newly formed vessels. This vasculature delivers proliferating and differentiating osteoblasts which migrate along the collagen columns and deposit osteoid. These collagen columns are formed in parallel and along the lines of distraction tension. Each of these osteoid-covered, longitudinal columns of collagen begins to mineralize starting from either end of the gap and progressing toward the central radiolucent zone. The mineralizing new bone columns resemble stalagmites and stalactites projecting from each osteotomy surface on radiographs. Each bone column expands transversely as more collagen fibers are incorporated circumferentially and mineralized until they reach a maximum diameter of 150 to 200 microns. The space between the bone columns consists of large, thin-walled vessels.[2,3,9,10,14] Once distraction is completed, the bone columns begin to bridge the peripheral aspect of the radiolucent central zone. Columns of mineralizing new bone then rapidly bridge the entire central radiolucent zone and are eventually interconnected transversely by woven bone plates forming a honeycomb-like pattern. Once bridging occurs, rapid secondary remodeling of the cortices ensues and the Haversian system is re-established. This remodeling process occurs much more rapidly than with classical fracture healing; partly because the collagen fibers are more orderly and aligned at the start of mineralization and therefore tend to remodel in a manner parallel with the long axis of the bone. In addition, the mechanical strain environment created in the distraction gap seems to promote robust angiogenesis, massive osteoblast recruitment and rapid production of osteoid.[13,14]

Technique

Clinical Factors Influencing Distraction Osteogenesis

The environment created during distraction osteogenesis is not identical to the environment seen during fracture healing. The optimal mechanical environment in which bone formation occurs clinically has not been fully determined. Several unique factors are known to influence regenerate bone formation. These include: frame type, osteotomy technique, delay interval between surgery and distraction **(latency period)**, the total distance moved per day **(distraction rate)**, and the number of increments used to achieve the total distance moved per day (rhythm).

Frame Type

Although Ilizarov attributed special biological effects to the use of ring fixators, distraction osteogenesis can also be achieved using linear fixators or hybrid frames. The two major advantages of using circular external fixation systems are 1) the axial micromotion that occurs under compressive loads with fine wire fixation and 2) the versatility of fixator components and spatial configurations possible with circular frames that allow precise movement of bone fragments while not compromising overall frame stability. Fine wire fixation exhibits nonlinear biomechanical behavior. Specifically, controlled micromotion of the bone segments occurs during weight-bearing yet stiffness in bending and torsion similar is maintained in a manner similar or superior to conventional linear fixators. Controlled axial micromotion is thought to be beneficial to bone formation.[5,21,22]

Ring diameter, wire tension, bone position within the frame and number of rings and wires per bone segment affect overall frame stability. Clinicians should be familiar with the biomechanical characteristics of circular fixator frames and the principles of Ilizarov to achieve ideal stability when designing and positioning the frame for a particular patient.[19,20,23]

Osteotomy Technique

Ilizarov considered the preservation of the meduallary vascular system and periosteum to be essential for bone distraction osteogenesis. His original technique involved carefully cutting the cortex with an osteotome while preserving the periosteal sleeve, a procedure he termed ***corticotomy***.[18,23] Since that time however, results of animal studies have shown that the quality and quantity of bone formed during distraction osteogenesis following an osteotomy created with an oscillating saw, osteotome or corticotomy is similar.[15] No advantage has been seen with the corticotomy technique over the more standard osteotomy techniques. An important point to remember, however, is to avoid thermal damage to the bone. If an oscillating saw is used to create the osteotomy prior to distraction or bone transport osteogenesis, copious lavage with cool saline is required.

Latency Period

Latency refers to the amount of time between creation of the osteotomy and commencement of distraction. This period of time is important for the formation of a soft callous. Several factors influence the choice of latency period including the degree of trauma to the soft tissue envelope, age of the patient, location of the osteotomy (metaphyseal versus diaphyseal), and patient-related co-morbidity issues. In dogs, suggested latency periods range from 2 to 7 days.[23] In a healthy patient, the author typically uses a 3 day latency period unless there are significant co-morbidity factors. Co-morbidity factors include advanced patient age, soft tissue trauma or loss, or other conditions that would delay healing such as concurrent use of chemotherapy or diabetes, etc. When these conditions are present, the latency period may be lengthened. Too long a latency period will result in premature healing requiring re-fracture.

Distraction Rate

A rate of 1mm of distraction per day is the most common distraction rate used in veterinary medicine for linear distraction. Choice of distraction rate depends upon many of the same factors that influence latency period. Distraction can be performed more rapidly in young animals, sometimes up to 4 mm per day. In dogs, mineralized bone is usually visible within the distraction gap on radiographs by day 14 to 21 of distraction. It is important to monitor the appearance of the regenerate bone on radiographs during distraction because the distraction rate may need to be adjusted during distraction. Radiographic evaluation of the regenerate bone is recommended every 7 to 10 days. If the regenerate bone begins to take on a thinning, ductile shape resembling an hourglass or the radiolucent central zone begins to progressively widen, the distraction rate may need to be decreased. Alternatively, if the wires nearest the distraction gap begin to bend toward the distraction gap and the central radiolucent zone begins to disappear, the distraction rate may need to be increased to avoid premature consolidation.[11]

Distraction Rhythm

The rhythm of distraction refers to the number of incremental lengthenings performed per 24 hour period to achieve the desired rate of distraction. The recommended rhythm for dogs ranges from 2 to 4. This means that the total amount of distraction achieved during any given 24 hour time period should be divided into 2 to 4 increments. The author recommends a distraction rhythm of 4.[11] This is easy for clients to do because the nuts used to perform distraction on the IMEX veterinary circular fixator system have four faces. The owner can be instructed to turn the nuts one face four times daily. The pitch of the all-thread rods used in the same fixator system is 1 mm. Therefore, one complete revolution of the distraction nuts will move the distraction wires 1 mm. Studies performed in goats have shown that increasing the number of increments up to 270 per day using an automated distractor system did not seem to have an advantage.[21] In the author's experience, diminishing the distraction rhythm to less than 3 or 4 tends to be associated with more soft tissue complications such as inflammation and tendon contracture. It is likely that the ideal distraction rhythm varies from patient to patient and is probably influenced by similar factors as rate and latency.

Consolidation Period

Once distraction is discontinued, the consolidation period begins. Consolidation involves rapid mineralization of the radiolucent central zone and remodeling of the regenerate bone. The new cortices become organized and marrow elements begin to reform. Consolidation will be delayed if the patient is not weight-bearing. There are likely many other factors that influence consolidation such as biomechanical properties of the fixator, anatomic location etc., but these factors are less well understood. Clinicians must use radiographic evaluation to decide when to remove the fixator. If mineralization and cross-sectional area of the regenerate are similar to the parent bone, it is typically safe to remove the fixator. Certain frame designs allow for progressive destabilization which may allow for a more rapid gain in stiffness. There is no exact formula for deciding when the fixator should be removed, but the more bone created by distraction osteogenesis, the longer consolidation will take to complete. A very rough rule of thumb is that the fixator should remain in place for 50% to 100% of the time needed to achieve the desired amount of new bone.

Regenerate Bone as a Bone Graft Alternative

The use of regenerate bone as a bone grafting alternative is less familiar to many surgeons and initially more technically complex. Distraction osteogenesis may not be the first option of choice in patients where standard autogeneous or allogeneic graft material is suitable. However, there are unique advantages to regenerate bone as a means to fill a defect or create a bony union, particularly in situations where infection is established or likely. Because regenerate is autogenous and its formation is associated with an immediate, robust blood supply, it can be used in situations when cortical allograft would be contraindicated. In human trauma, distraction osteogenesis is most commonly used for severe soft tissue and bone loss following extremity shear injuries, such as those sustained in motorcycle accidents. Because this method of reconstruction does not require internal fixation, such as with cortical allografts, surgeons can begin bony repair prior to establishment of a healthy soft tissue envelope. Other unique uses include chronic osteomyelitic non-unions. In these patients, distraction osteogenesis is used to achieve union, but also as a means to resolve the infection and replace resorbed bone. Ilizarov was the first to note the remarkable ability of distraction osteogenesis to treat osteomylelitis without the aid of antibiotics in his patients. His phrase for this observation was that distraction osteogenesis "burned the infection in the flame of the regenerate", referring to the effect of angiogenesis and subsequent arrival of immune cells that successfully eradicated infection.

Theoretically, distraction osteogenesis can create limitless quantities of bone. This is in contrast to large-segment cadaveric bone allografts, where supply is often limited and procurement and storage is expensive; and to cortical autograft, where donor site morbidity limits the anatomic location and amount of bone available. In addition, the use of autogeneous tissue eliminates the risk of disease transmission from donor to recipient, a significant concern in human medicine.

Future Directions

To date, the major limitations to the use of distraction osteogenesis as an alternative to bone grafting in veterinary medicine have been the relatively lengthy period of time required to reconstruct large defects and the small number of veterinary surgeons comfortable with the technique. Circular and hybrid fixators have recently become more "main stream" as veterinarians become familiar with their versatility. Research is ongoing to understand more about the biology of osteogenesis, thereby allowing clinicians to manipulate the distraction osteogenesis process using novel growth factors and gene therapies to create bone more rapidly. Double level distraction osteogenesis has been described in veterinary patients to diminish the time needed to reconstruct large diaphyseal defects. Newer hybrid fixator designs and components allow distraction in more than one anatomic plane at a time and, as clinical experience accumulates, surgeons will become more comfortable with case selection and management. Clinical applications for distraction osteogenesis are likely to expand, but will probably be used as a solution in the more challenging orthopedic situations, rather than in cases where simple grafting is routinely successful.

Section M

Appendicular Skeleton – Thoracic Limb

Chapter 55

Scapula and Shoulder Joint

Repair of Scapular Fractures

Randy Willer and Jennifer Fick

The scapula is a large, flat bone of the shoulder which serves as support for the thoracic limb and is attached to the trunk by several large muscle masses. The scapula is located adjacent to the chest wall with extensive muscle mass surrounding it, a configuration that helps to prevent the occurrence of fractures. In one study, the incidence of scapular fractures was reported to be 2.4% of fracture cases treated, with most resulting from vehicular trauma.[1] A retrospective study in 105 cases revealed most scapular fractures occur in young (<4 years of age), male, medium-large (>10kg) dogs.[2] Because of the increased forces necessary to create such a fracture in this location, a thorough physical, neurologic, and orthopedic exam is necessary to detect other possible concurrent problems such as spinal, skull, brachial plexus injuries, and other musculoskeletal injuries which may influence prognosis. In patients with scapular fractures, approximately two-thirds have concurrent thoracic cavity lesions which include pneumothorax, pneumomediastinum, pulmonary contusions, cardiac arrhythmias, and fractured ribs.[1] Prognosis and treatment options depend on the anatomic location of the fracture which are classified as the body, spine, acromion, neck, supraglenoid tubercle and glenoid of the scapula.[1,3]

Diagnosis and Clinical History

Clinical signs on presentation of a scapular fracture vary depending on the location and the severity of the fracture. Signs range from a mild weight bearing lameness to a severely dysfunctional non-weight bearing lameness of the limb. The latter is usually associated with intra-articular fractures of the glenoid and neck fractures that cause the animal to carry the injured leg lower than the opposite limb, with the carpus held in a flexed position or the paw dragging.[4] Localized pain, swelling, and crepitus on palpation may be present. Comparing findings of palpation of the opposite normal limb with those of the injured limb is valuable when attempting to localize the source of the problem. A thorough history, physical exam, and radiographs are necessary to make a diagnosis.

Radiographs are necessary to confirm the anatomic location and extent of the fracture. Heavy sedation or general anesthesia may be required to position the scapula accurately while also maintaining comfort for the animal. Four views may be necessary to maximize visualization of the entire scapula. Caudocranial views are taken with the animal positioned in dorsal recumbency and the affected limb drawn forward but with the sagittal plane of the thorax rotated 30° away from the affected limb to prevent superimposition of bony densities[5] (Figure 55-1). The mediolateral view is taken with the animal in lateral recumbency, the affected limb against the film and extended approximately 45° craniad with the opposite limb pulled caudad. The positioning prevents superimposition of the ribs and sternum.[5] The scapular neck, glenoid, and supraglenoid tubercle are best visualized radiographically with this position but to view the body of the scapula with the mediolateral view, the affected limb should be superimposed over the cranial thorax with the opposite limb pulled craniad instead of caudad.[5-7] The distoproximal (axial) radiographic view may be helpful in visualizing and diagnosing scapular fractures when other views do not. The dog is placed in dorsal recumbency with the elbows extended and the limb pulled caudad and parallel to the table surface. The humerus is at a 90o angle to the scapular spine and the scapula is perpendicular to the table top. The thickness of the tissues is measured at the level of the greater tubercle of the humerus and the beam is centered over the shoulder joint.[8]

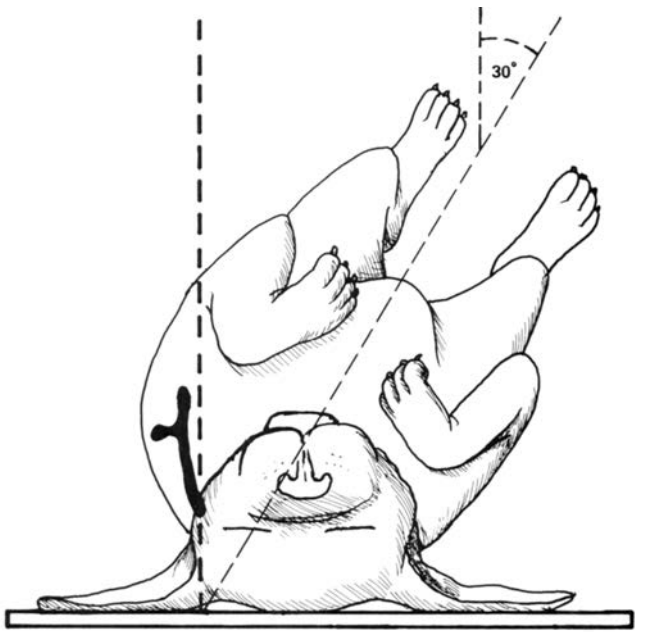

Figure 55-1. A caudocranial radiograph of the scapula is taken with the sagittal plane rotated 30° away from the affected side.

Treatment Options

Recommended treatment options have not changed significantly over the past 25 years. The healing potential of the scapula is excellent because of the abundance of cancellous bone, the intrinsic support from the musculature, and the abundant contribution of blood supply from the musculature and surrounding soft tissues.[9] Fractures of the scapula can be managed either conservatively or with internal fixation. The method chosen depends on the anatomic location and type of fracture. In general, fractures

of the scapula can be managed conservatively except when they involve the articular surface (glenoid), when the fracture results in a distinct change in the angulation of the shoulder joint articulation (displaced scapular neck and body fractures), and when the injury is an avulsion fracture of the acromion and supraglenoid tubercle. Conservatively managed fractures require only limited activity for 3-4 weeks, whereas others may benefit from a modified Velpeau sling or spica splint.[3] Support bandages add to the comfort of the animal during the healing period.

Surgical Techniques

Approaches to the scapula, which vary and depend on the anatomic location of the fracture, have been well described and illustrated.[10] Approaches to the scapular neck, glenoid, and supraglenoid tubercle are more difficult and require more advanced surgical skills than approaches to the scapular body. These approaches may include an osteotomy or a muscle separation technique.[11] Anatomically, the suprascapular nerve, artery and vein course across the lateral aspect of the scapular neck distal to the acromial process and should be avoided and protected. Damage to the nerve can lead to atrophy of the supraspinatus and infraspinatus muscles.

Scapular Body and Spine Fractures

Fractures that involve the body and spine of the scapula are most often managed conservatively. Limited activity should be advised until a clinical union of the fracture is determined. Because of the abundance of cancellous bone and the inherent support of the fracture by the surrounding musculature along with the presence of an abundant blood supply, healing progresses rapidly, and many animals are clinically normal within 4 weeks, although others may require a longer period of healing.[1] Limitation in activity should be dictated by clinical progression of the animal. The fracture may not be completely healed when clinical function first appears normal; therefore, activity is limited for an additional few weeks. If a modified Velpeau sling is used for immobilization or to provide comfort for the animal, the bandage should be monitored closely and removed in 2-3 weeks to allow for return to normal shoulder joint function and to prevent unwanted contracture of soft tissues and limitations in joint motion.[4] Fractures that are severely displaced or comminuted or those that change the angle of the normal joint articulation should be repaired with internal fixation. Internal fixation improves the cosmetic result, especially in short-haired dogs, and provides the support necessary for early return to ambulation better function.

Internal fixation of scapular body and spine fractures consists primarily of the use of wires, plates, or a combination of both (Figure 55-2). When placing interfragmentary wires, predrilling the holes and preplacing wires (18, 20, 22 gauge wire) simplifies the procedure. The fractures are then reduced and the wires are tightened. If the spine of the scapula is fractured, tension band wiring may be used. The scapula lacks an abundance of harder cortical bone and care should be taken when tightening the wires so they do not cut through the bone. Minimal fixation can be combined with a Velpeau sling. Interfragmentary wires may be adequate for small dogs and cats, whereas a plate may be required in larger dogs or when angulation displacement is not controlled by wire alone. For plate fixation, the surgeon should place a plate in the angle formed between the junction of the body and the spine and place the screws at an angle for maximum screw purchase in the thickest portion of the bone (Figure 55-2B): Plate placement in the ventral half of the scapula should be along the cranial aspect of the scapular spine/body junction, with screws placed at a 45° angle to the spine. Conversely, a caudal approach should be considered when plating the dorsal half of the scapula.[12] Inverting a semitubular plate and placing it in this location may enhance the fit of the plate to the bone. Cerclage wires placed around the plate may be used in conjunction with the screws for added fixation support of the plate if the screws do not purchase the bone well. Plastic plates may also be placed on both sides of the spine and secured with nuts and screws to provide the support and fixation necessary for preventing angulation and overriding displacement of the fractures (Figure

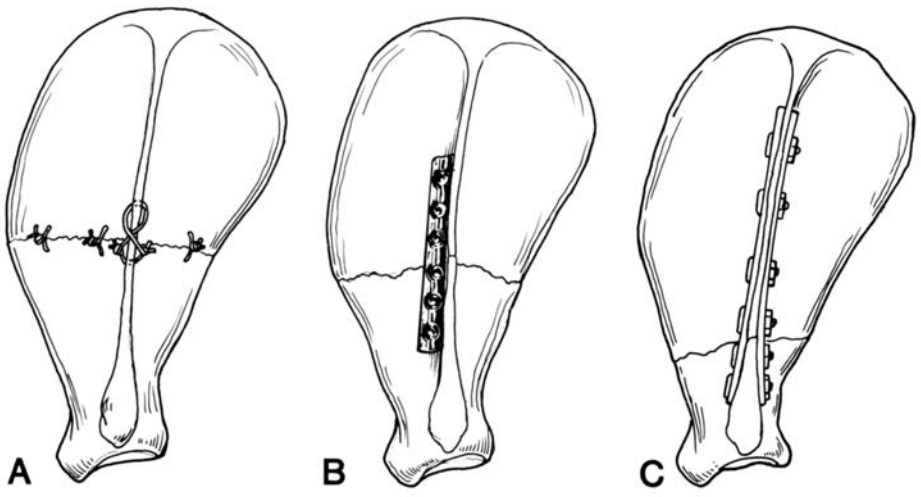

Figure 55-2. Repair of scapular body fractures. **A.** Interfragmentary wires with a tension band in the scapular spine. **B.** Inverted semitubular steel plate with screws directed at an angle into the thickest bone at the junction of the scapular spine and body. **C.** Plastic plate secured to the spine of the scapula with screws and nuts.

55-2C). In a mechanical study, when comparing single versus double semitubular plate fixation, single plate fixation of scapular body fractures may be sufficient. Any difference between single and double plating is likely not clinically relevant.[13] Locking plate technology has the potential to increase stability of the repair in light of the poor bone quality of the scapula.[5] However, in a scapular fracture model, locking SOP plates were not shown to have a different load to failure than an LC-DCP.[14] Locking plates have not yet been evaluated for scapular fractures in a clinical setting, or in a cyclic load model at the time of this manuscript preparation. Perfect fracture alignment and anatomic reconstruction may not be consistently achieved, but the goal of preventing overriding and angulation of the fracture segments with internal fixation methods is adequate to allow for good functional and cosmetic results.

Acromial Fractures

The bony prominence of the distal end of the spine of the scapula, the acromion, is the site at which the acromial head of the deltoid muscle arises and runs distally. The acromion is easily palpable under the skin and can be compared to the opposite limb for asymmetry and identification of a fracture. Fracture of the acromion results in distal displacement created from the pull of the acromial head of the deltoid muscle. The diagnosis can be made with palpation and radiographic findings. The animal typically has a weightbearing lameness and pain is elicited upon palpation. With constant pull from the acromial head of the deltoid, all forms of closed reduction and fixation are inadequate and internal fixation is required.[4] Typically, one of two methods is used to stabilize the fragment. Either two small pins and a tension band wire can be applied, or two twisted stainless steel interfragmentary wires are placed, depending on the size of the animal and the fragment (Figure 55-3). If the fixation is secure, no additional support is required, limited activity is advised for 6 to 8 weeks, and the prognosis for a complete recovery is good.

Scapular Neck Fractures

Animals with scapular neck fractures often present with severe lameness and dysfunction of the limb. If the fracture is not displaced, a spica splint may be applied for immobilization to prevent further displacement. The placement of a Velpeau sling may create stress on the fracture site by creating internal rotation and flexion of the shoulder.[4] The distal segment often displaces medially and proximally, and closed reduction is difficult. The risk of suprascapular nerve damage is present and the client should be warned of the possibility. As a result, the supraspinatus and infraspinatus muscles may atrophy, leaving a cosmetically altered appearance and impaired function. Internal fixation is recommended to achieve the best result. The suprascapular nerve should be retracted and protected during repair. Many combinations of methods can be used to repair fractures

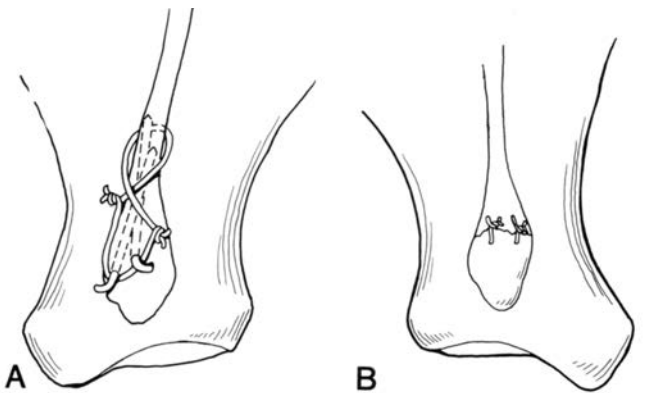

Figure 55-3. Acromial features repaired with Kirschner wires and a tension band **A.** or with wire sutures **B.**

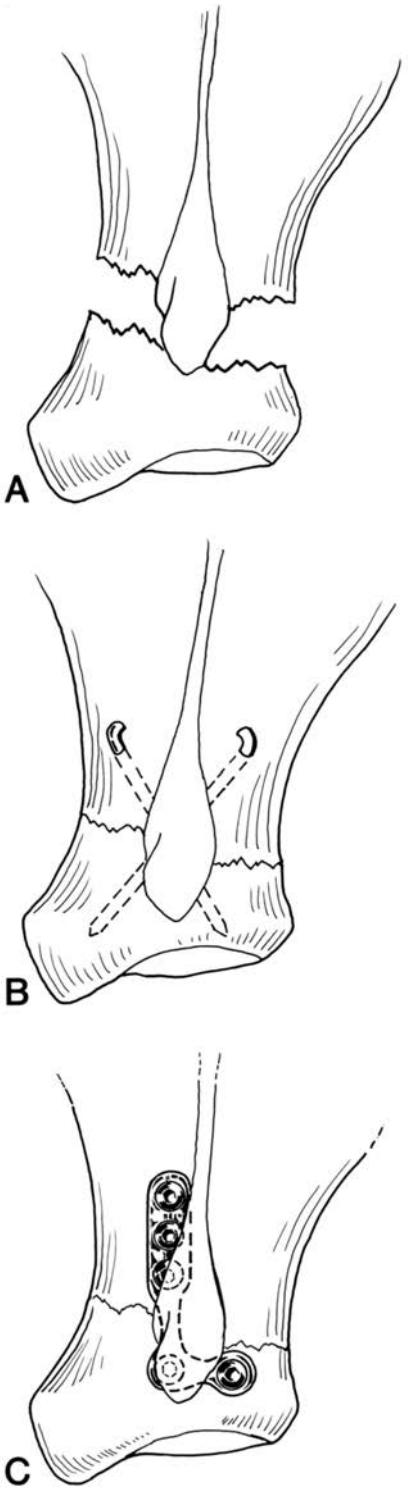

Figure 55-4. Scapular neck fracture **A.** repaired by cross-pinning with Kirschner wires introduced from the body into the neck **B.** or with an L-shaped bone plate in large dogs **C.**

of the neck. Cross-pinning the fracture with Steinman pins or Kirschner wires inserted from the body into the neck is often adequate stabilization for these fast healing fractures (Figure 55-4A and B). The cross pins alternatively can be placed from the supraglenoid tubercle across the neck fracture into the body and the other pin can be inserted from the caudal aspect of the glenoid across the fracture in a similar fashion. In larger breeds, the use of a screw placed in lag fashion or T or L plates can be used to provide more rigid fixation (Figure 55-4C). The technique depends on the size of the animal, nature of the fracture, and the level of exposure created by the surgeon who should be willing to expose as much as necessary to achieve adequate anatomic reduction and stable fixation. Because these methods of fixation are stable, further support is usually not necessary, and with adequate limitation of activity for 6 to 8 weeks, return to normal function is expected.

Glenoid Fractures

Fractures of the glenoid are intra-articular (Figure 55-5A). The animal will present with severe lameness and a dysfunctional limb. Palpation reveals an unstable shoulder with crepitus demonstrated when the joint is manipulated. Radiographs are necessary to assess the extent of the fracture. The fracture may involve the cranial half of the glenoid which is most common,[15] or the caudal half of the glenoid; alternatively, both portions may be fractured involving a neck fracture as well (T or Y fracture). (An ununited accessory caudal glenoid ossification center should not be confused with a glenoid fracture, although it may result in variable lameness.[16]) The degree of comminution may vary. This fracture requires great external forces, and the possibility of other injuries should be explored. Most patients have concurrent injury to another body region.[15] Brachial plexus injuries and thoracic trauma should be considered. Unless the fracture is so severely comminuted that it cannot be repaired, internal fixation is required. Closed methods of repair are not adequate and should only be considered if the goal is to allow the fractures to heal and later perform an arthrodesis or excision of the humeral head and glenoid as a salvage procedure. A spica splint should be placed with the leg in a more natural functional angle if this option is pursued. Partial scapulectomy is another salvage option, as it has been well described for tumor removal, and there is a single case report of its successful use in treatment of a glenoid fracture.[17] The goal of surgical repair is to expose the surgical site adequately and perfectly reconstruct the alignment of the articular surface of the glenoid to minimize secondary osteoarthritis as a result of incongruence of the articular surface. A combination of pins and screws are used to repair the glenoid first, and if the scapular neck is also fractured, it is repaired with one of the techniques described previously. Depending on the type and location of the fracture segments, various methods of cross pinning, lag screws, and plating may all be used to achieve a congruent and stable fracture repair (Figure 55-5). The prognosis for regaining function of the limb is good but an extended convalescent period can be expected, and most patients will have some degree of continued lameness following fracture repair.[15]

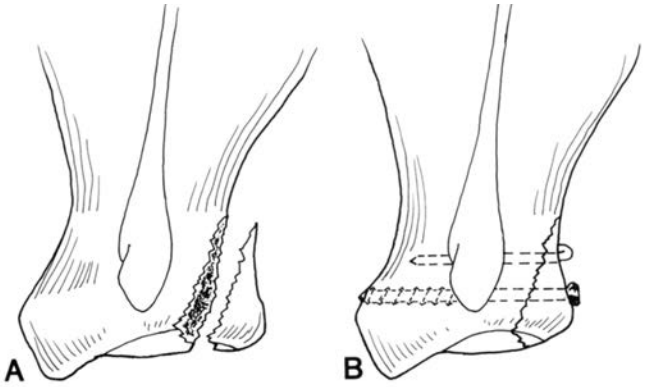

Figure 55-5. Glenoid fracture **A.** compressed with an interfragmentary lag screw and derotational Kirschner wire **B.** Anatomic alignment of the joint surface is important.

Supraglenoid Tubercle Fractures

The supraglenoid tubercle is the point of origin of the tendon of the biceps brachii muscle on the cranial portion of the glenoid. The supraglenoid tubercle develops as a separate center of ossification and through endochondral ossification, should fuse to the glenoid by 5 months of age.[18] In the skeletally immature dog, before endochondral ossification is complete, an avulsion fracture may develop through the growth plate and the pull of the biceps brachii muscle distracts the fragment. This type of fracture can occur in the mature animal as well. Utilizing principles of a pin and tension band technique or lag screw fixation can be used successfully to repair the fracture (Figure 55-6). The surgical exposure to accomplish this repair can be challenging. If the fragment is too small, removal may be necessary and the biceps tendon is secured to the proximal humerus creating a tenodesis or it may be released without securing the biceps tendon and allow it to retract without stabilization.

Conclusions

All animals identified as having scapular fractures should be examined carefully for concurrent body injuries, specifically cardiopulmonary, neurologic, and other musculoskeletal injuries. Scapular fractures tend to heal rapidly. In general, fractures of the body and spine of the scapula do not require repair if the displacement is minimal and the angulation of the shoulder articulation is not impaired, whereas intra-articular fractures must be properly aligned and stabilized to achieve good long term functional results. Velpeau slings or spica splints can be used to immobilize the fracture and provide comfort for the animal during the early healing period. Fractures of the glenoid, supraglenoid tubercle, acromion, and most neck fractures require internal fixation for best results. Inadequate anatomic reconstruction and instability can result in malalignment of the fractures, nonunion, secondary degenerative joint disease, unsatisfactory cosmetic appearance, and poor limb function. The suprascapular nerve should be retracted and protected during repair of scapular fractures to prevent iatrogenic injury resulting in muscle atrophy and impaired function. The surgeon should be familiar with the anatomy, different surgical approaches, and be willing to achieve the exposure necessary to reconstruct the fractures in a stable and anatomic fashion. Pins, wires, screws and plates provide adequate means for stabilizing scapular fractures.

Surgical Treatment of Shoulder Luxation

Kent Talcott

Introduction

Scapulohumeral luxation is an uncommon problem in the dog and rarely occurs in the cat. Luxation is typically the result of traumatic injury or congenital glenoid abnormality. Lateral luxation most commonly occurs in large breed dogs with historical trauma. Medial luxation typically occurs in small dogs with congenital capsular laxity or glenoid dysplasia. Cranial and caudal luxations are documented but occur less frequently than lateral or medial luxation.

Anatomical Considerations and Surgical Approach

It is important to establish a thorough knowledge of anatomy and understanding of anatomical function prior to performing surgical correction for scapulohumeral luxation. Errors in surgical technique are not well tolerated and may contribute to persistent lameness or disability. The following is a brief review of anatomy and surgical approach. A more detailed review of this information is highly recommended for individuals with limited experience in shoulder surgery.

Scapulohumeral stability is the combination of articular stability and soft tissue restraints. The primary soft tissue restraints include the joint capsule and its associated glenohumeral ligaments, and "rotator cuff" tendons. Glenohumeral ligaments are described as thickened regions of the joint capsule and are not grossly apparent from external evaluation (Figure 55-7). However, they are distinct structures when viewed arthroscopically. The medial glenohumeral ligament is "Y" shaped with a cranial and caudal component while the lateral glenohumeral ligament is a wide solitary band that tapers near its insertion. Luxation is not possible without disruption of the joint capsule and its associated glenohumeral ligament. The four "cuff tendons" provide dynamic support with minimal contribution during static conditions. The "cuff tendons" include the supraspinatus cranially, subscapular medially, infraspinatus laterally, and teres minor caudolaterally. Collectively, soft tissue structures are important restraints to joint motion and contribute to joint stability. Identifying injury to such structures is important when selecting methods of stabilization.

A craniomedial approach is most often used for surgical treatment of medial and lateral luxation while a craniolateral approach is performed for cranial luxation. The following craniomedial approach provides general access to the shoulder. Once the shoulder is approached, further dissection varies dependent upon technique and is further described within the relevant section of this chapter. With the patient in dorsal recumbency, a parahumeral incision originating from the medial or cranial aspect of the scapular neck is extended distally to the medial aspect of the humeral mid-diaphysis. Subcutaneous fat is incised exposing the brachiocephalicus muscle. A fascial incision is created the entire length of the lateral border of the brachiocephalicus muscle which requires ligation and division of the omobrachial vein. The brachiocephalicus is elevated and retracted caudomedially while the humerus is externally rotated. The insertion of the superficial pectoral is incised from the humerus along its proximal border to the omobrachial vein.

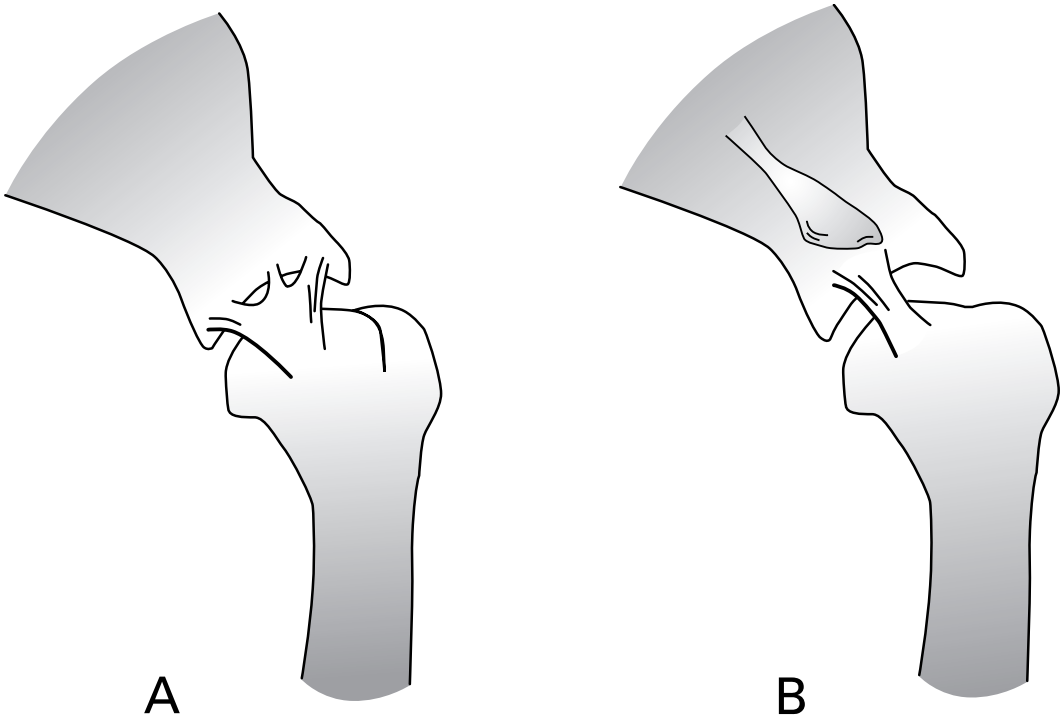

Figure 55-7. Medial view illustrating both bands of the medial glenohumeral ligament **A.** The lateral glenohumeral ligament is a solitary band of connective tissue within the joint capsule **B.** (From Talcott KW, Vasseur PB: Luxation of the Scapulohumeral joint. In Slatter D (ed): Textbook of Small Animal Surgery, 3rd ed. Saunders, Philadelphia, 2003, p 1898.).

Similarly, the deep pectoral muscle is freed from its insertion but requires separation from the overlapping supraspinatus muscle proximally. Both pectoral muscles are retracted medially and the supraspinatus caudolaterally.

Lateral Scapulohumeral Luxation

Lateral luxation commonly presents in large breed dogs with historical trauma. The mechanism is not well defined but is presumably caused by extreme adduction of the limb. Lateral humeral luxation requires tearing of the lateral aspect of the joint capsule, its associated glenohumeral ligament, and infraspinatus tendon.

Diagnosis

Patients present with the forelimb held in flexion and concurrent internal rotation of the foot. The greater tubercle is prominent and displaced laterally. Joint manipulation is painful with overt crepitus. A neurologic examination is indicated to identify

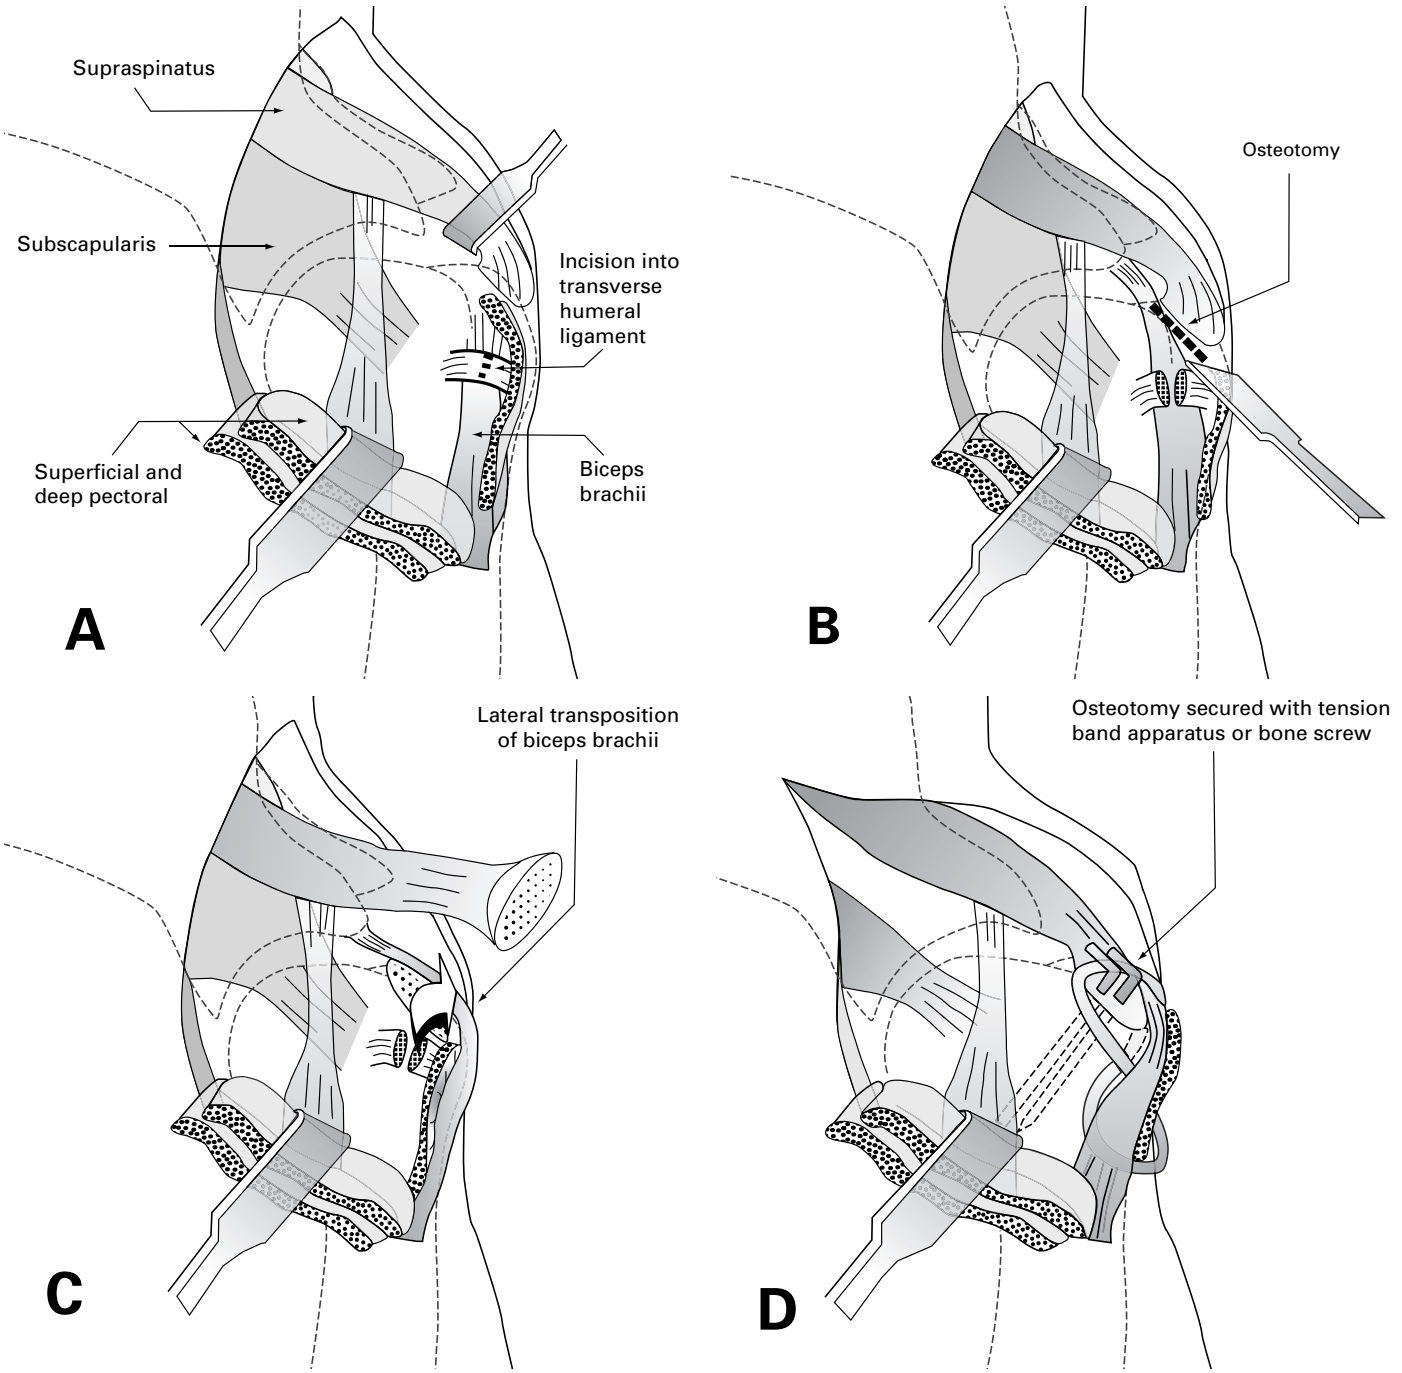

Figure 55-8. Craniomedial approach to the shoulder. The pectoral muscles are retracted ventrally and the supraspinatus proximally. The transverse humeral ligament is incised to free the biceps tendon **A.** Osteotomy is required to free the supraspinatus muscle **B.** The biceps brachii tendon is transferred laterally over the cut surface of the greater tubercle **C.** The greater tubercle is stabilized with a pin and tension band apparatus, maintaining the biceps brachii in a lateral position **D.** (From Talcott KW, Vasseur PB: Luxation of the Scapulohumeral joint. In Slatter D (ed): Textbook of Small Animal Surgery, 3rd ed. Saunders, Philadelphia, 2003, p 1899).

concurrent brachial plexus injury. Survey radiographs are performed to confirm the diagnosis and identify concurrent fractures or glenoid rim erosion. Stress radiography may be useful to identify dynamic luxation or subluxation.

Treatment

Closed reduction and splintage is considered in patients with acute injury and mild to moderate joint instability. Under general anesthesia the limb is extended and medial pressure is applied to the humeral head while counter pressure is applied to the scapular neck. Range of motion and joint stability are assessed after reduction and either a spica splint or non-weight bearing carpal sling is maintained for 10 to 14 days. A Velpeau sling is contraindicated for lateral luxation as it applies lateral translation to the humeral head. Results of nonsurgical treatment for lateral luxation are variable and are contingent upon the magnitude of soft tissue disruption, success of splintage, and patient/owner compliance regarding activity restriction. Surgical stabilization should be considered when reluxation is easily elicited.

Surgical intervention is performed for patients with acute unstable injury, concurrent fracture, or chronic luxation. Numerous procedures are described including prosthetic ligament reconstruction, biceps tendon transposition, transarticular pinning, glenoid excisional arthroplasty, and arthrodesis. The method of repair is based upon etiology of luxation, concurrent fracture, or the ability to restore glenoid integrity if a fracture is present. The advantages and disadvantages of each technique should be considered in relationship to patient signalment, health status, and patient compliance.

Lateral transposition of the biceps tendon is the most documented technique in the literature and is the preferred method of repair when patient variables are appropriate (Figure 55-8). A craniomedial approach is used for biceps transposition. Once the pectoral muscles are retracted medially and the supraspinatus caudolaterally, the transverse humeral ligament is incised and the biceps tendon is freed from regional fascial and capsular tissue. The greater tubercle is osteotomized to allow lateral transfer of the biceps tendon over the cut surface of the greater tubercle. The tubercle is reattached with a screw or pin and tension band apparatus. The joint capsule is closed with absorbable suture and the pectoral muscles are apposed to deltoid fascia. Remaining fascia, subcutaneous fat and skin are routinely closed. Seroma formation is common in this area and may be avoided with careful implant technique, tissue apposition, and postoperative recovery. Strict activity restriction and confinement are required for 2 to 3 weeks. Passive range of motion may be performed in the initial recovery period. Short controlled leash walks begin 2 weeks postoperatively followed by a gradual return to full function over an additional 6 to 12 weeks.

Prognosis and Complications

Normal return to function and full range of motion has been reported with long-term evaluation of this technique. Mild distortion of joint congruity is common at the time of repair but resolves as weightbearing forces cause stretching and relaxation of the tendon. Progression of osteoarthrosis is expected and the biceps tendon is at risk for midsubstance tearing in the future. In spite of such adverse effects, the technique is still recommended as excellent clinical function is the most commonly reported outcome. This technique is less successful in patients with chronic luxation or glenoid dysplasia; in which case arthrodesis or glenoid excisional arthroplasty should be considered.

Medial Scapulohumeral Luxation

Medial luxation is more common than lateral and is reported in small and large breed dogs. Medial luxation in large breed dogs is typically associated with trauma while congenital luxation is more common in small breed dogs. Congenital luxation may be bilateral and is associated with developmental laxity or glenoid dysplasia which is difficult and potentially impossible to correct.

Diagnosis

The historical presentation and physical examination findings vary depending upon the etiology for luxation. Traumatically induced medial luxation presents with an acute persistent lameness with the affected limb held in flexion with external rotation of the foot. Joint manipulation is typically painful during extension and medial displacement of the greater tubercle.

In contrast, congenital luxation may present with intermittent to continuous lameness and joint manipulation is often well tolerated. Mild to moderately dysplastic luxations are often easily reduced and reluxated. More severely dysplastic luxations are commonly non-weightbearing, pain is variable, and joint reduction is difficult.

Radiographic evaluation of traumatically induced medial luxation is scrutinized for concurrent glenoid fracture. Congenital luxation is carefully evaluated for hypoplastic glenoid development and erosion of the medial glenoid rim. Stress radiography should be considered to document luxation in patients with intermittent lameness.

Treatment

Conservative management for medial luxation is contraindicated when glenoid dysplasia is present. However, conservative management is considered for traumatically induced medial luxation when reasonable joint stability is achieved following closed reduction. Closed reduction is performed under general anesthesia with the patient in lateral recumbency and the limb in a neutral standing position. Traction and slight adduction are initiated while lateral pressure is applied to the proximal medial humerus and counter pressure is applied to the scapular neck. A Velpeau sling is ideal stabilization for medial luxation as it eliminates weightbearing and compresses the humeral head laterally. The Velpeau sling is maintained for 2 weeks followed by careful gradual return to function over 4 to 8 weeks.

Surgical techniques reported for medial luxation include prosthetic collateral suture, supraspinatus transposition, transarticular pinning, medial biceps transposition, arthrodesis, excisional arthroplasty, and amputation. Choosing a method of repair is based upon glenoid conformation, concurrent injury, patient size and chronicity of luxation.

In patients with acute traumatic luxation without glenoid dysplasia; medial transposition of the biceps tendon is the preferred technique (Figure 55-9). A craniomedial approach is performed and once the pectoral muscles are reflected, the leg is externally rotated to access the subscapularis muscle. The insertion of the subscapularis is incised allowing caudal retraction of the subscapularis and coracobrachialis while the biceps tendon is freed by incising the transverse humeral ligament and regional capsular attachments. At the lesser tubercle, a craniodorsal hinged flap of bone is created with a crescent-shaped osteotomy. Cancellous bone is removed beneath the flap to accommodate transposition of the biceps tendon. Once the luxation is reduced, the biceps tendon is transferred and secured into the preformed groove by reattaching the bone flap with Kirschner wires. Medial capsular imbrication is performed with absorbable suture and the subscapularis is advanced and attached to the insertion of the deep pectoral muscle. The pectoral muscles are secured to the deltoid and deep brachial fascia. The brachiocephalic muscle is sutured to brachial fascia. The remaining fascial, subcutaneous and skin layers are closed separately. The repair is supported with a Velpeau sling for 7 to 10 days followed by gradual return to function over 4 weeks.

An alternative to biceps transposition is prosthetic collateral repair. It is less time consuming, less invasive, and simpler to perform. The technique is not appropriate for large dogs but should be considered for acute traumatic luxation in small dogs without glenoid dysplasia. The technique is performed using a standard craniolateral approach with tenotomy of the infraspinatus tendon. A curved incision starts at the distal third of the scapular spine extending distally across the joint craniolaterally to the mid-diaphysis of the humerus. Subcutaneous fat and fascia are dissected and the deep brachial fascia is incised from the cranial aspect of the acromion process extending distally along the cranial border of the acromial part of the deltoid muscle. The deltoid is retracted caudally allowing transaction of the infraspinatus tendon which is reflected dorsally. The joint capsule is incised transversely and intra-articular structures are inspected. The joint capsule is closed and a hole is drilled from lateral to medial through the center of the humeral neck. A similar hole is drilled in the center of the scapular neck paying careful attention to protect the suprascapular nerve. Suture is passed from lateral to medial through the scapular bone tunnel and medial to lateral in the humeral tunnel (Figure 55-10). External rotation of the limb and retraction of the brachiocephalic and pectoral muscles medially is required to expose the medial aspects of the humerus and scapular neck for suture advancement. The joint is reduced, suture is tied in moderate tension, and joint mobility and stability are assessed. This technique reported using double strands of 0 or number 1 monofilament polybutester for its elastic properties. The infraspinatus tendon is reattached and routine closure is performed. The repair is supported with a Velpeau sling for 14 to 21 days followed by 4 weeks of passive range of motion and gradual rehabilitation.

If the biceps tendon is damaged or if previous repair is unsuccessful, partial supraspinatus transposition may be considered (Figure 55-11). The approach is identical to the biceps transposition technique, however, the biceps tendon and transverse humeral ligament are repaired and medial capsular imbrication

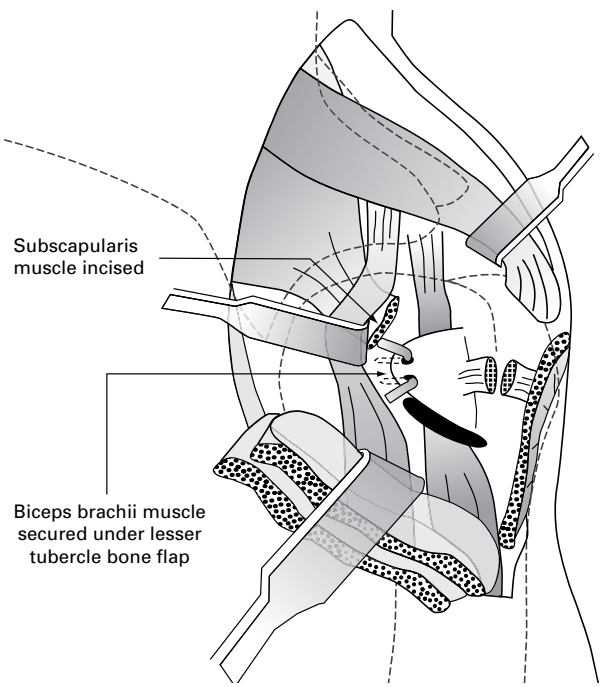

Figure 55-9. The biceps brachii muscle is released and is secured into a tunnel, covered by a bone flap that is secured with Kirschner pins. (From Talcott KW, Vasseur PB: Luxation of the Scapulohumeral joint. In Slatter D (ed): Textbook of Small Animal Surgery, 3rd ed. Saunders, Philadelphia, 2003, p 1900).

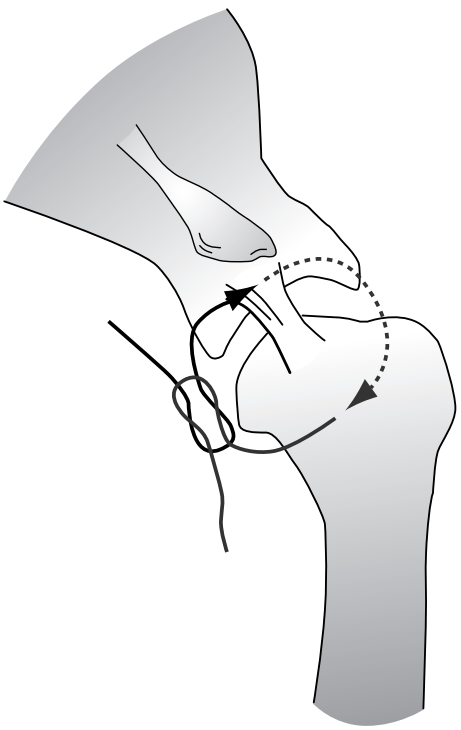

Figure 55-10. Heavy nonabsorbale suture is passed from lateral to medial in the scapular neck and from medial to lateral through the neck of the humerus. Careful dissection and placement of bone tunnels are required to avoid injury to the suprascapular nerve located distal to the acromion process. (From Talcott KW, Vasseur PB: Luxation of the Scapulohumeral joint. In Slatter D (ed): Textbook of Small Animal Surgery, 3rd ed. Saunders, Philadelphia, 2003, p 1901).

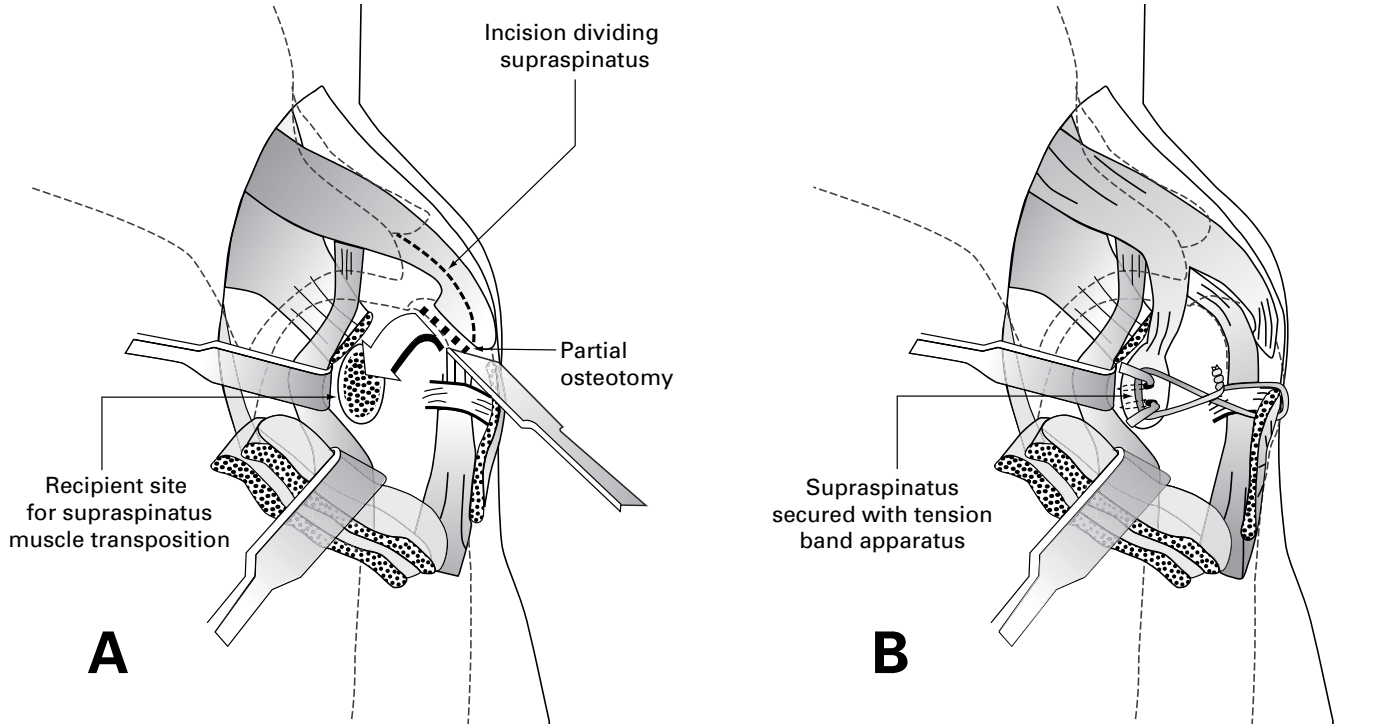

Figure 55-11. A portion of the supraspinatus muscle is mobilized by performing a partial osteotomy of the greater tubercle. A recipient site is created medially by removing cortical bone to facilitate bone union **A.** The bone fragment is secured to the recipient site with pins and tension band **B.** (From Talcott KW, Vasseur PB: Luxation of the Scapulohumeral joint. In Slatter D (ed): Textbook of Small Animal Surgery, 3rd ed. Saunders, Philadelphia, 2003, p 1901).

is performed. The greater tubercle is osteotomized such that the superficial one-half of the supraspinatus tendon is released. The insertion of the subscapularis muscle is incised and a recipient site of exposed cancellous bone is created at the lesser tubercle with a burr, rasp, or osteotome. The supraspinatus is divided only to the extent that the oseotomized tubercle may reach the recipient site with moderate tension. Recurrence of luxation is contingent upon proper tension in the transferred component of the supraspinatus tendon. The transferred tubercle is stabilized with multiple Kirschner pins or pin and tension band. The subscapularis is advanced to the pectoral insertion and pectoral muscles are attached as far cranial as possible to augment medial support of the shoulder. Remaining layers are closed separately. A Velpeau sling is maintained for 7 to 10 days followed by gradual return to function.

Arthrodesis is indicated for patients following failed attempts at surgical repair or in patients with significant glenoid dysplasia or degenerative joint disease. Standard principles of arthrodesis apply to the shoulder. In small dogs, a single screw through the scapular neck and into the humerus combined with a spica splint may be adequate for stabilization. Large dogs typically require bone plate application along the scapular spine and proximal humerus. More detailed information is covered in the arthrodesis section of this chapter.

Excisional glenoid arthroplasty has been described as an alternative to arthrodesis. Excisional arthroplasty may achieve pain-free movement with limited compromise of limb length and joint motion. More detailed information is covered in the excisional glenoid arthroplasty section of this chapter.

Amputation is reserved as a salvage procedure for patients with multiple failed surgical correction, severe glenoid dysplasia, or severe degenerative joint disease. Amputation may not be appropriate for giant breed dogs. Candidates for amputation should be carefully assessed for congenital or traumatic contralateral limb abnormalities.

Prognosis and Complications

Prognosis after medial biceps transposition is variable. The majority of dogs are expected to achieve satisfactory limb function; however, intermittent to persistent lameness occurs is approximately 50% of cases. Similar to lateral biceps tendon transfer, transient joint incongruity, osteoarthrosis, and midsubstance biceps tendon tearing have been reported for medial transfer of the biceps tendon. In general, experience with this technique is favorable.

Full return of limb function was reported in dogs 2 to 3 months following collateral prosthetic ligament reconstruction with polybutester suture. This is the authors preferred technique provided case selection is limited to small dogs without preexisting joint abnormalities. There are no reports of this technique in cats, however; intuitively, this technique may provide similar favorable results.

Prognosis of partial supraspinatus tendon transfer is limited to a single case report describing normal function and full range of motion 2 months following surgery. Adverse effects of joint incongruity and tendon tearing are less apt to occur but further study has not been performed.

Reports of shoulder arthrodesis are generally favorable due to mobility of the scapula. Best results are seen in small dogs, whereas, large dogs have a varied outcome and more apparent gait abnormality.

Excisional glenoid arthroplasty was reported to achieve good to excellent results in one study. This technique is limited to patients with severe glenoid dysplasia or degenerative joint disease. Clients should be informed that mild reduction in joint mobility, muscle atrophy, and limb shortening are expected.

Cranial and Caudal Luxation

Cranial and caudal scapulohumeral luxation are rare. Reports in the veterinary literature are limited to a few case reports. Etiology of cranial and caudal luxation appears to be associated with trauma. The only described technique for cranial luxation is transfer of the biceps tendon cranially into a groove within the greater tubercle (Figure 55-12). A craniolateral approach is performed and the greater tubercle is osteotomized. A groove is made into the cut surface of the osteotomy. The transverse humeral ligament is incised and the biceps tendon is mobilized into the preformed groove. The capsular tissue is imbricated and the greater tubercle is reattached with pins and tension band apparatus. Standard closure is performed and a spica splint is maintained for 10 days.

Caudal luxation has been treated with caudal and lateral imbrication in combination with a non-weightbearing sling for 10 days.

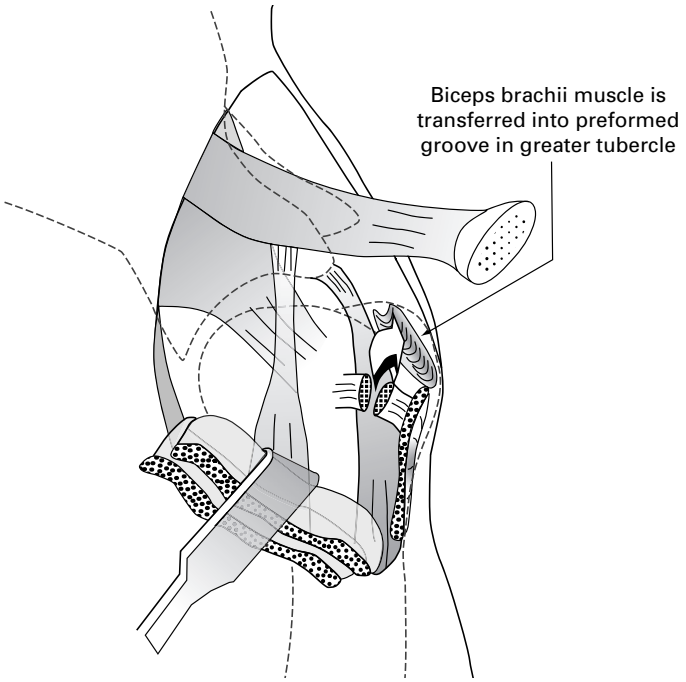

Figure 55-12. The biceps brachii tendon is transferred into a bone tunnel created at the osteotomy site of the supraspinatus muscle insertion. The biceps is secured in the groove by attaching the greater tubercle to its insertion site with a tension band apparatus. (From Talcott KW, Vasseur PB: Luxation of the Scapulohumeral joint. In Slatter D (ed): Textbook of Small Animal Surgery, 3rd ed. Saunders, Philadelphia, 2003, p 1902).

Prognosis is difficult to predict as no long-term studies have evaluated cranial or caudal luxation repair. Limb function is presumed to be satisfactory but further study is needed.

Caudal Approach to the Shoulder Joint for Treatment of Osteochondritis Dissecans

Dean R. Gahring

Introduction

Treatment of osteochondritis dissecans (OCD) of the shoulder joint involves removal of all loose and damaged fragments of cartilage and bone from all aspects of the joint. OCD lesions in the shoulder almost always occur on the caudal aspect of the humeral head. Loose fragments of cartilage can migrate into the caudal cul-de-sac of the joint and/or into the cranial bicipital tendon sheath. There is no effective surgical approach to both areas, so dealing with each area requires two separate approaches. Consequently, I usually recommend doing an arthrogram prior to surgery to determine whether or not the bicipital tendon sheath needs to be explored. Arthroscopy can also be used.

Surgical management of OCD of the caudal humeral head involves removal of all loose cartilage with a sharp curette so that no cartilage remains elevated and unattached to underlying bone. The removal and curettage of damaged bone and cartilage will decrease pain and inflammation resulting from irritation and impingement of the joint capsule and other joint elements. Exposed subchondral bone is curetted to bleeding surfaces so that the resultant defect can be resurfaced with new fibrocartilage. If any cartilage is left unattached to subchondral bone, it may fragment and produce loose bodies in the joint. Loose cartilage is unlikely to re-attach to the underlying bone.

This caudal approach to the shoulder joint allows excellent visualization of, and access to, the caudal humeral head and both the medial and lateral aspects of the caudal joint cul-de-sac. It is primarily a muscle-separating approach. No tendons are incised, so recovery is rapid with minimal post-operative complications.

Surgical Technique

The patient is placed in lateral recumbency with the affected leg in an upward position and hung so it can be completely draped and be free for extensive manipulation during surgery. The location of the skin incision is identified by connecting the midpoint of the scapular spine with the midpoint of the humerus (Figure 55-13). The skin, subcutaneous tissue, and superficial fascia are retracted to expose a whitish linear fascial raphe between the spinous (or scapular) head of the deltoid muscle and the long head of the triceps muscles (Figures 55-14 and 55-15). This fibrous raphe is incised either bluntly or sharply. Blunt dissection between these two muscles is continued until the caudal shoulder joint capsule is identified (Figures 55-16 and 55-17). It is easier to start the blunt separation digitally between the spinous (scapular) head of the deltoid muscle and the long head of the triceps muscle slightly above the level of the caudal shoulder joint and proceed in a cranioventral direction than to begin the blunt dissection from

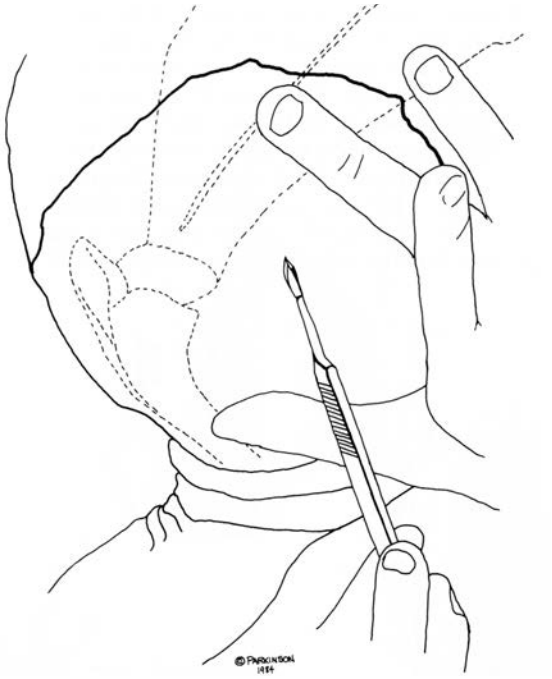

Figure 55-13. The skin incision is made from the midpoint of the scapular spine to the midpoint of the humerus. (From Gahring, DR. A modified caudal approach to the canine shoulder joint. J Am Anim Hosp Assoc. 1985:21:613).

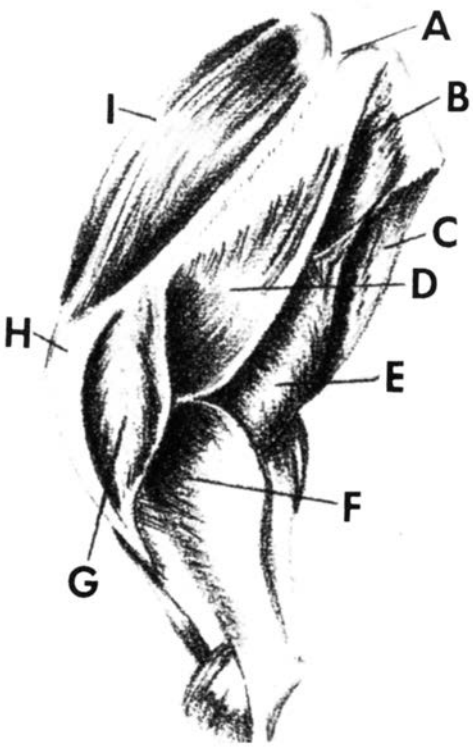

Figure 55-14. The landmark to look for is the fascial raphe between the spinous (or scapular) head of the deltoid and the long head of the triceps muscles: *A,* spine of scapula; *B,* infraspinatus muscle; *C,* teres major muscle; *D,* spinous (or scapular) head of the deltoid muscle; *E,* long head of the triceps muscle; *F,* lateral head of the triceps muscle; *G,* acromial head of the triceps muscle; *H,* greater tubercle of the humerus; *I,* supraspinatus muscle. (From Gahring, DR. A modified caudal approach to the canine shoulder joint. J Am Anim Hosp Assoc. 1985:21:613).

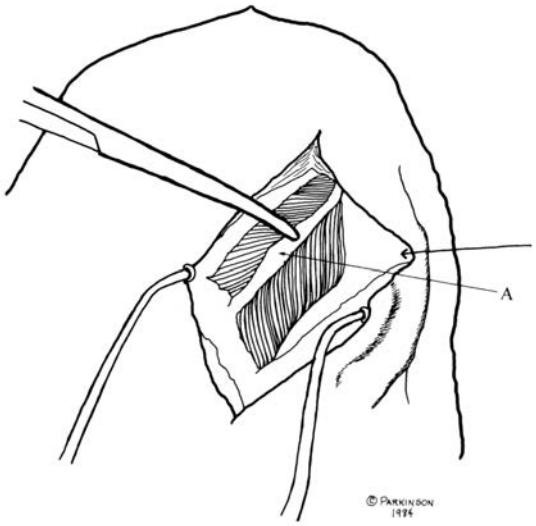

Figure 55-15. Using the landmarks in Figure 55-13, the fascial raphe between the spinous (or scapular) head of the deltoid and the long head of the triceps muscles *(A)* should be immediately beneath the skin and subcutaneous tissue incision. The large arrow depicts retraction of subcutaneous areolar tissue. (From Gahring, DR. A modified caudal approach to the canine shoulder joint. J Am Anim Hosp Assoc. 1985:21:613).

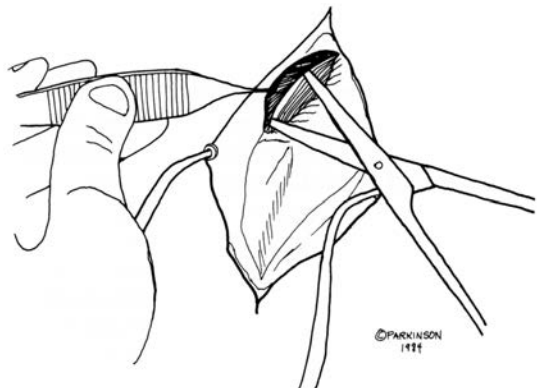

Figure 55-16. Blunt or sharp separation of the fascial raphe between the spinous (or scapular) head of the deltoid and the long head of the triceps muscles is performed. (From Gahring, DR. A modified caudal approach to the canine shoulder joint. J Am Anim Hosp Assoc. 1985:21:613).

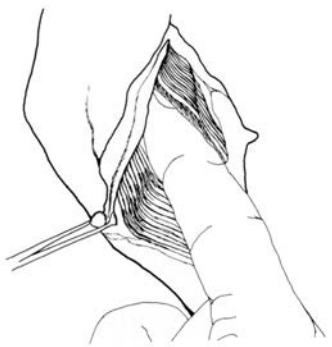

Figure 55-17. Digital blunt dissection between the spinous (or scapular) head of the deltoid and long head of the triceps muscles is carried out to the caudal shoulder joint capsule. (From Gahring, DR. A modified caudal approach to the canine shoulder joint. J Am Anim Hosp Assoc. 1985:21:613).

below the caudal shoulder joint and proceed in a craniodorsal direction. Thus the surgeon does not have to deal with the lateral head of the triceps muscle (See Figure 55-14). The few small muscular branch vessels encountered are either retracted or ligated. A self-retaining retractor is used to maintain separation of the spinous (scapular) head of the deltoid and the long head of the triceps muscles (Figure 55-18). The teres minor is seen crossing the dorsal aspect of the caudal joint capsule (Figures 55-19 and 55-20). The axillary nerve is identified as it crosses the ventral aspect of the caudal joint capsule (Figures 55-21 and 55-22). An incision into the joint capsule is made transversely (perpendicular to the long axis of the humerus) between and parallel to, the teres minor muscle and the axillary nerve (Figure 55-23). This incision

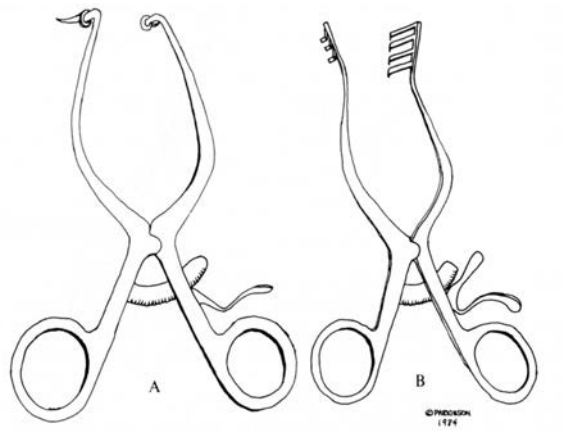

Figure 55-18. Self-retaining Gelpi **A.** or Weitlaner **B.** retractors aid the exposure. (From Gahring, DR. A modified caudal approach to the canine shoulder joint. J Am Anim Hosp Assoc. 1985:21:613).

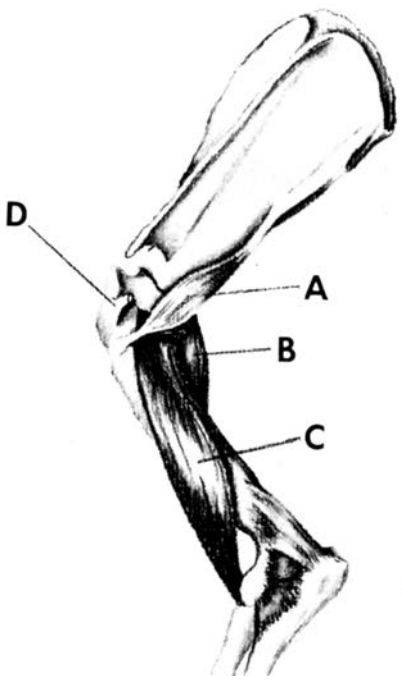

Figure 55-19. The caudal shoulder joint capsule exposed by the muscle separation described in Figures 55-14 and 55-17 lies caudoventrally to the teres minor muscle belly *(A). (B)* coracobrachialis muscle; *(C)* brachialis muscle; *(D)* tendon of insertion of the infraspinatus muscle. (From Gahring, DR. A modified caudal approach to the canine shoulder joint. exposes the caudal glenoid, caudal humeral head, and caudal joint cul-de-sac (Figure 55-24). Another self-retaining retractor may be used here to retract the cut edges of the joint capsule if desired (See Figure 55-18).

A lesion of osteochondritis dissecans can be identified and treated (Figure 55-25). Manipulation of the leg by an assistant aids in identifying the full extent of the lesion (Figure 55-26). The caudal cul-de-sac can be examined and flushed (Figure 55-27).

The caudal shoulder joint capsular incision is closed with a horizontal mattress absorbable suture (Figure 55-28). The fasciae of the spinous (or scapular) head of the deltoid and the long head of the triceps muscles are reapposed with simple continuous absorbable suture (Figure 55-29). The subcutaneous and skin closures are routine (Figure 55-30). Restricted activity is allowed for the first two weeks postoperatively. Slings and splints are not necessary nor are they advised.

Summary and Results

This surgical approach to the caudal shoulder joint offers a number of advantages to other surgical approaches. It is primarily a muscle-separating approach where no tendons or ligaments are incised. It offers excellent visualization of the caudal humeral head and caudal joint cul-de-sac. The skin and the joint capsule are the only tissues sharply incised. This approach offers a less traumatic, less time consuming, and more effective way to manage shoulder OCD. There is no resultant loss of range of motion of the shoulder joint with this procedure. It offers good visualization of the joint (albeit not as exquisite as can be seen with arthroscopy) and recovery is remarkably comfortable and rapid in most patients. The caudomedial joint can be explored via this approach, an area unavailable via a caudolateral approach. In addition, the vascular and neural plexuses are easier to retract and avoid in the caudal approach than in the caudolateral approaches.

Complications are minimal. Seroma formation is extremely rare. Some manipulation of the leg is necessary to fully identify the full extent of some lesions of OCD on the caudal humeral head, but this has not ever precluded visualization of the entire extent of the lesion at surgery. The facts that the surgery can be performed quickly and relatively comfortably makes this approach an excellent alternative to the more time-intensive use of arthroscopy. Closure is quick and simple and patients usually return to near normal activity within days after surgery.

Surgical Treatment of Biceps Brachii Tendon Injury

James L. Cook

This topic is written based on the available literature through 2010 and does not cover the most current literature on this topic.

Background

Injury or insult to the biceps tendon has been reported as a frequent cause of forelimb lameness in dogs that typically requires treatment.[1-9] Reported pathologic conditions of the biceps tendon include tenosynovitis, partial or complete rupture, avulsion, tendinitis, tendinosis, displacement, and bipartite tendon. The pathology, epidemiology, and diagnostics associated with these conditions have been described.[1-9] Biceps tendon injuries occur most commonly in middle-aged medium and large breed dogs that participate in athletic activities. There is no documented gender predisposition to the author's knowledge. Apart from rupture or avulsion, dogs with biceps tendon pathology are presented for a unilateral forelimb lameness of insidious onset. Dogs are typically weightbearing on the affected limb. Rupture or avulsion may result in a lameness that is acute and more severe.

Diagnostics

Physical examination findings in dogs with biceps tendon pathology are very similar regardless of the specific cause. The most consistent findings include mild to moderate atrophy of the affected spinatus muscles, pain on shoulder flexion (especially with the elbow extended), and pain on direct palpation of the biceps tendon and/or manual tensioning of the biceps muscle.[1-6,23]

Definitive diagnosis and characterization of the type of pathology of the biceps tendon typically require more advanced imaging modalities such as contrast arthrography, ultrasonographic evaluation and/or arthroscopic visualization. Plain radiographic views of the affected shoulder joint provide relevant information regarding secondary bone and soft tissue changes and should be included in the diagnostic database. "Skyline" radiographic views may aid in evaluating the biceps groove.[3,7] In cases of bicipital tenosynovitis, radiographs may show evidence of osteophytosis and enthesiophytosis associated with the biceps tendon and groove (Figure 55-31). Contrast arthrography provides additional information regarding the anatomy and integrity of the biceps tendon. Contrast arthrography is reported to be sensitive for identifying biceps tenosynovitis,[7] but generally does not delineate type or extent of the pathology or give information regarding changes within the tendon tissue.[1-3,7-9] Ultrasonography of the biceps tendon, performed by an experienced individual, provides for assessment of intratendinous pathology, associated effusion, and pathologic changes of the biceps groove (Figure 55-32).[5,7,21] Ultrasonography is helpful for determining the type and severity of the pathology in the majority of cases. Arthroscopic evaluation of the shoulder joint allows for visualization and assessment of all intra-articular structures providing definitive evidence of visible biceps pathology as well as involvement of other tissues (Figure 55-33). Techniques for exploratory arthroscopy of the

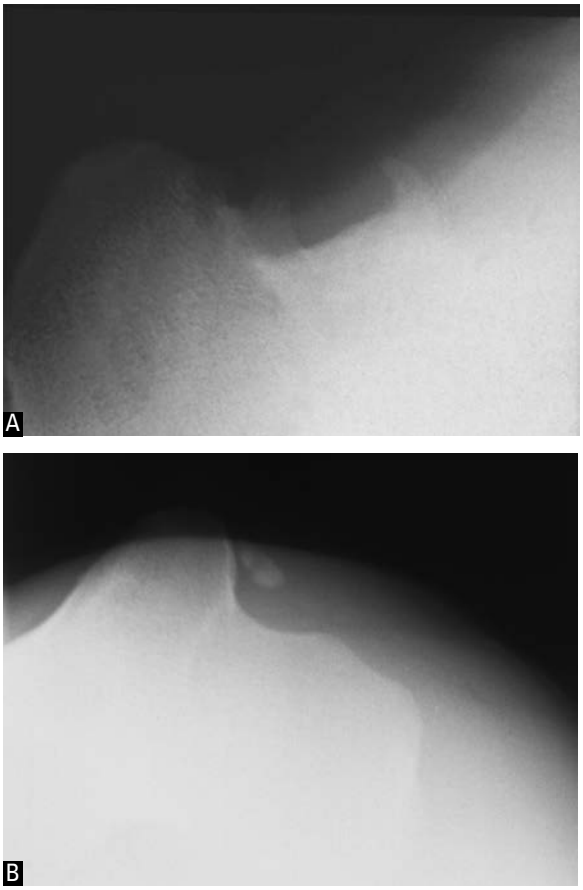

Figure 55-31. "Skyline" radiographic views showing osteophytosis and enthesiophytosis associated with the biceps groove **A.** and tendon **B.**

shoulder joint of dogs have been previously described.[4,5,10,21,22,23] Arthroscopic evaluation of the shoulder joint is recommended as the diagnostic modality of choice as it allows for visualization, "palpation", biopsy, and when necessary, treatment, of pathology. More advanced imaging techniques such as computed tomography and magnetic resonance imaging are currently being investigated for their usefulness for diagnosis of shoulder joint pathology in dogs.[19,26,28]

It is critical to perform a comprehensive diagnostic evaluation of dogs suspected, or even confirmed, to have biceps tendon pathology. Biceps tendon pathology can be a secondary or incidental finding. Many dogs with biceps tendon problems will also have elbow pathology, neurologic dysfunction, or neoplasia. In addition, the biceps tendons of insertion may be a primary or additional source of pain in these cases.[24,28] It is vital to look for other pathology in every dog diagnosed with biceps tendon disorders as these other problems are often more clini-

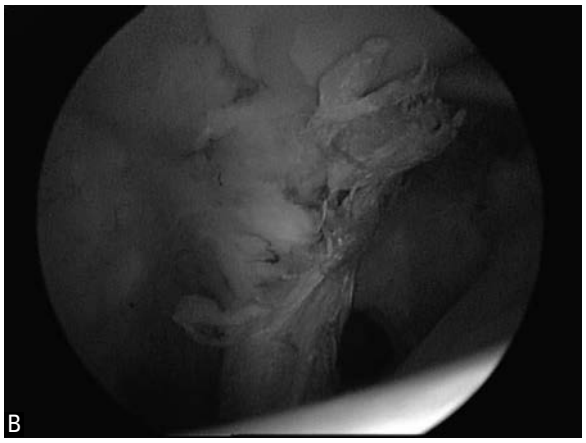

Figure 55-33. Arthroscopic views of a normal biceps tendon **A.** a biceps tendon with severe partial tearing **B.** and a biceps tendon with tenosynovitis and partial avulsion.

cally important and will greatly affect treatment and prognosis. Complete neurologic examination and radiographs of the elbows are recommended in all cases.

Surgical Treatment

When biceps tendon pathology is determined to be a significant cause of pain, lameness, and/or dysfunction in dogs, treatment is indicated. Non-surgical management of biceps tendon pathology consisting of activity modification, non-steroidal anti-inflammatory drugs, analgesics, and/or intra-articular injections may be effective in many cases.[1-3,8,22] However, surgical management often becomes necessary in a significant number of these patients.[1-5,8] The reported surgical treatment options for biceps tendon disease include tenodesis, tenotomy, primary repair, debridement, transposition, and lavage.[1-5,8] Primary repair, debridement, and transposition are rarely indicated for primary lesions of the biceps tendon and will not be addressed further in this chapter. Based on the published veterinary literature, biceps tenodesis via an open approach and open or arthroscopic biceps tendon release (tenotomy) are the most common surgical procedures used to treat biceps tendon problems in dogs.[1-4,8,20] Arthroscopic tenodesis has also been reported to be a successful means of treatment for biceps disorders in dogs.[5]

Tenotomy

Open tenotomy is performed through a modified cranial approach to the shoulder joint.[11] After incision of the skin over the cranial aspect of the distal scapula and medial aspect of the greater tubercle, the supraglenoid tubercle can be palpated proximal to the pectoral muscles. The fascia and joint capsule over the supraglenoid tubercle can be incised taking care to avoid the suprascapular nerve and associated vessels proximally. The biceps tendon can then be visualized and tenotomized at its origin using a scalpel blade, scissors, or other appropriate cutting device. Routine closure of the joint capsule, fascia, subcutaneous tissues, and skin is performed.

For arthroscopic tenotomy,[4] a caudolateral camera portal and craniolateral instrument portal are used.[10] Complete arthroscopic assessment of the joint is performed, and the biceps tendon is identified and assessed. The biceps tendon is tenotomized at its origin using a scalpel blade (beaver blade or #11 blade), arthroscopic scissors or basket forceps, a motorized shaver, radiofrequency, or electrosurgical device placed through the instrument portal (Figure 55-34). The skin incisions are closed routinely.

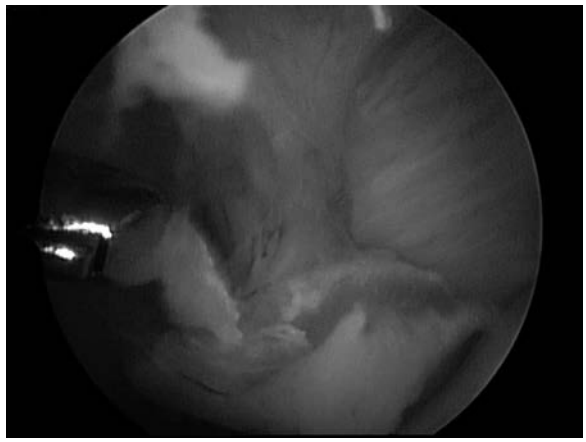

Figure 55-34. Arthroscopic view of a biceps tendon after tenotomy performed using basket forceps shown.

Tenodesis[3]

After performing a cranial approach to the shoulder,[11] the biceps tendon is visualized and detached from its origin on the supraglenoid tubercle. The tendon is then transposed laterally and fixed to the proximal humerus in one of three ways: 1) the tendon can be passed from medial to lateral through a hole drilled through the greater tubercle that is large enough to accommodate the diameter of the tendon and then sutured to the periosteum laterally and medially; 2) the greater tubercle can be osteotomized, the tendon placed at the site of osteotomy and the tubercle reattached over the tendon using a tension band wire technique; or 3) a longitudinal incision is made in the biceps tendon, a cancellous bone screw with spiked washer is placed through the incision and into the bone to attach the tendon at its transposed location. The elbow is held in extension and adequate length of tendon ensured prior to fixation. Routine closure of the joint capsule, muscle and fascia, subcutaneous tissues, and skin is performed. Postoperative radiographs should be obtained in all cases.

Arthroscopic Tenodesis[5]

The technique is performed using a caudolateral camera portal and two instrument portals (i.e., craniolateral and cranial) (Figure 55-35). The arthroscope is inserted and the joint thoroughly evaluated for pathology of all relevant structures. The biceps tendon is identified and a 16-gauge spinal needle, or other

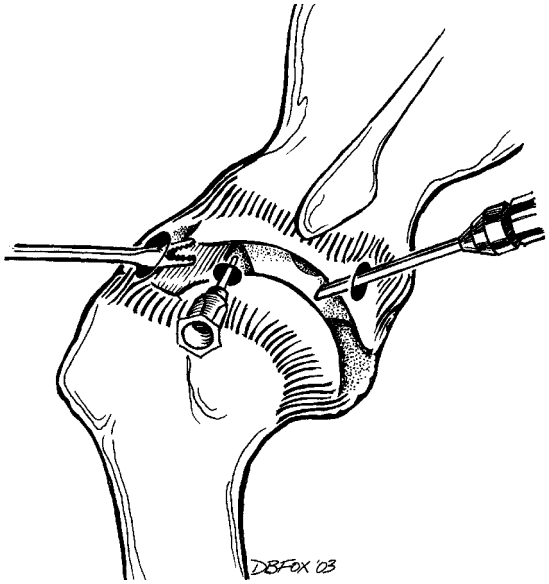

Figure 55-35. Illustration showing the anatomical locations of the three arthroscopic portals used for arthroscopic assisted tenodesis (reprinted from Cook JL, et al. J Am Anim Hosp Assoc 2005; 41:121-127 with permission).

suture-passing device, inserted through the craniolateral portal and through the biceps tendon at its proximal aspect. Suture (#2 braided polyblend suture (FiberWire suture, Arthrex, Naples, FL 34104) or 0 polypropylene suture (0 Prolene, Ethicon, Somerville, NJ 08876) with the needle removed) is passed through the tendon. The suture-passing device is removed, and both ends of the suture are grasped through the cranial portal and pulled through the skin using arthroscopic grasping forceps. The suture ends are clamped with a mosquito forceps. The biceps tendon is then released at its attachment of origin on the supraglenoid tubercle using a basket forceps, scalpel blade, motorized shaver, or other cutting device (Figure 55-36). An intramedullary pin is then inserted through the cranial portal to locate the point of drilling for tendon fixation insertion. The point of fixation placement should be the most distal point in the biceps groove that is visible arthroscopically with the shoulder held at a weight bearing angle (approximately 110 to 130°). The appropriate drill sleeve for the intended fixation device is then inserted over the pin. The pin is removed and the appropriate drill bit inserted through the drill sleeve and used to drill a hole through the cis cortex of the proximal humerus. The drill bit and sleeve are removed and the fixation device is inserted and tightened to fix the tendon to the proximal humerus (Figure 55-37). It is imperative that the elbow be held in extension and that adequate tendon length is verified prior to insertion of the fixation device. At least two different devices can be used for fixation. When using the Arthrex® Biceps Tenodesis 5.5 mm non-absorbable cannulated interference screw system (Bio-Tenodesis System, Arthrex, Naples, FL 34104), the suture in the tendon is pulled through the cannulated screw using the driver. The screw is inserted into the hole pulling the tendon with it, and the screw is tightened until it is flush with the bone (Figure 55-38). A 3.0 mm cannulated screw (3.0 mm cannulated screw, Synthes, Monument, CO 80132) and tissue washer (spiked washer, Synthes, Monument, CO 80132) can also be employed effectively (Figure 55-39). When using the cannulated screw and washer, the cannulation wire is placed

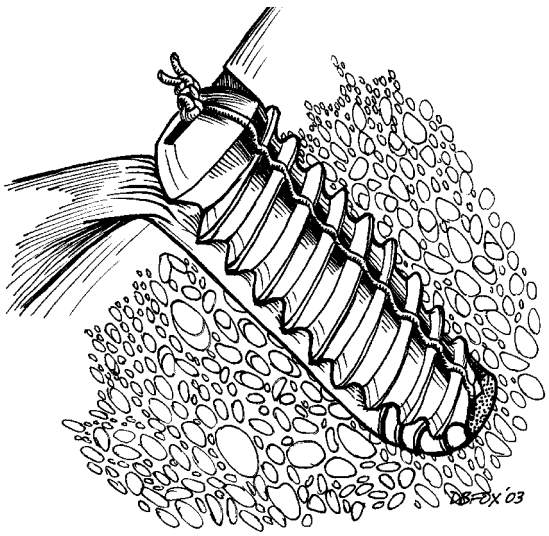

Figure 55-38. Illustration showing the method of fixation of the biceps tendon when using the Arthrex biceps tenodesis cannulated interference screw with suture for arthroscopic biceps tenodesis (reprinted from Cook JL, et al. J Am Anim Hosp Assoc 2005; 41:121-127 with permission).

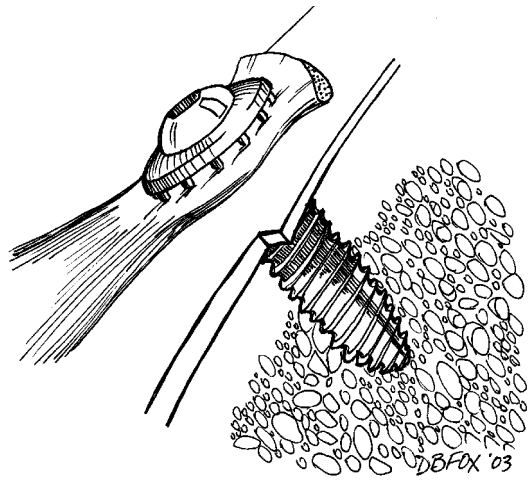

Figure 55-39. Illustration showing the method of fixation of the biceps tendon when using the screw and tissue washer method for arthroscopic biceps tenodesis (reprinted from Cook JL, et al. J Am Anim Hosp Assoc 2005; 41:121-127 with permission).

through the tendon at the level of the suture. The drill bit is then inserted over the wire and the hole is drilled. The cannulated screw with washer is then driven through the tendon into the hole and tightened until the washer firmly engages the tendon and contacts the underlying bone. Again, the elbow should be held in extension during final screw insertion. The skin incisions are closed routinely and postoperative radiographs are taken.

Postoperative Care

For open tenodesis cases, home care instructions included 10 to 15 minute walks 3 to 4 times a day, and ice packing the surgery site for 5 to 10 minutes twice daily. Jumping, running, or off leash activity were prohibited for 2 weeks. The use of a Velpeau sling for 10 days and restriction of exercise to on-leash activities for 6 to 8 weeks following open tenodesis has been recommended.[3]

For arthroscopic tenodesis cases, clients are instructed to allow short leash walks only, and to restrict the dog to a cage, crate, or kennel when unobserved. These restrictions apply to the first 6 weeks after surgery. If the dog can bear weight on the operated limb with no evidence of pain or displacement of the biceps muscle, and no evidence of implant failure is present at the 6 week recheck, a progressive return to full activity is encouraged over the subsequent 6 weeks. Range-of-motion exercises and non-concussive activities such as swimming and leash walking are encouraged during the second 6 week period. Full, unrestricted activity is allowed after 12 weeks of rehabilitation. Additional restrictions and rehabilitation modalities are tailored to each individual case.[4,25]

Complications

If osteoarthritis is present in the affected joint at the time of surgery, progression is likely regardless of the surgical technique employed. For arthroscopic tenotomy cases, reported complications include progression of radiographic pathology, continued pain and lameness and/or recurrence of pain and lameness.[4,20] Other complications that have been associated with open or arthroscopic tenotomy include seroma formation, change in appearance of the brachial musculature, and infection.

In cases of open tenodesis, delayed union of the tubercle osteotomy, implant migration, and seroma formation have been reported.[3] In the published report on arthroscopic tenodesis, seroma formation was the only reported complication.[5] No biceps muscle displacement or laxity was reported for any of the tenodesis cases following surgery.

Prognosis

For arthroscopic biceps tenotomy for treatment of bicipital tenosynovitis, good to excellent results were obtained in all five dogs in one series based on subjective measures over a 6 month follow-up period.[4] In another series of cases, excellent outcomes were reported for 22 of 25 shoulders assessed of a mean of 26 months postoperatively.[20]

Open tenodesis has been associated with good and excellent outcomes in more than 90% of dogs treated.[3,8] In the single published report on arthroscopic tenodesis, all 6 dogs treated were judged to have good or excellent outcomes according to the owners.[5] Owners reported that full return to function was typically evident by 12 to 18 weeks after surgery. Follow-up times range from 5 months to 18 months (mean = 11.7 months, median = 12.5 months). Return of spinatus and brachial muscle mass symmetry and resolution of lameness were evident in all cases based on subjective evaluation by the surgeon.

The published literature regarding surgical treatment of biceps tendon pathology suggests that weight management and physical rehabilitation are critical for a successful outcome when treating biceps tendon problems using any modality.[1-5,8] In addition, maximal function may not be reached until 6 months following surgery in the majority of cases.

Summary

Both tenotomy and tenodesis are used in people for treatment of biceps tendon pathology.[12-18] Indications and recommendations for tenotomy versus tenodesis vary among types of pathology; patient age; activity level and expectations; and surgeons' preferences.[12-18] Good and excellent results have been reported for both tenodesis and tenotomy in people, and many surgeons recommend achieving competence in both techniques to provide comprehensive treatment options and patient care.[14-18] Tenotomy has been reported to provide similar outcomes in terms of cosmetic appearance, anterior shoulder pain, and degree of muscle spasms in humans with chronic bicipital pain.[14] However, to the authors' knowledge, no studies have compared functional outcomes of arthroscopic biceps tenotomy versus tenodesis in terms of limb strength and activity levels in the human or veterinary literature. Tenodesis is typically recommended over tenotomy in athletic people, especially those who participate in overhead athletic activities.[16-18] Similarly, athletic dogs may benefit from tenodesis when compared to tenotomy. In addition, since dogs have the added function of weight bearing in the forelimb, tenodesis might be advantageous for dogs. This consideration was supported by the excellent long-term results of open biceps tenodesis reported by Stobie, et al.[3] The theoretical advantages of tenodesis may be further optimized by employing an all-arthroscopic technique in order to minimize soft tissue

disruption and the associated pain, morbidity, complications, and recovery time. While arthroscopic tenodesis is technically demanding, repetition and experience allow for more efficient and precise implementation of the procedure. The technical demands, surgical time, and costs associated with arthroscopic tenodesis far exceed those for tenotomy. However, the indications, as well as the long-term outcomes, of arthroscopic biceps tenotomy versus tenodesis have not been determined in dogs. Therefore, it is important to explore the feasibility and results of both techniques until definitive conclusions regarding their efficacy can be drawn from scientific data. Long-term studies are needed to determine the effects of arthroscopic tenotomy versus tenodesis on muscle, elbow, and limb function before definitive recommendations regarding indications, complications, and prognosis can be made.

Excision Arthroplasty of the Shoulder Joint

Donald L. Piermattei and Charles E. Blass

Introduction

Excision arthroplasty of the glenoid rim and humeral head provides a pseudoarthrosis based on fibrous tissue. It is an alternative to arthrodesis or amputation in conditions in which the shoulder joint cannot be adequately reconstructed. Indications for excision arthroplasty include chronic shoulder luxations in which the labrum of the glenoid cavity is excessively worn, severe degenerative joint disease, and irreparable intra-articular fractures, of which gunshot wounds are the most common example. The traditional method of treatment in these animals has been arthrodesis, which is technically demanding and requires bone-plating equipment in most cases.

While encouraging results have been obtained with this procedure, it has only been performed in a small number of patients. We recommend this procedure only as a salvage procedure with a fair to good prognosis for pain free normal, nonathletic function. As in the case of excision arthroplasty of the hip, more normal function can be anticipated in small breeds of dogs than in large breeds. The technique has been performed

bilaterally in a small-breed dog with good functional results by 4 months postoperatively.

Surgical Technique

The shoulder joint is exposed by a craniolateral approach with osteotomy of the acromion process. The tendons of insertion of the infraspinatus and teres minor muscles are transected and retracted caudally with stay sutures. The joint capsule is cut close to the glenoid rim and opened widely, and the tendon of origin of the biceps brachii muscle is transected near the supraglenoid tubercle (Figure 55-40). Ostectomies of the glenoid rim and humeral head (Figure 55-41) are made with and sharp osteotome, oscillating saw, or high-speed rotating burr. Care is taken to protect the suprascapular nerve and caudal circumflex humeral artery during the ostectomies. If the suprascapular nerve passes too closely to the ostectomy site, a notch may be cut in the base of the scapular spine to allow proximal displacement of the nerve. An alternative to ostectomy of the glenoid rim is removal of the articular cartilage of the glenoid to expose subchondral bone, thus opening vascular channels. This also obviates the necessity to detach the biceps tendon.

If the tendon of the biceps brachii was detached, it is reattached to the fascia of the supraspinatus muscle. The teres minor muscle is pulled between the cut surfaces of the scapula and humerus and sutured to the biceps tendon and medial joint capsule (Figure 55-42). The remaining jont capsule is pulled into the ostectomy site and sutured to the teres minor muscle and tendon. This interposition of soft tissues between the cut surfaces of the scapula and humerus is thought to hasten the formation of a fibrous false joint (pseudoarthrosis). The infraspinatus muscle is sutured to its insertion on the humerus. Finally, the acromion process is reattached to the spine of the scapula. It may be necessary to wire the acromion process more proximally than normal to remove laxity in the deltoideus muscle. Subcutaneous tissues and skin are closed routinely.

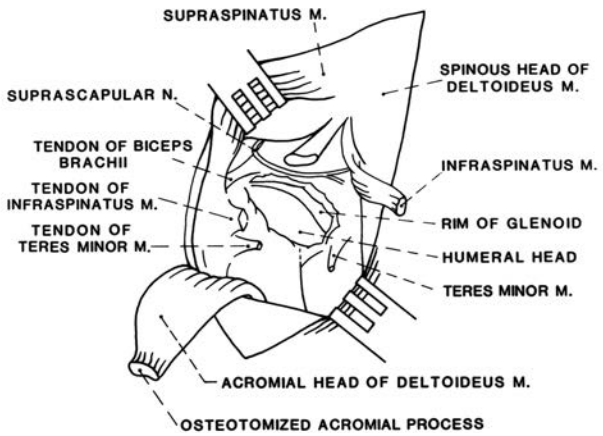

Figure 55-40. Following a craniolateral approach to the shoulder, tenotomies are performed on the biceps brachii, infraspinatus, and teres minor muscles. The joint capsule is cut close to the glenoid rim while preserving its attachment to the humeral head. (From Piermattei DL, Flo GL, DeCamp CE: Brinker, Piermattei, and Flo's Handbook of Small Animal Orthopedics and Fracture Repair, 4th ed. Philadelphia. W. B. Saunders, 2006).

Figure 55-41. Location of ostectomies in the glenoid rim andhumeral head. A small notch may be cut in the base of the scapular spine to allow the suprascapular nerve to be positioned more proximally ig it courses too near the ostectomy site(From Piermattei DL, Flo GL, DeCamp CE: Brinker, Piermattei, and Flo's Handbook of Small Animal Orthopedics and Fracture Repair, 4th ed. Philadelphia. W. B. Saunders, 2006).

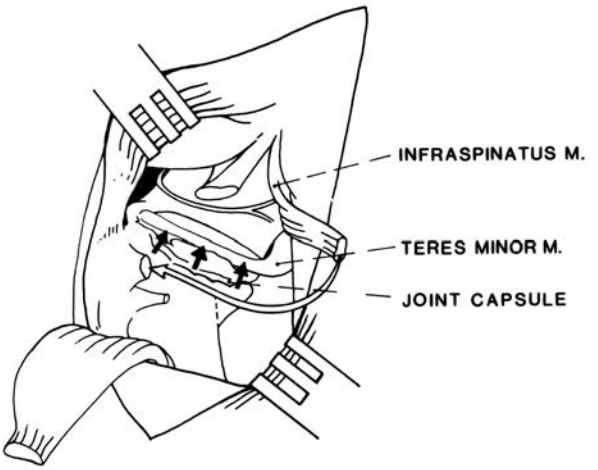

Figure 55-42. After ostectomies are completed, the teres minor muscle is pulled medially and sutured to the biceps tendon, which has previously been sutured to the fascia of the supraspinatus muscle. Joint capsule from the humeral head is sutured to the teres minor (arrows). The infraspinatus is reattached to its insertion, and the acromion process is wired to the spine more proximally than normal. (From Piermattei DL, Flo GL, DeCamp CE: Brinker, Piermattei, and Flo's Handbook of Small Animal Orthopedics and Fracture Repair, 4th ed. Philadelphia. W. B. Saunders, 2006).

Postoperative Care and Prognosis

Early use of the leg is encouraged by leash walking. Passive flexion and extension of the shoulder joint as well as analgesic therapy may be helpful in encouraging use of the leg. More vigorous activity is forced beginning 10 days postoperatively, and swimming is encouraged following suture removal. Early use of the leg stimulates the fibrosis necessary to create a functional pseudoarthrosis. Professional physical therapy starting at two weeks postoperatively will speed recovery.

Thirteen cases have been reported in two small series (Breucker and Piermattei 1988, and Franczuski and Parkes 1988). Good to excellent pain-free-function was obtained in each case. As previously noted, resection of the glenoid rim and humeral head must be considered a salvage procedure, and return to normal function of the limb cannot be expected. Pain-free use of the leg is usually achieved, although a mild gait abnormality and shoulder girdle muscle atrophy will be seen. Full recovery generally requires 3 to 6 months.

Shoulder Arthrodesis

Arnold S. Lesser

Indications

Arthrodesis of the shoulder joint is not common but any condition resulting in intractable pain and dysfunction is an indication for arthrodesis. Malunion and highly comminuted articular fractures can lead to severe DJD. Untreated OCD and chronic luxation of the shoulder especially medial luxation in miniature breeds is another cause of DJD. It is unusual for the arthritis to be severely debilitating. But, when it is and conservative therapy is no longer controlling the pain arthrodesis becomes an option.

Surgical Approach

The approach to the shoulder is simplified by both an osteotomy of the acromial process of the scapula, and the greater tubercle of the humerus. The acromion process can then be retracted distally with the deltoid muscle. Osteotomy of the greater tubercle allows retraction of the supraspinatus muscle and also provides a smooth bed for the plate. The suprascapular nerve should be isolated and protected where it crosses the neck of the scapula. The biceps tendon can be transected from the supraglenoid tubercle if necessary (Figure 55-43).

Procedure

The cartilage is removed from both articular surfaces and a pin or K-wire is used to hold the joint in the proper position. This position is about 105 degrees and can be measured from the standing angle of the controlateral shoulder joint. Two flat congruent surfaces can be formed with an oscillating saw or osteotome. This will create a stable junction and also dictate the angle of the arthrodesis, an important consideration when making these cuts. Cancellous bone graft or substitute is placed between and around the fresh surfaces. Plates provide good long term, stable fixation and are the recommended implant. Compression should be used whenever possible. The scapula is a very thin bone and to get the best purchase for the screws the plate is placed along the cranial aspect of the spine and is twisted caudally to engage the bone where the spine arises from the body. Distally the plate is placed over the craniolateral aspect of the humerus. At least 4 to 5 screws should be placed in the humerus and in the scapula. The longer the plate the more the stresses are distributed and therefore not concentrated over the arthrodesis site. This is especially true of the scapular portion because of the thin bone

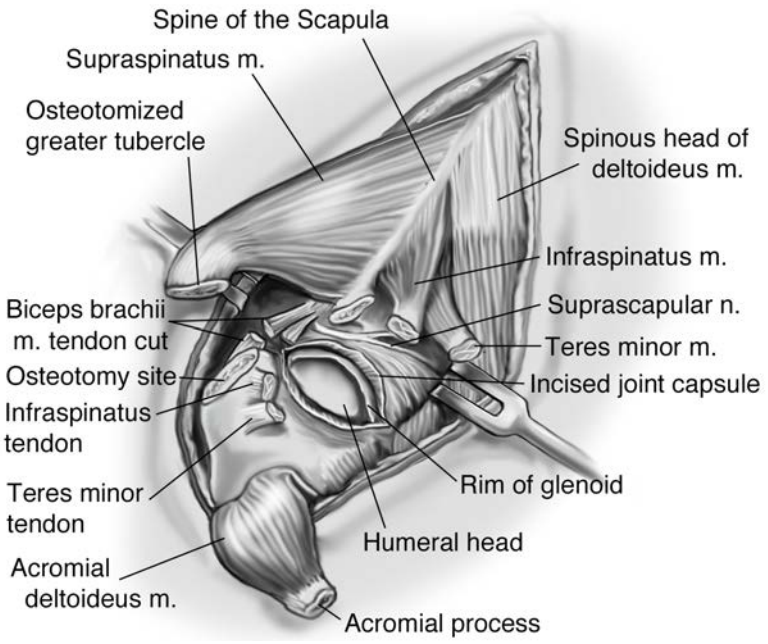

Figure 55-43. The approach to the shoulder joint is facilitated by osteotomy of the acromial process and greater tubercle. The suprascapular nerve should be isolated and protected.

and poor screw purchase. Care must be taken where the plate crosses the suprascapular nerve. The nerve can be placed under or over the plate depending on which places the least tension on the nerve itself. Part of the greater tubercle can be used for graft and the remainder can be attached to the humeral head. If the biceps tendon was transected it can be reattached to the humeral head with a screw and washer (Figure 55-44).

In small or miniature breed dogs combinations of compression screws and pins can also be used but with the availability of 1.5 mm and 2.0 mm plates I would still recommend plate fixation. After removing the cartilage, small pins or Kirschner wires can be passed from the glenoid or neck of the scapula into the humeral head and vise versa. A screw under compression can also be placed from the humeral head into the neck. The surfaces are prepared as described above. The problem with this fixation is that all the implants are concentrated right at the arthrodesis site where there are significant forces trying to create motion because of the long lever arm of the humerus. A secondary support such as a spica cast or splint extending over the shoulder and back will help distribute these forces and should be used with pin and screw fixation. The splint should be left on until signs of fusion are evident radiographically. Even with a plate fixation secondary coaptation is beneficial but does not need to be left on as long.

Even with a successful arthrodesis of the shoulder function may vary from patient to patient. However, there is still some motion preserved from the muscular sling that attaches the scapula to the body wall.

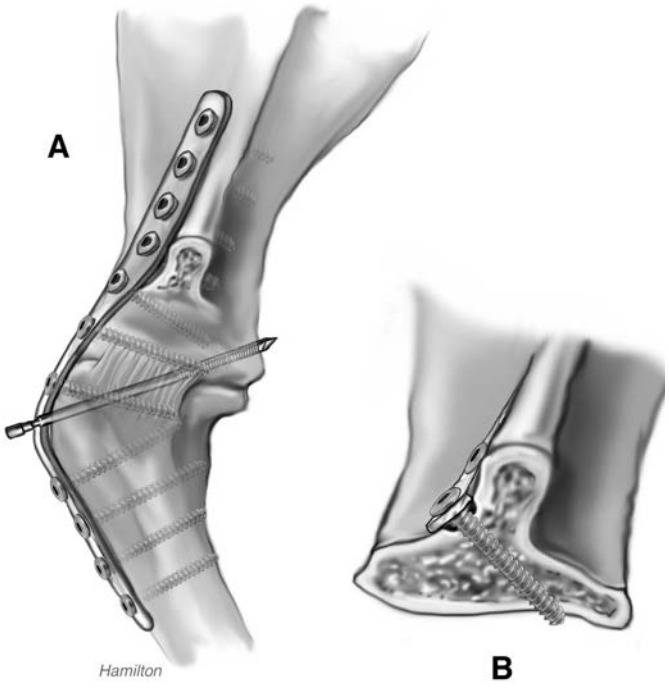

Figure 55-44. A longer plate angled to engage the base of the spine should be used because of the thin bone of the scapula. A pin should be paced across the joint to hold it in position prior to plate placement. The suprascapular nerve should be placed so there is no tension from the plate.

Chapter 56

Humerus and Elbow Joint

Repair of Fractures of the Humerus

Dennis A. Jackson

Editor's Note – The reader is encouraged to review other sections of this text regarding more recent options for the repair of humeral fractures: Chapter 50 – Interlocking Nailing; Chapter 51 – SOP Locking Plates; Chapter 52 – Plate-Rod Fixation; and Chapter 53 – Hybrid External Skeletal Fixation.

Proximal Fractures

Greater Tubercle

Fractures involving the greater tubercle of the humerus are rare. In young animals, these fractures are stabilized with two Kirschner wires or small Steinmann pins. In mature animals, a tension band wire technique is recommended. In both cases, open reduction is required through a craniolateral approach to the proximal humerus. External coaptation is not required, but restricted weightbearing is recommended until bone healing is confirmed by radiographic evaluation.

Humeral Head

Most fractures of the humeral head are caused by gunshot injuries and are highly comminuted. Reconstruction of the articular surface must be exact and is paramount to the successful return of joint function. Exposure of the articular surface of the humeral head can be difficult. A craniolateral approach to the shoulder joint is combined with an osteotomy of the acromion process and tenotomy of the infraspinatus and teres minor muscles as required to obtain surgical exposure. A supraspinatous tenotomy may be necessary to provide adequate visualization of the joint.

The fracture is reduced, and large articular fragments are compressed with lag screw fixation. Small fragments are reduced and are stabilized with multiple Kirschner wires or Stille nails placed at divergent angles. All pins and screws should be countersunk below the articular cartilage. Small Kirschner wires may be used to immobilize articular fragments temporarily while lag screws are placed. The Kirschner wires can be removed once lag screw fixation is completed. Autogenous cancellous bone grafts are used to fill large bone defects. After placement of each implant, the joint should be palpated in all planes to evaluate range of motion and crepitus. If crepitus is detected, the fixation is adjusted before the placement of the remaining implants. The fracture is stabilized, and the joint is lavaged thoroughly before joint capsule closure. Osteotomy of the acromion process is repaired with a tension band wire. The tenotomies and remaining soft tissues are sutured routinely.

For patients with fractures with severe comminution of the articular surface, surgical arthrodesis should be considered as a salvage procedure. Arthrodesis is especially indicated in medium to large breed dogs with severe joint comminution. For small dogs and cats with irreparable joint damage, the humeral head may be excised, or a Velpeau bandage or spica splint may provide adequate coaptation for functional healing. The goal of external coaptation or excision of the humeral head is to produce a functional, pain-free joint or pseudoarthrosis. Failure to obtain functional use of the limb or persistent pain in these patients is an indication for arthrodesis of the joint.

Growth Plate Injuries

Growth plate injuries, which occur in young animals with an open epiphyseal plate, are usually secondary to direct trauma or avulsion injuries. Physeal or epiphyseal plate injuries are classified by the Salter system. This clarifies the site of injury and is useful when selecting treatment and for predicting outcome. A Salter I fracture extends across the epiphyseal plate parallel to the joint surface. A Salter II fracture extends through the epiphyseal plate and includes a small portion of the metaphysis. These fractures are the most common growth plate injuries of the proximal humerus, and both carry a good prognosis if they are repaired early and accurately.

Most Salter I and II fractures require open reduction and internal fixation. The exception is selected Salter I fractures of less than 24 hours' duration in small dogs and cats. These fractures may be managed by closed reduction with the animal under general anesthesia. Manual traction of the distal limb is performed to fatigue the muscle contraction and to achieve reduction and alignment. The proximal physeal fragment is immobilized by grasping the acromion process of the scapula while the distal segment is gently reduced by abduction and adduction of the elbow. Care must be taken to avoid splitting the proximal physis at the thin junction between the humeral head and greater tubercle. Once reduction is achieved, closed normograde pinning using Kirschner wires or Steinmann pins is performed. The pins or wires are passed from the craniolateral aspect of the greater tubercle at a 20 to 30° angle to the long axis of the humeral shaft (Figure 56-1). Alignment and fixation are evaluated with anteroposterior and lateral postreduction radiographs.

Failure to obtain closed reduction or fracture duration of more than 24 to 36 hours is an indication for an open craniolateral approach to the proximal humerus. The fracture should be reduced carefully by gentle levering and distraction to ensure that soft tissues do not become interposed in the fracture site. A small Adson periosteal elevator or a Hohmann retractor facilitates levering and reduction of the fragment. Small Kirschner wires, Steinmann pins, or double Rush pins are the preferred methods for internal fixation. Tension band wires, screws, and bone plates are not used because they cross the epiphyseal plate, create compression, and may lead to premature physeal arrest and growth deformity. Double Rush pinning, with the pins placed craniomedially and craniolaterally through the greater tubercle, is the preferred method of repair. Prebending the pins and using a Rush awl to create guide holes facilitate their

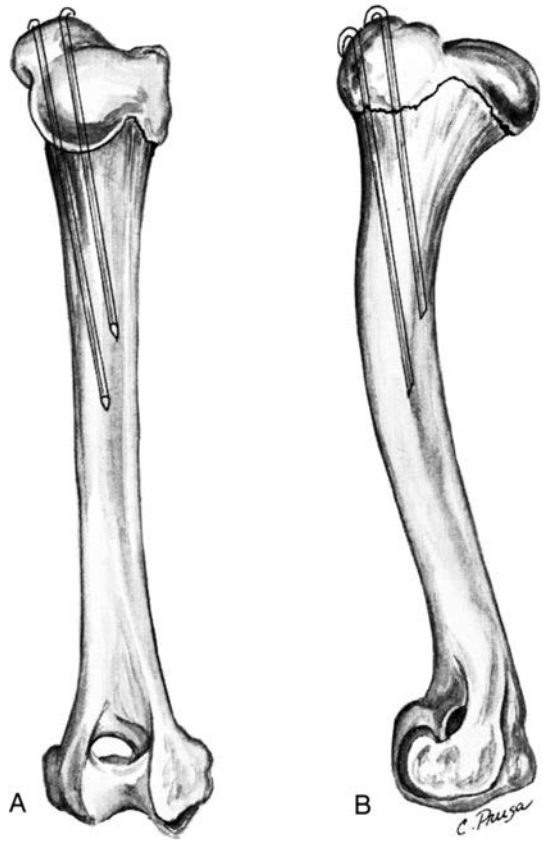

Figure 56-1. A Salter I proximal epiphyseal fracture repaired with two pins or Kirschner wires passed in a normograde fashion from the greater tubercle into the metaphysis after closed or open reduction. **A.** Caudocranial view. **B.** Lateral view.

insertion. Rush pins of appropriate size are driven in normograde fashion at an angle of approximately 20° to the long axis of the bone. While placing the pins, the lateral pin is directed toward the caudomedial cortex and the medial pin is directed toward the caudolateral cortex of the shaft (Figure 56-2). The pins should cross distal to the fracture site and should seat firmly against the cortex to provide rigid three-point fixation. For small dogs and cats, Kirschner wires can be substituted for Rush pins by a similar technique. No additional fixation is required, and early restricted weightbearing is encouraged postoperatively.

Infrequently, Salter injuries of the physis may occur simultaneously with fractures of the greater tubercle and humeral head. In young, growing animals, the repair involves pin fixation of the greater tubercle and humeral head through a craniolateral approach to the shoulder joint combined with tenotomy of the infra-spinatous and teres minor muscles. Pin fixation technique is selected in these animals to avoid interfering with future growth potential of the physis (Figure 56-3).

In mature animals, these fractures are repaired using tension band wire fixation of the greater tubercle combined with lag screw and Kirschner wire stabilization of the humeral head (Figure 56-4). Surgical exposure is through a craniolateral approach, with tenotomy of the infraspinatus and teres minor muscles, as described for a young, growing animal.

General Comments on Treating Proximal Fractures

For surgery, the animal is positioned in lateral recumbency, and the site is aseptically prepared from the proximal scapula to the level of the elbow. The limb is positioned through the body drape to facilitate surgical manipulation of the fragments. When exposing the proximal humerus by osteomy of the acromion process, the surgeon should be careful to preserve the suprascapular nerve, which courses deep to the infraspinatus muscle. The nerve lies lateral to the joint and medial and deep to the acromion process. In cats, a small metacromion protuberance is encountered just proximal to the acromion process. Its presence has no clinical significance and does not alter the surgical approach. The acromion process frequently is not ossified in young animals, and tenotomy of the acromion deltoid, rather than osteotomy, is recommended for exposure. For most proximal fractures, external support is usually not required, and an early return to weight-bearing is encouraged after surgery. The exception is a questionable repair of a comminuted articular fracture. Unstable articular repairs should be immobilized with a Velpeau bandage or a spica splint for 2 to 4 weeks postoperatively. Active physical therapy of the shoulder joint combined with swimming is recommended to obtain the best functional results. For patient comfort, appropriate analgesics should be used in the postoperative period to control pain and to facilitate physical therapy sessions. Early limb use is encouraged by slow, controlled leash walking. Activity during the third through eighth postoperative week should be confined to house and leash. For cases of articular fractures, the client should be advised of the possibility for developing secondary degenerative joint disease and the potential need for anti-inflammatory therapy.

Healing time with epiphyseal injuries can be as short as 3 to 4 weeks. Articular fractures may take several weeks to obtain clinical union. Depending on the age of the animal and the type of fracture, follow-up radiographs are scheduled for 3 to 6 weeks postoperatively. Serial radiographs are obtained at 3 to 4 months postoperatively to evaluate bone healing further. Unless contraindicated, all implants should be removed once radiographic union is complete.

Shaft Fractures

Proximal Metaphysis

The proximal metaphysis of the humerus is broad and strong relative to the rest of the bone. Proximal fractures may be described as transverse, short or long oblique, spiral, segmental, or comminuted. Fractures of this area are rare and usually result from a gunshot injury, vehicle injury, or other direct force or from a pathologic condition. Most cases occur in medium to large breed dogs. When animals are presented with pathologic fractures, nutritional, metabolic, or neoplastic causes should be considered and managed appropriately.

Simple transverse metaphyseal fractures of short duration in immature dogs and cats can be managed by closed reduction and normograde intramedullary pinning. A single intramedullary pin of appropriate size is placed normograde from the greater tubercle

and is passed toward the medial epicondyle and seated at that site. A smaller-diameter pin placed in similar fashion often exits through the medial epicondyle in close proximity to the ulnar nerve. Stack-pinning with two or more smaller pins may be used to increase resistance to rotational forces. Application of an external half- or full Kirschner splint in combination with intramedullary pinning may also be used to neutralize rotational forces.

Open reduction is required if the fracture is of long duration or if soft tissue swelling is significant. Fixation can be achieved with two Rush pins placed as described for repair of a proximal Salter epiphyseal fracture (See Figure 56-2). Alternatively, pins and tension band wire may be applied using appropriately sized Kirschner wires or Steinmann pins and orthopedic wire. With the tension band technique, pins are placed parallel and penetrate the midpoint of the greater tubercle. The wire is positioned in figure-of-eight fashion over the pins and is anchored in the distal fragment through a hole drilled in the bone (Figure 56-5).

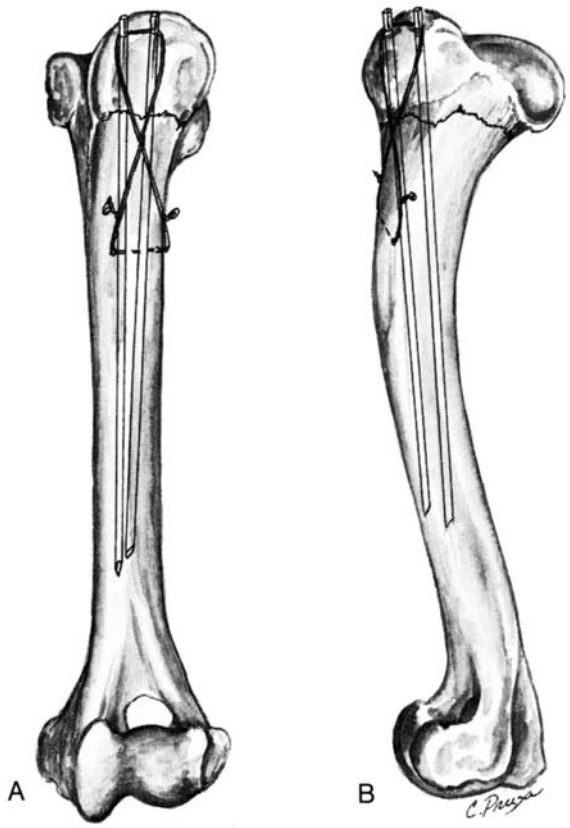

Figure 56-5. A proximal metaphyseal fracture stabilized with a tension band wire and two Kirschner wires or small Steinmann pins passed in normograde fashion from the greater tubercle into the shaft. **A.** Craniocaudal view. **B.** Lateral view.

Proximal Shaft

Proximal shaft fractures usually occur at or just distal to the deltoid tuberosity. Contraction of the deltoideus and latissimus dorsi muscles produces caudal displacement of the proximal fragment. Closed reduction with normograde intramedullary pinning or application of a Kirschner splint may be difficult because of fragment distraction and soft tissue swelling.

For oblique, segmental, and comminuted fractures of this area, open reduction is the preferred method of repair. A craniolateral approach to the proximal shaft with subperiosteal elevation of the deltoideus muscle is used to gain exposure. Several options are available for fixation, including single intramedullary pinning, stack-pins, Rush pinning, pin and tension band wire, hemicerclage wire, half- or full Kirschner splint, and bone plating.

Intramedullary pinning combined with half- or full Kirschner splinting usually provides good fixation for transverse fractures. Shear forces that occur with oblique fractures may be neutralized by the addition of full-cerclage or hemicerclage wire, Kirschner pins, or interfragmentary screws. Secure placement of cerclage wires is enhanced by creating grooves in the cortex or by placing transverse Kirschner pins to prevent the wires from migrating distal on the shaft and becoming loose. The use of single cerclage wires is avoided because it may create a fulcrum effect.

In large to giant breed dogs, or in animals with segmental and comminuted fractures of the proximal shaft, bone plating is the preferred method of repair. Evaluation of preoperative radiographs should ensure that sufficient bone is present to allow placement of two and preferably three bone screws on either side of the fracture site. Subperiosteal elevation of the insertion of the deltoid muscle is performed to provide exposure for reduction of the fracture, and the limb is held in external rotation to facilitate application of the bone plate. The bone plate is conformed to the cranial aspect of the proximal shaft and is applied to the bone.

Comminuted proximal fractures with loss of bone, as occurs with gunshot injuries, result in an unstable fracture and slow bone healing. These fractures are subjected to considerable rotational, compression, and bending forces and are susceptible to infection. Such fractures require rigid internal bone plate fixation combined with an autogenous cancellous bone graft. Alternatively, intramedullary pinning (single or stack) combined with autogenous cancellous bone grafting and Kirschner splint may be used. With open fractures of this type, Penrose drains should be placed at the surgical site. The Penrose drains are removed 3 to 5 days postoperatively.

Middle and Distal Shaft

Most humeral fractures involve the middle or distal diaphyseal regions of the bone. They present as transverse, oblique, spiral, comminuted, or multiple fractures. Overriding of bone fragments is common with midshaft to distal shaft fractures, and most cases require open reduction for repair. Select transverse midshaft fractures can be managed by closed reduction and intramedullary pinning.

Open intramedullary pinning is most applicable to transverse and short oblique shaft fractures in cats and small to medium breed dogs. This type of fixation can also be used for long oblique, spiral, comminuted, or multiple fractures in combination with cerclage wires, stack-pins, and Kirschner splints. Kirschner splints alone are most frequently used to stabilize open or closed, multiple, or comminuted shaft fractures. Bone plates are used most commonly for midshaft to distal shaft fractures in large and giant breed dogs.

Intramedullary Pin Fixation

Closed Reduction and Pinning

Closed reduction may be possible in small breed dogs and cats with recent transverse or short oblique midshaft to distal shaft fractures; closed reduction may be possible if the fracture site can be readily palpated. In medium to large breed dogs, closed reduction can be difficult because of the large muscle mass, soft tissue swelling, and fragment distraction. Open reduction is usually required for repair of shaft fractures in these breeds of dogs. When closed reduction is possible, an intramedullary pin is placed by inserting the pin in normograde fashion from the midpoint of the greater tubercle into the shaft. An intramedullary pin is selected that fills 70 to 75% of the medullary cavity at the fracture site. The size of the medullary cavity can be readily estimated and used to select the pin size based on the preoperative craniocaudal radiograph.

The pin is passed down the medullary cavity to a point just distal to the fracture site. The fracture is reduced by toggling the distal fragment onto the exposed pin. The pin is advanced to the distal fragment and is seated at a point just proximal to the supratrochlear foramen. Care is taken at this point to avoid penetrating the olecranon fossa (Figure 56-6). The joint should be palpated to ensure a full range of crepitus-free motion after pin placement. For closed intramedullary pinning of fractures at the junction of the middle and distal third of the shaft, a smaller pin is selected to allow for placement into the medial epicondyle. The pin should be of sufficient size to fill the medial epicondyle, based on the preoperative craniocaudal radiograph. The pin is inserted at the midpoint of the greater tubercle, is passed in normograde fashion down the medullary cavity, and is seated in the medial epicondyle. The pin is advanced until the tip is felt to penetrate the distal surface of the medial epicondyle. To ensure that the pin does not penetrate the medial olecranon fossa, the joint should be palpated repeatedly for crepitus and limited range of motion during pin placement. After insertion of an intramedullary pin for stabilizing either middle or distal diaphyseal fractures, persistent rotational instability can be controlled by closed application of a half-Kirschner splint.

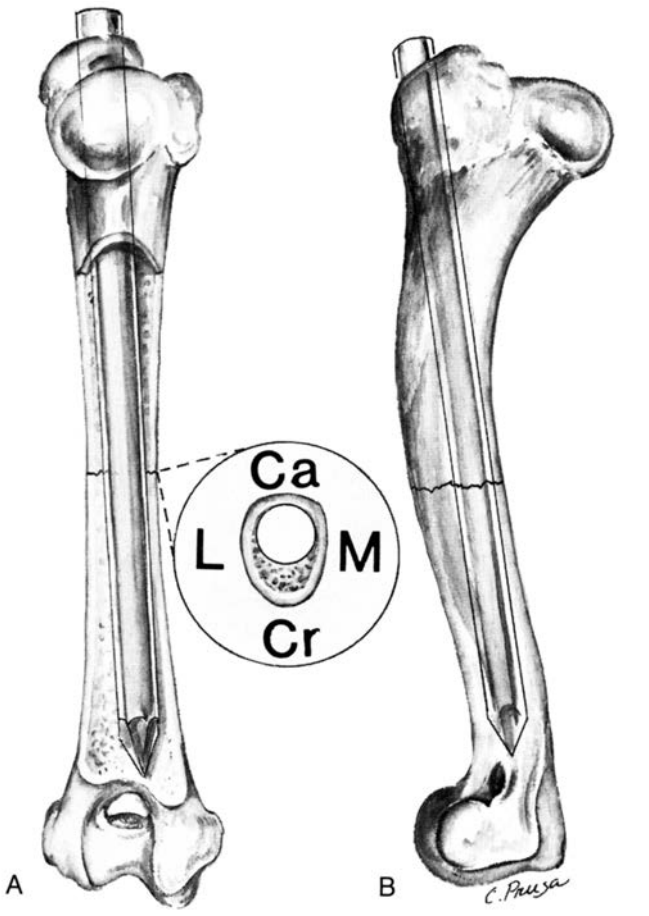

Figure 56-6. A transverse midshaft fracture demonstrating pin placement at the fracture site. The pin, which fills approximately 70 to 75% of the medullary cavity and contacts the caudal cortex of the bone at the fracture site, is inserted into the medullary cavity to a point just proximal to the supratrochlear foramen. **A.** Caudocranial view. *Ca*, caudal cortex; *L*, Lateral cortex; *M*, medial cortex; *Cr*, cranial cortex. **B.** Lateral view.

Open Reduction and Pinning

Although closed reduction is possible, open reduction is preferred for repair of midshaft and distal shaft fractures in all breeds of dogs and cats. The animal is placed in dorsal recumbency to allow for a lateral or medial approach to the shaft. Although the medial approach avoids muscle mass, it does encounter extensive neurovascular structures; for this reason, most fractures are handled by a lateral approach. The lateral approach provides exposure of the proximal three-fourths of the humeral shaft. The superficial cephalic vein and radial nerve lying between the brachialis muscle and the lateral head of the triceps brachii muscle should be identified and preserved. Proximal exposure of the shaft, when necessary, can be obtained by subperiosteal elevation of the deltoideus muscle. Distal exposure can be gained by extending the incision to the lateral epi-condyle and by dissecting the brachialis muscle to allow cranial and caudal retraction of the muscle and radial nerve as a unit. Gelpi retractors placed at either end of the wound facilitate muscle retraction and surgical exposure.

Reduction of shaft fractures often requires considerable traction with bone-holding forceps or the use of a bone distractor in large breed dogs to correct overriding from muscle contraction. In small dogs and in cats, open reduction and fixation may be achieved with a single intramedullary Steinmann pin. A pin of appropriate size is passed in retrograde fashion from the fracture site to the greater tubercle, the fracture is reduced, and the pin is seated in the distal fragment. To ensure proper pin placement, the pin is directed to accentuate placement either in the distal medullary cavity just proximal to the supratrochlear foramen or in the medial epicondyle. For midshaft fractures repaired by intramedullary pinning, the pin is started against the caudal cortex of the proximal fragment and is directed toward the greater tubercle (See Figure 56-6). For distal shaft fractures in which pin placement is desired in the medial epicondyle, the pin is started against the caudomedial cortex of the proximal fragment and is directed toward the midpoint of the greater tubercle (Figure 56-7). If the fracture remains unstable after single intramedullary pinning, additional fixation by cerclage wire, stack-pins, or a half-Kirschner splint is added. The intramedullary pin can be included within a hemicerclage wire to gain additional stability by compressing the pin against the cortex of the bone. Fractures

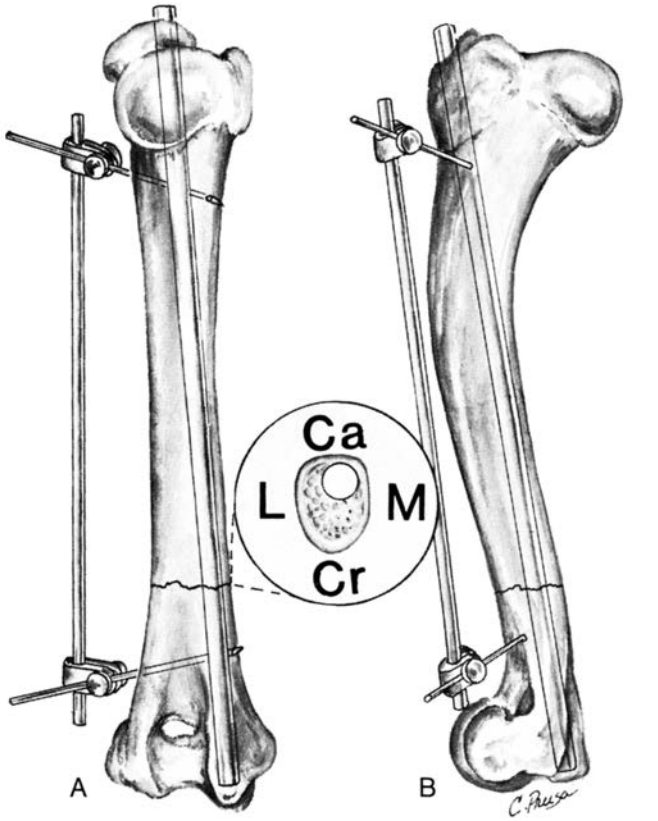

Figure 56-7. A distal transverse shaft fracture showing pin placement at the fracture site and application of a half-Kirschner splint. The intramedullary pin can be directed in a retrograde fashion against the caudomedial cortex of the proximal fragment to accentuate placement in the medial epicondyle. **A.** Caudocranial view. *Ca*, caudal cortex; *L*, Lateral cortex; *M*, medial cortex; *Cr*, cranial cortex. **B.** Lateral view.

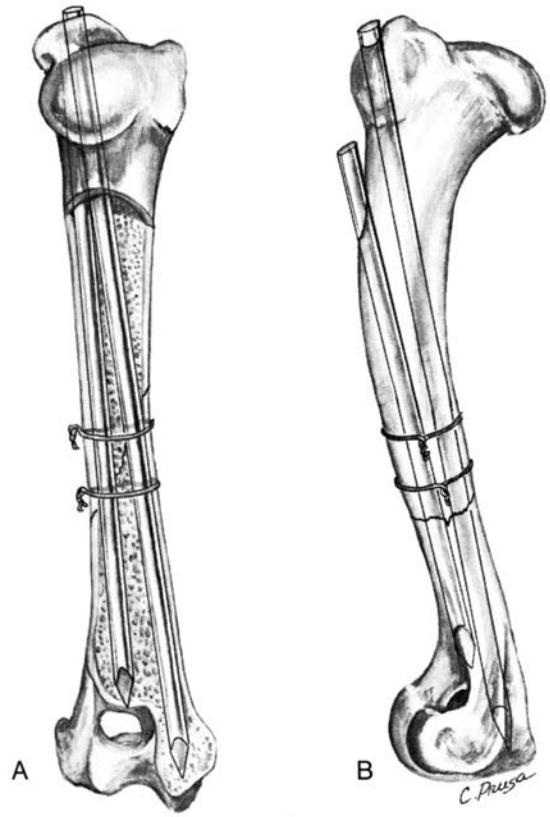

Figure 56-8. An oblique midshaft fracture repaired with stack-pins and full-cerclage wires. The first pin is passed in a retrograde direction from the caudomedial cortex of the fracture site and is placed in the medial epicondyle. The second pin is inserted in a normograde fashion from craniodistal to the greater tubercle to a point proximal to the supratrochlear foramen. **A.** Caudocranial view. **B.** Lateral view.

most applicable to full-cerclage wire technique include fissure fractures, long oblique fractures, and spiral fractures of the shaft. For cerclage techniques, monofilament wire of sufficient size and strength should be used. Twenty- to 22-gauge wire is usually sufficient for small dogs and cats. Eighteen-gauge wire should be used for medium to large breed dogs. When using cerclage, a minimum of two wires is recommended to avoid creating a fulcrum effect.

In large dogs with spacious medullary cavities, stack-pins provide more points of bone contact and improve rotational stability. Two pins or more of appropriate size are placed by directing the first pin in retrograde fashion into the proximal fragment and then seating it in the medial epicondyle. Alternatively, the second or subsequent pins are started at a point cranial and distal to the greater tubercle and are passed in a normograde direction down the medullary cavity to a point just proximal to the supratrochlear foramen. The second and subsequent pins can also be passed in a retrograde direction into the proximal fragment and then seated distally (Figure 56-8).

Half-Kirschner splints may be used with intramedullary pinning to provide rotational stability. A single intramedullary pin is seated in the medial epicondyle, allowing sufficient room between the pin and the cranial cortex of the shaft for placement of two Kirschner pins. Estimation of the combined Kirschner and intramedullary pin diameters can be obtained by studying the preoperative lateral radiograph. A Kirschner pin is placed in each fragment at 35 to 40° to the long axis of the bone and should penetrate both cortices. Both pins enter the bone through separate stab wounds away from the primary incision site. The pins are joined by a connecting bar and two single Kirschner clamps (Figure 56-7). The half-Kirschner splint is usually removed in 3 to 6 weeks after development of a bridging callus, as demonstrated by radiographic examination.

Full Kirschner Splint Fixation

A full Kirschner splint can be used as the sole means of fixation for shaft fractures in cats and in small to medium breed dogs (Figure 56-9). Kirschner splints, when used alone, are placed by closed reduction or by a limited approach to the fracture site to facilitate reduction and fixation. They cause minimal disruption of blood supply and allow for free joint movement and the nursing care of open wounds during the healing period. When deciding on pin placement for a full Kirschner splint, preoperative radiographs should be evaluated carefully for the presence and location of fissure fractures. The presence of fissures may necessitate altering pin placement or may contraindicate the application of a Kirschner splint.

When placing a full Kirschner splint, two pins are positioned craniolaterally in each major fragment. When possible, all pins

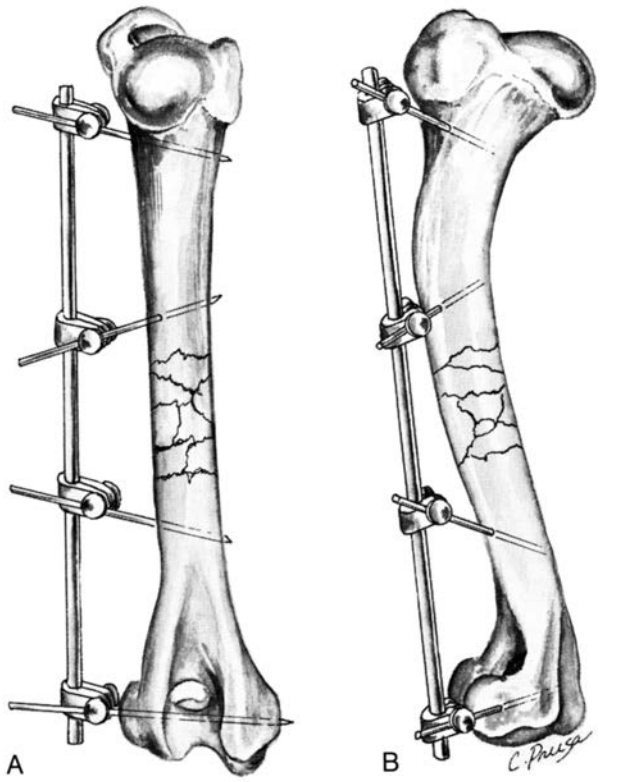

Figure 56-9. A comminuted midshaft fracture repaired with a full Kirschner splint. The splint is positioned on the craniolateral surface of the humerus, with the pins driven through both cortices at approximately 35° to the long axis of the bone. **A.** Caudocranial view. **B.** Lateral view.

are placed at 35 to 40° to the long axis of the bone and should penetrate both proximal and distal cortices. The proximal pin is placed just distal to the greater tubercle, and the distal pin is placed just proximal to the supratrochlear foramen or in transcondylar fashion using the epicondyles as landmarks. The two pins are joined with a connecting bar containing empty Kirschner clamps for placement of the two middle pins. The deltoid tuberosity is used as a landmark for placement of the second pin in the proximal fragment. The second pin in the distal fragment is placed just proximal to the epicondylar ridges. The surgeon must be careful to avoid striking the radial nerve when placing this pin. For Kirschner splinting, a limited lateral approach can be useful to facilitate fracture reduction. For both closed and open repairs, a half-Kirschner splint is initially positioned as described, and traction is applied to obtain axial alignment of the proximal and distal fragments. The two end Kirschner clamps are tightened to maintain reduction while the two middle pins are placed and seated in the bone through clamps previously positioned on the connecting bar. When inserting the two middle pins, medial support should be provided with the surgeon's free hand to prevent medial collapse of the fragments and loss of reduction. When open reduction is performed through a limited surgical approach, lag screws or cerclage wires can be combined with the Kirschner splint as needed to provide additional fixation. Cortical defects should be packed with autogenous cancellous bone grafts harvested from the iliac crest, proximal tibia, or proximal humerus.

Bone Plate Fixation

Bone plates can be applied to most shaft fractures, but they are especially indicated in large and giant breed dogs and for multiple and comminuted fractures. A dynamic compression plate is recommended, with three screws placed on each side of the fracture. When plating the humeral shaft, the surgeon should use as broad a plate as possible. In cases with oblique, spiral, or multiple fractures, lag screws or cerclage wires can be combined with plate fixation as indicated to provide additional fixation.

Exposure is through a craniolateral approach to the proximal shaft, with subperiosteal elevation of the superficial pectoral and deltoideus muscles and caudal retraction of the brachialis and triceps brachii muscles. For midshaft fractures, the plate is conformed to the bone and is placed on the cranial surface of the shaft (Figure 56-10).

For distal shaft fractures, the plate is positioned laterally along the musculospiral groove, the lateral epi-condyle, and the lateral epicondylar crest (Figure 56-11). The plate is conformed to the surface of the distal musculospiral groove and lateral epicondyle and is positioned under the brachialis muscle. Exposure is obtained using a lateral approach to the shaft, and the incision is extended proximally and distally as required.

For distal-third shaft fractures with a comminuted medial cortex, the plate can be applied to the caudal medial surface of the medial shaft and epicondyle (Figure 56-12). Surgical exposure can be

achieved using a medial approach to the distal shaft. Care must be taken to preserve the brachial and collateral ulnar vessels and the ulnar and median nerves. The nutrient artery located on the caudal surface of the bone should also be preserved. A transolecranon osteotomy can be performed if additional distal exposure is required.

General Comments for Managing Shaft Fractures

For repair of shaft fractures, the animal is positioned in lateral recumbency with the injured limb suspended and aseptically prepared from the midradius to the proximal scapula. Placing the affected limb outside the body drape facilitates fracture manipulation and reduction.

Midshaft fractures frequently occur where the radial nerve crosses the musculospiral groove medially to laterally. These patients often have considerable overriding of sharp bone fragments, especially with oblique or spiral fractures. Radial nerve function should be evaluated carefully in these animals because of the close proximity of the nerve to the fracture site. The radial nerve courses over the musculospiral groove of the distal humerus in association with the brachialis muscle. During the surgical procedure, the nerve should be identified, tagged, and assessed for damage. A large-diameter Penrose drain is passed around the brachialis muscle and radial nerve and is used to retract these structures cranially and caudally during the reduction process.

Autogenous cancellous bone grafts enhance healing of severely comminuted or multiple shaft fractures repaired with open reduction and internal fixation. Indications include middle-aged and older patients or patients with large bone defects at the fracture site. Cancellous bone is taken from surgically prepared sites at the greater tubercle, the tibial crest, or the wing of the ilium. Once the graft is harvested, it is immediately placed in the fracture site before closure of the soft tissues.

Severely comminuted shaft fractures with large bone defects may require full-cylinder cortical bone grafting. Suitably prepared cortical bone allografts can be used for this purpose. Bone grafts of this type are usually reserved for comminuted shaft fractures that cannot be repaired by conventional reconstructive techniques.

Postreduction radiographs are obtained to evaluate reduction and fixation. Appropriate analgesics are provided to ensure patient comfort. Most patients with shaft fractures benefit from a Robert Jones bandage applied to the limb for 3 to 5 days postoperatively to control swelling. Twice-daily hydrotherapy is recommended to clean pin sites when a Kirschner splint is used. For patients with these fractures, activity is restricted to house and leash for 6 to 8 weeks or until bone healing is demonstrated by radiograph examination.

Supracondylar and Condylar Fractures

Supracondylar Fractures

Most supracondylar fractures pass through the supratrochlear

foramen. In young animals, an epiphyseal separation may occur in association with a supracondylar fracture. Metaphyseal fractures with no involvement of the supratrochlear foramen can also be seen. Closed reduction is not advisable with this type of fracture. Open reduction with internal fixation provides early joint motion and weightbearing and produces the best results. Surgical exposure is through a medial or lateral approach to the distal shaft, or, if necessary, the two approaches are combined to facilitate reduction. A transolecranon approach provides the best exposure for large breed dogs requiring double bone plating for multiple or comminuted supracondylar fractures.

Transverse Fractures

The preferred method for repair of transverse supracondylar fractures involving the foramen is open intramedullary pinning combined with cross-pinning of the lateral epicondyle (Figure 56-13). This technique provides rigid internal fixation for most transverse supracondylar fractures and is applicable to all sizes of dogs and cats. The fracture is reduced, and the proximal fragment is immobilized with bone-holding forceps. With the patient's elbow flexed, a pin of sufficient size to fill the medial epicondyle is passed in normograde fashion from the medial epicondyle to the greater tubercle. The pin is advanced parallel to the caudomedial cortex of the medial epicondyle and penetrates the greater tubercle. During pin placement, reduction is maintained by counterforce applied through Kern bone-holding forceps attached to the proximal fragment. Rotation of the distal fragment is controlled by bone-holding forceps placed over the fracture site of the lateral epicondyle. The fracture site is inspected repeatedly during pin placement to ensure that reduction is maintained. When the pin penetrates the greater tubercle, the bone chuck is removed, and the distal point of the pin is cut off. The bone chuck is reapplied to the proximal portion, the distal part of the pin is drawn into the medial epicondyle, and the proximal pin is cut off at the greater tubercle.

An alternate method advances the pin in a retrograde direction up the caudomedial cortex of the proximal fragment from the fractured site. The fracture is reduced and the pin is passed into the distal fragment and is seated in the medial epicondyle. With both methods, a Kirschner wire or a small Steinmann pin is passed from distal and caudal to the lateral epicondyle to penetrate the medial cortex of the humeral shaft. The pin in the lateral epicondyle should pass between the intramedullary pin and cranial cortex of the shaft (Figure 56-13C).

Double Rush pinning provides an alternative technique for repair of transverse supracondylar fractures. Rush pins of appropriate size are prebent to facilitate their insertion and are placed slightly distal and caudal to the medial and lateral epicondyles. During pin placement, reduction is maintained with bone-holding forceps. Guide holes are made with an intramedullary pin or a Rush awl to allow introduction of the pins at approximately 20 to 30° to the long axis of the bone. The pins should be placed so they cross above the fracture site and provide rigid three-point fixation (Figure 56-14). In small dogs and in cats, Kirschner wires or small Steinmann pins can be substituted for Rush pins and placed in similar fashion.

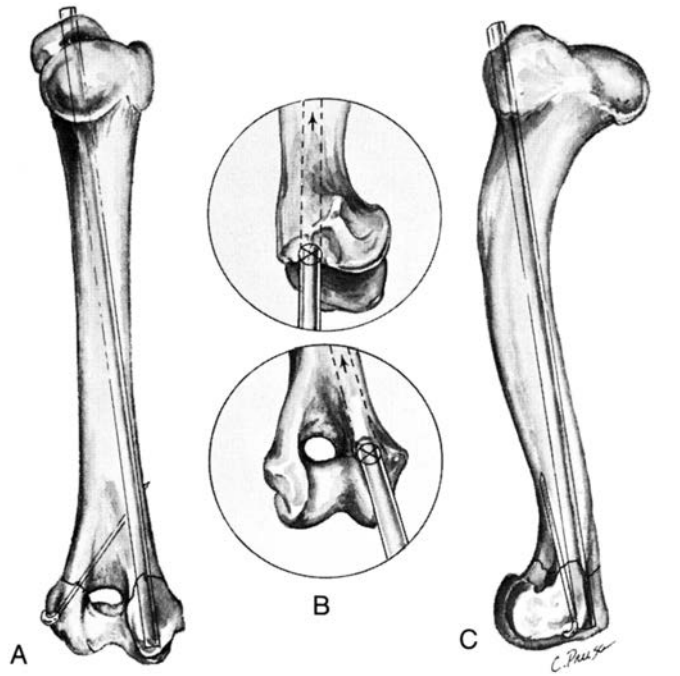

Figure 56-13A-C. A transverse supracondylar fracture showing normograde placement of an intramedullary pin parallel to the caudal cortex of the medial epicondyle. A Kirschner wire or a small Steinmann pin is passed through the lateral epicondyle to penetrate the medial cortex and to provide rotational stability. **A.** Caudocranial view. **C.** Lateral view.

Oblique Fractures

Oblique supracondylar fractures in cats and small to medium breed dogs can be repaired with intramedullary pinning and hemicerclage wires. The intramedullary pin is directed from the fracture site in a retrograde fashion into the proximal fragment, the fracture is reduced, and the pin is seated in the medial epicondyle. Hemicerclage wire, preplaced through the bone and around the pin, is tightened to provide additional stability and rotational control. To control rotational forces unstable fractures may require addition of a half-Kirschner splint.

Multiple and Comminuted Fractures

Fixation of multiple and comminuted supracondylar fractures in cats and small to medium breed dogs can be achieved by intramedullary pinning of the medial epicondyle combined with cerclage wire and a full Kirschner splint (Figure 56-15). Surgical exposure for repair of these fractures requires a combined medial and lateral or transolecranon approach. Reduction and repair are first attempted through a combined lateral and medial approach. If surgical exposure is inadequate, a transolecranon osteotomy can be performed. A Steinmann pin is placed in the medial epicondyle in retrograde fashion, and the fracture site is reduced. The pin is advanced in normograde fashion into the proximal fragment and exits at the greater tubercle. For additional fixation, a full-Kirschner splint is applied to the craniolateral aspect of the bone. The proximal Kirschner pin is inserted below the greater tubercle and passes between the intramedullary pin and the cranial cortex of the bone. The distal pin is placed in transcondylar fashion from the lateral epicondyle and angles toward the medial epicondyle. A connector bar containing two single Kirschner clamps for placement of the middle pins is connected between the proximal and distal pins. Traction is applied, and the fragments are placed in axial alignment and are immobilized temporarily by tightening the proximal and distal Kirschner clamps. The Kirschner splint can be adjusted as required to provide for surgical manipulation and reduction. The proximal and distal clamps are tightened once reduction is achieved. Cerclage wires or lag screws are used to stabilize any comminuted or multiple bone fragments. The cortex of the bone is grooved to accept the cerclage wire and to prevent it from becoming loose. At this point, the second Kirschner pin in the proximal fragment is seated in the shaft between the intramedullary pin and the cranial cortex. The second pin in the distal fragment is placed in transcondylar fashion from the lateral to the medial epicondyle. The result is two Kirschner pins placed in cross-pin fashion within the condylar bone. Care is taken to support the fracture site during placement of the two middle Kirschner pins to prevent medial collapse and loss of fracture reduction (Figure 56-16).

In large dogs, double bone plating is usually required to provide fixation for comminuted or multiple supracondylar fractures (Figure 56-17). A transolecranon approach creates the best exposure for application of the plates. To use the bone plating technique, the condylar fragment must be large enough to allow

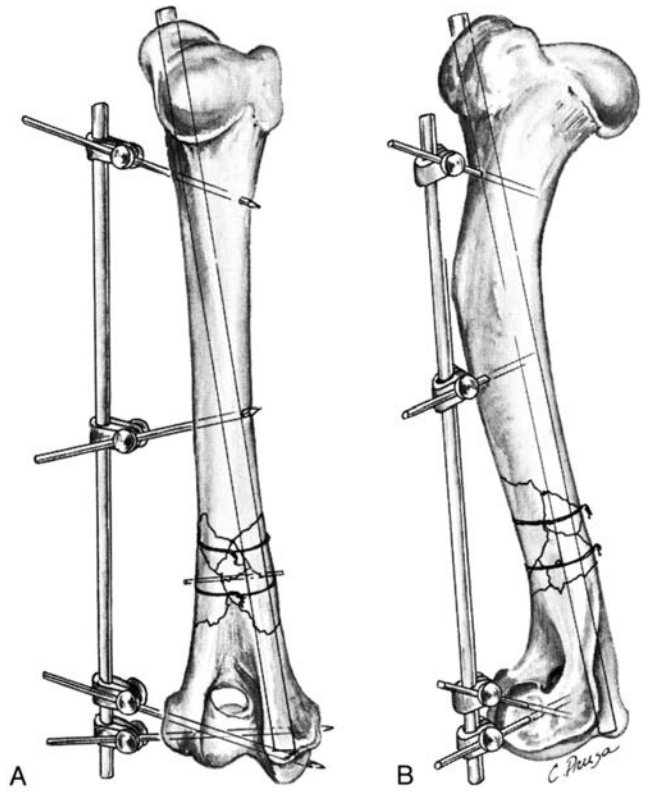

Figure 56-15. A comminuted supracondylar fracture stabilized with an intramedullary pin placed in the medial epicondyle and application of a full Kirschner splint. The intramedullary pin is directed in a retrograde fashion into the medial epicondyle and then is advanced into the proximal fragment. Full-cerclage wires are used to stabilize the multiple bone fragments. **A.** Caudocranial view. **B.** Lateral view.

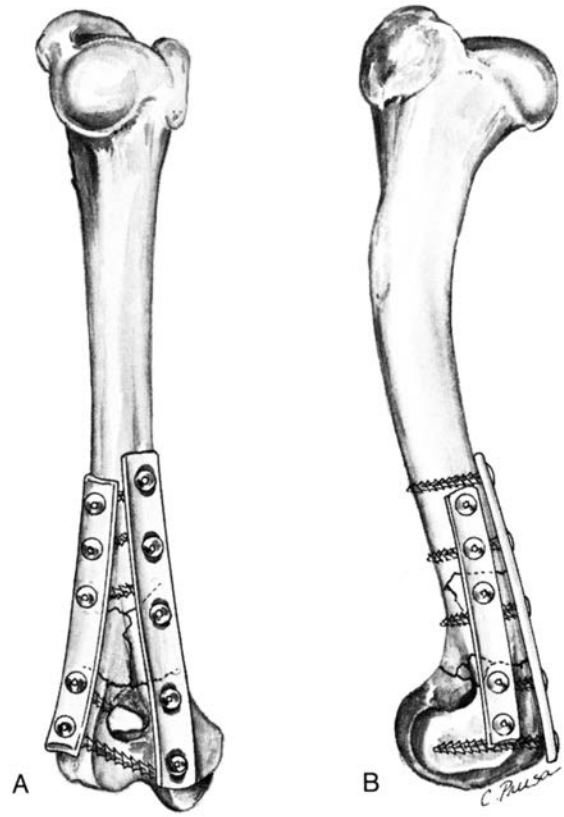

Figure 56-16. A double bone plate repair of a multiple supracondylar fracture. A minimum of two screws should be placed distal to the fracture site in each plate. **A.** Caudocranial view. **B.** Lateral view.

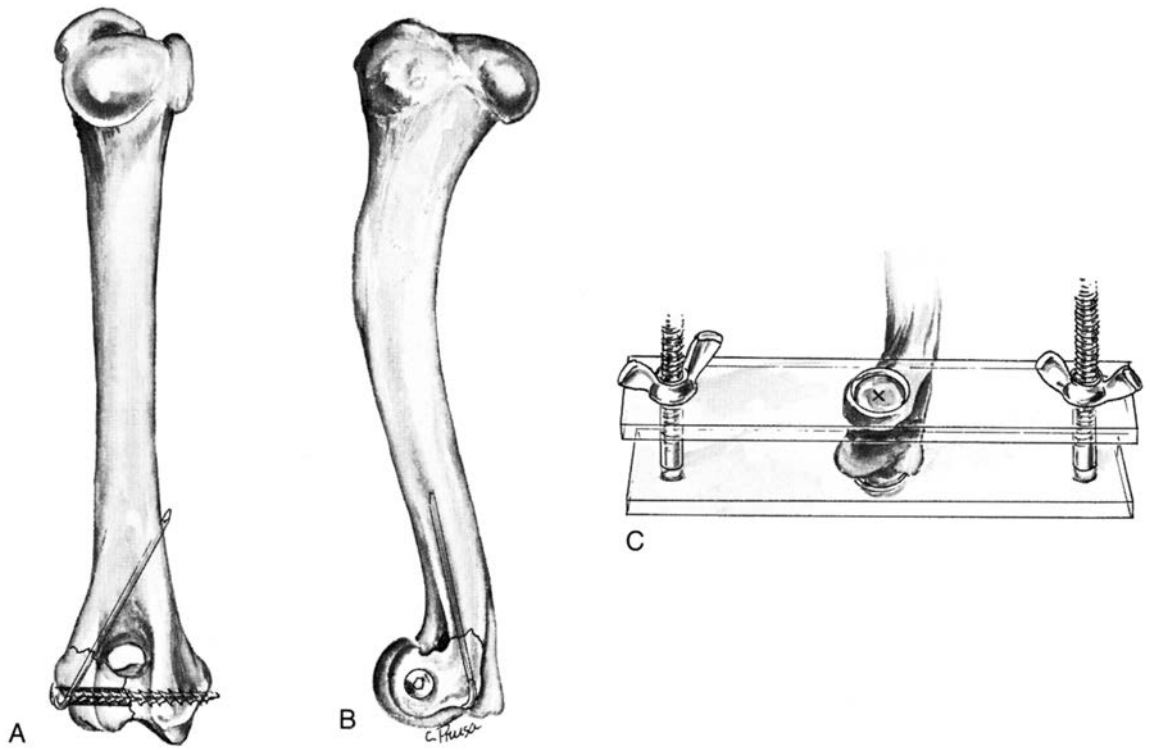

Figure 56-17. A lateral condylar fracture stabilized with a transcondylar cortical lag screw and Kirschner wire. The lateral condyle can be reduced temporarily with a condyle clamp (C) during placement of the transcondylar screw. Overdrilling the lateral condyle provides lag screw compression at the fracture site. The Kirschner wire placed in the condyle prevents rotation of the fragment. A. Caudocranial view. B. Lateral view.

placement of at least two screws distal to the fracture site. The larger plate is positioned on the caudomedial surface of the medial epicondyle. The second, smaller plate is placed on the caudal surface of the lateral epicondyle and the lateral epicondylar crest. Consideration is given to placement of all screws in both plates before drilling the holes to allow interdigitation of the screws. Compression of large bone fragments by lag screws placed through the plates should be performed whenever possible. Inadvertent placement of screws into the joint or olecranon fossa must be avoided to ensure an unrestricted, crepitus-free range of motion and a functional joint.

Condylar Fractures

Fractures of the lateral condyle of the humerus occur more frequently than medial condyle fractures. Forces transmitted along the radius largely affect the lateral condyle, creating shear forces and predisposing it to fracture. Radiographs of lateral condyle fractures usually reveal a subluxated elbow joint with cranial and lateral rotation of the fragment secondary to contraction of the extensor muscles. Fracture of the medial condyle causes caudal and medial displacement of the fragment.

Closed reduction of lateral condyle fractures is possible if soft tissue swelling is minimal and if the fracture is not of more than 24 to 36 hours' duration. Closed reduction requires considerable surgical expertise and is not generally recommended.

Lateral and medial condyle fractures are best managed by open reduction. A transolecranon approach provides the best exposure, although a medial or lateral approach may be adequate in selected cases. Subperiosteal elevation of the extensor carpi radialis muscle provides better visualization for reduction of lateral condyle fractures. Accurate anatomic reduction is paramount to a successful repair of the articular surface. Gentle curettage of the fracture site removes fibrin clots and interposed soft tissue that facilitates reduction. The fragment is reduced by digital manipulation and is stabilized temporarily with a condyle or bone clamp placed over the epicondyles. The clamp is positioned to allow access to an area slightly distal and cranial to the epicondyles for placement of a transcondylar screw. Reduction is evaluated by palpating the caudal surface of the lateral epicondyle, by assessing joint motion and by direct articular visualization. In cats and small breed dogs, a C-clamp placed across the condyles maintains reduction and provides a guide for drilling the condylar hole. The hole is measured with a depth gauge and is tapped to receive a cortical bone screw. The fracture is separated, the condyle fragment is overdrilled to create a glide hole, and the fracture is reduced. A transcondylar cortical screw of appropriate length is inserted and is tightened to provide lag screw compression.

An alternate technique predrills the lateral or medial condyle fragment from the fracture site and uses the hole as a guide to drill the opposite condyle. With both techniques, a Kirschner wire is placed caudal to the screw head and is driven up the lateral or medial epicondyle to the opposite cortex to prevent rotation (Figure 56-18). The transolecranon approach is repaired and is stabilized using a tension band wire technique. The joint is palpated to ensure a crepitus-free and unrestricted range of motion before closure. Postreduction radiographs are taken to assess implant placement, fracture reduction, and alignment of the articular surface.

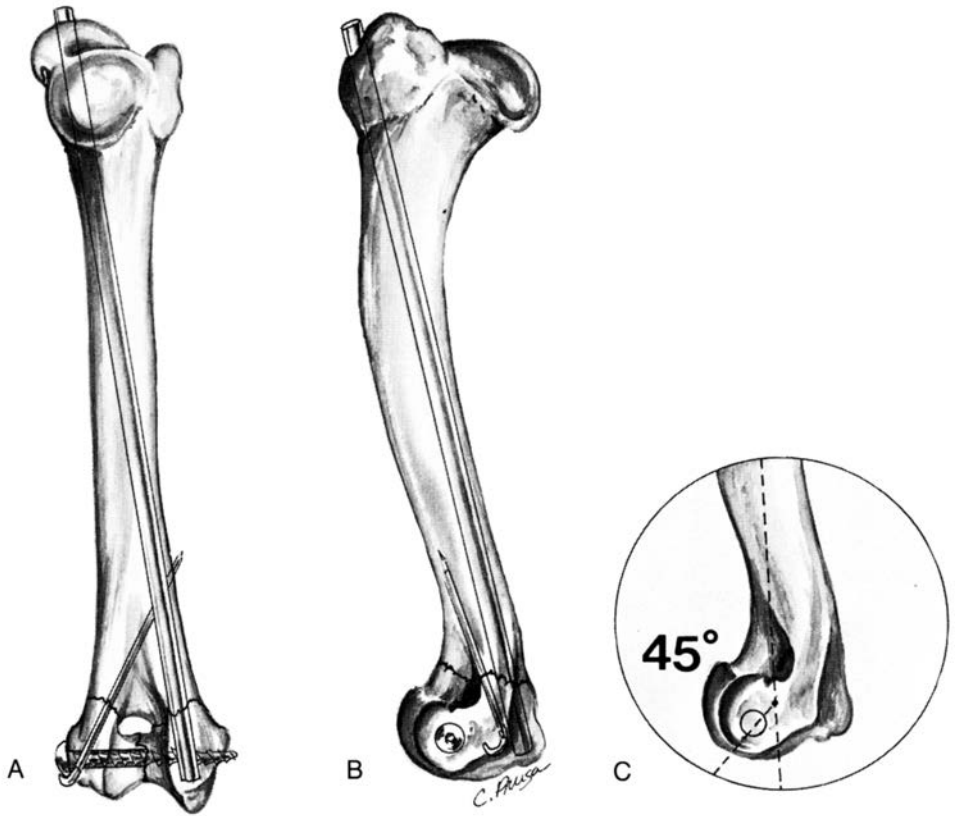

Figure 56-18. A double bone plate repair of a multiple supracondylar fracture. The plates are positioned on the caudomedial surface of the medial epicondyle and the caudal surface of the lateral epicondyle. A minimum of two screws should be placed distal to the fracture site in each plate. **A.** Caudocranial view. **B.** Lateral view.

General Comments for Management of Supracondylar and Condylar Fractures

For repairs of this type, the animal is positioned on its back, and the affected limb is aseptically prepared from the scapula to the carpus. A lateral approach is made, and the skin and subcutaneous layer are undermined and reflected as required to expose both sides of the elbow joint and distal shaft. When approaching the supracondylar area in cats, special care should be taken to preserve the median nerve, which passes through the supratrochlear foramen, and the ulnar nerve, which is located under the medial head of the triceps brachii muscle. Comminuted or multiple supracondylar fractures may require autogenous cancellous bone grafting, as described for comminuted shaft fractures. When bone grafting is anticipated, one or more donor sites are prepared preoperatively. After reduction and fixation, the graft is harvested and is placed in the fracture site immediately before closure.

A Robert Jones bandage is placed on the limb for 2 to 3 days postoperatively to control soft tissue swelling. Early physical therapy and restricted weightbear-ing are encouraged for the first 6 to 8 weeks. Unless contraindicated, removal of implants is recommended when the bone has healed, as demonstrated by radiograph examination. Appropriate analgesics are administered postoperatively to provide for patient comfort.

Intercondylar Fractures

Supracondylar fractures of the humerus occurring simultaneously with a condyle fracture are referred to as T or Y fractures. They are usually seen in mature animals in which the epiphysis has fused. Closed reduction with external fixation is not advisable. These fractures involve articular surface, and open reduction with internal fixation should be recommended as early as possible.

A transolecranon approach provides good visualization and facilitates anatomic reduction of the articular surface. The fracture site is exposed and is curetted to remove fibrin clots and interposed soft tissue. Reduction is performed and evaluated by observing the articular surface of the condyles and the alignment of the humeral shaft with the epicondylar ridges. The multiple fracture is converted to a single supracondylar injury by first repairing the intercondylar fracture. The condyles are immobilized with a condyle clamp or bone forceps, and two small Kirschner wires are passed in a transcondylar fashion to provide temporary fixation. A guide hole for a drill bit is placed distal and cranial to the lateral epicondyle using a small intramedullary pin. The drill site is located on a line 45° cranial and distal to a line passing through the lateral epicondyle and shaft of the humerus (Figure 56-19). The drill is directed toward a similar point cranial and distal to the medial epicondyle. Placement of the screw should be in the center of the condyles and parallel to the joint surface. In small breed dogs and cats, a C-clamp can be used to immobilize the condyles and to provide a guide for screw placement. A depth gauge is used to determine the screw length, and the hole is threaded with a bone tap. The lateral fragment is overdrilled to create a glide hole, and a cortical screw is inserted to create lag screw compression. Care must be taken to avoid over-compressing the fracture when tightening the screw and collapsing the soft cancellous bone of the condyle.

An alternative method for drilling the condyle is to predrill the proximal hole from the fracture site to a point cranial and distal to the lateral epicondyle. The hole is carefully centered in the lateral condyle. The fracture is reduced and is immobilized with a condyle clamp or small Kirschner wire. The medial condyle is drilled using the hole in the lateral condyle as a guide. The depth of the hole is measured, and the entire length is threaded with a bone tap. The lateral condyle is overdrilled, and a cortical screw is selected and inserted to provide lag screw compression. The transcondylar Kirschner wires are removed, except when additional fixation may be desirable. In cats and extremely small dogs, threaded pins or Kirschner wires can be substituted for screws to provide fixation.

Before repairing the supracondylar fracture, the condyles are palpated to ensure a crepitus-free, unrestricted range of motion. The condyles are attached to the shaft using the intramedullary pinning technique described for supracondylar fractures. After reduction of the supracondylar fracture, a pin of sufficient size to fill the medial epicondyle is selected, based on assessment of the preoperative craniocaudal radiograph. The pin is passed parallel to the caudal cortex of the medial epicondyle and is advanced in normograde fashion to penetrate the greater tubercle. The distal pin is cut off, and the bone chuck is applied to the proximal pin. The distal pin is drawn into the medial epicondyle, and the proximal portion is cut off at the greater tubercle. During placement of the intramedullary pin, the supracondylar and condylar fracture sites are checked repeatedly to ensure that reduction is maintained.

An alternative method of intramedullary pin placement passes the pin in retrograde fashion through the medial epicondyle. The fracture is reduced, and the pin is passed in normograde fashion up the humeral shaft, penetrating the greater tubercle. The pin is cut off as described in the previous technique. A Kirschner wire or a small Steinmann pin of appropriate size is directed up the lateral epicondyle to provide rotational stability. This pin enters the epicondyle immediately caudal to the transcondylar screw head, passes between the intramedullary pin and the cranial cortex of the humeral shaft, and penetrates the medial cortex (See Figure 56-18B). The combination of transcondylar screw fixation with pinning of the supracondylar fracture is applicable to all sizes of dogs and cats and provides an excellent method of fixation for this type of fracture.

A third technique for repair of these fractures uses double Rush pinning or cross-pinning of the supracondylar fracture combined with transcondylar lag screw fixation of the condylar fracture. This technique is more challenging, and maintaining anatomic reduction between the condyles and the shaft during pin placement can be more difficult (Figure 56-19).

Comminuted T or Y condylar fractures are unstable and usually require double bone plating for repair. These challenging fractures require exact anatomic reduction to achieve the best functional results. A trans-olecranon approach provides good exposure for reducing and stabilizing the fracture. A transcondylar lag screw is used to stabilize the condyles, and two bone plates are applied. One plate is positioned over the medial epicondyle and humeral shaft, and the other is placed over the lateral epicondyle and lateral epicon-dylar crest. For each plate, two screws are placed in the condylar fragment, and three screws are positioned in the humeral shaft. An autogenous cancellous bone graft is harvested and is placed in the fracture site before closure. The transolecranon osteotomy is repaired with a tension band wire technique.

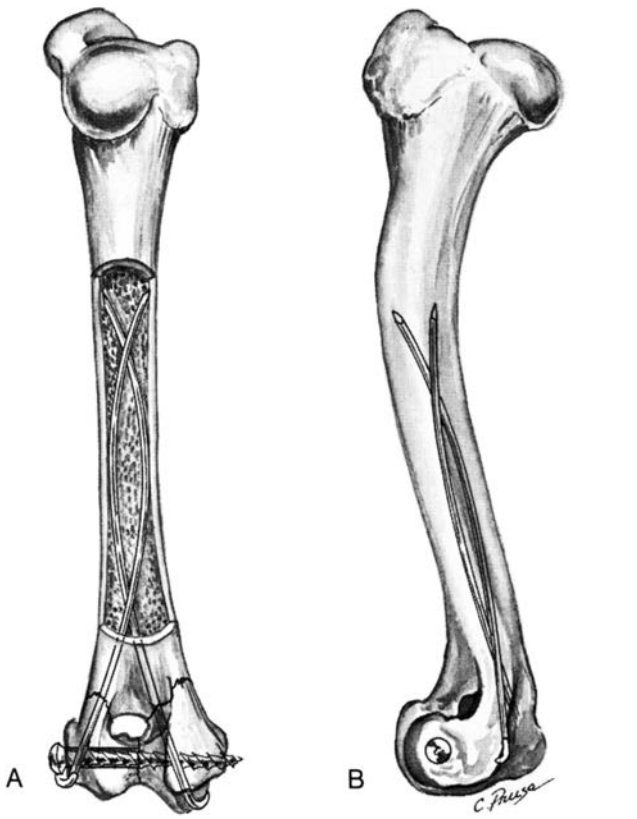

Figure 56-19. An intercondylar T fracture is stabilized with a transcondylar cortical lag screw and double Rush pins. **A.** Caudocranial view. **B.** Lateral view.

Postreduction radiographs are obtained to assess articular reduction and implant placement. Analgesics are administered to ensure patient comfort in the postoperative period. A Robert Jones bandage is applied to the limb for 3 to 5 days, followed by swimming physical therapy and range-of-motion exercises with controlled weightbearing for 6 to 8 weeks. The intramedullary pin should be removed when the bone has healed. The transcondylar screw, Kirschner wires, Steinmann pin, and bone plates are usually not removed unless they loosen or cause soft tissue irritation.

Treatment of Elbow Luxations

Robert A. Taylor

Elbow luxation refers to the disruption of the articular congruity of the three bones that constitute the elbow joint. Luxation can be traumatic or congenital, with the former more common. Most acute traumatic luxations can be reduced by closed methods; chronic luxations sometimes require open reduction. Surgical repair of congenital elbow luxation is directed at the underlying defect.

The elbow joint is a compound joint formed by the articulation of the humeral condyle, the radial head, and the semilunar notch of the ulna. It is classified as a hinge joint; that is, its major motion is confined to swinging in one plane. The humeral radial articulation allows for 90° supination of the distal extremity.[1] The unique configuration of the articulation with the anconeal process located deep in the olecranon fossa, the prominent medial epicondyle of the humerus, and the ligaments of this joint creates a stable articulation. The medial and lateral collateral ligaments connect all three bones; in addition, the oblique ligament, olecranon ligament, and annular ligament further enhance the stability of the elbow.

Congenital Luxations

Congenital elbow luxation is most common in small breed dogs and is thought to have a hereditary basis.[2] Agenesis or hypoplasia of the medial collateral ligament allows for rotation of the proximal radius and ulna with subsequent subluxation. The humeral trochlea and anconeal process usually are underdeveloped, and other secondary joint changes may exist in affected animals. This disorder has been reported to occur in combination with ectrodactyly.[3]

Closed and open methods of reduction of congenital elbow luxation have been reported.[4] Limb salvage and function, rather than complete articular reconstruction, should be the main objectives of surgical correction. Closed reduction has been recommended for dogs under 4 months of age. In older animals with long-standing luxation, open reduction is necessary.

Surgical repair of congenital elbow luxation may involve capsulorrhaphy, reconstruction of the humeral trochlea, reconstruction of the semilunar notch, partial removal of the anconeal process, and capsular imbrication. One should be aware of possible iatrogenic injury to the physis associated with elbow development during surgical reduction. In some cases, owners may elect conservative treatment or euthanasia. Owners should be counseled with regard to the probable hereditary nature of this problem.[2]

Traumatic Luxations

In the absence of fractures, traumatic elbow luxation results in caudolateral or lateral displacement of the radius and ulna. The larger size of the medial condylar surface of the humerus compared with the lateral condyle partly explains the motion of luxation. In addition, the orientation of the oblique ligament and the olecranon ligament is such that lateral luxation is more likely than medial luxation.

Animals with acute traumatic elbow luxation present with a nonweightbearing lameness of the affected limb. The limb usually is flexed, abducted, and pro-nated. Pain is evident on manipulation, and crepitus and articular incongruity are present. The elbow usually is twice its normal width.

Radiographs taken in two planes are needed to confirm the diagnosis (Figure 56-20). The surgeon must rule out articular fractures before attempting closed reduction of a luxated elbow.

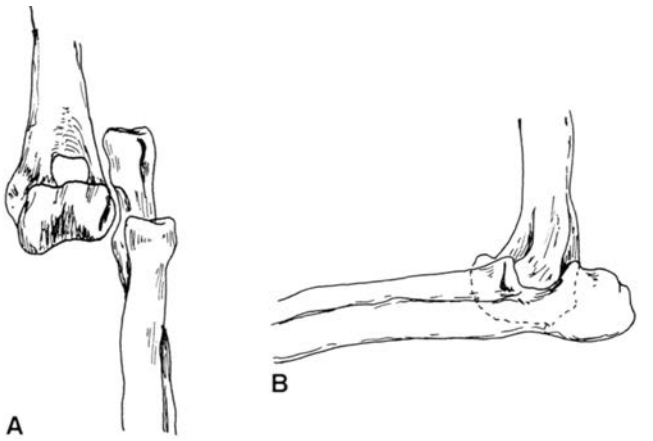

Figure 56-20. Craniocaudal and lateral views of the elbow showing the typical position of the radius and ulna after lateral luxation of the elbow.

Closed Reduction

General anesthesia is required for closed reduction of elbow luxations. Because the animal has sustained a recent trauma, a careful physical examination and assessment of associated injury must be performed before anesthesia is induced.

The animal is positioned in lateral recumbency with the affected limb uppermost. In long-haired patients, clipping the hair may be helpful to aid in the manual reduction of the luxation. Radiographs should be examined to determine the location of the anconeal process. If the anconeal process is laterally luxated, the elbow is flexed and the forepaw is rotated internally to force the anconeal process into the olecranon fossa.

With digital pressure on the radial head, the elbow is held flexed and the radius is pushed onto the humeral capitulum; the leg is then extended and flexed several times to ensure joint congruity. With the elbow flexed 90°, the forepaw can be rotated medially and laterally to check for collateral ligament integrity. If marked postreduction instability is present, surgical repair of the ligaments is indicated.

A soft padded bandage is used to support the limb and to limit swelling. Because early mobilization of the joint surfaces is necessary, the duration of immobilization is limited to 5 to 7 days. During this time, passive range-of-motion exercise should be encouraged.

The trauma necessary to produce luxation in a joint as stable as the elbow invariably results in damage to the articular cartilage, joint capsule, and collateral ligamentous support. Given time, some degree of degenerative joint disease usually results, and owners should be made aware of this possibility.

Open Reduction

Open reduction rarely is required in patients with acute elbow luxations; however, those with chronic luxations with associated capsular adhesions and contractures may require open reduction. In general, a lateral approach to the elbow is satisfactory, although in long-standing cases, a transolecranon approach gives greater exposure.[5] It is helpful to lever the radius and ulna[6] into place with a smooth periosteal elevator. Caution is necessary to avoid undue articular cartilage damage. Once reduced, the joint is worked through a normal range of motion, and any fibrin tags and debris are removed. If the lateral collateral ligament has been ruptured, the surgeon must decide to select primary repair or use screw and suture augmentation of the ligament.

Postreduction support is similar both with surgically reduced elbow luxations and with manually reduced luxations. Early activity, range-of-motion exercise, and weightbearing are important for proper rehabilitation.

Surgical Treatment of Ununited Anconeal Process of the Elbow

Ursula Krotscheck

Anatomy

The elbow, or cubital, joint is the convergence of three separate bones: the humerus, radius, and ulna. These form a hinge (ginglymoid) joint composed of three smaller joints: the humeroulnar (trochlea and trochlear notch), humeroradial (capitulum and radial head), and proximal radioulnar joints. The olecranon fossa of the humeral condyle articulates with the anconeal process (AP) of the ulna during joint extension beyond 90 degrees and restricts elbow movement in the sagittal plane.[8,38] The normal elbow joint has 3 distinct areas of contact: the craniolateral aspect of anconeus, the radius, and medial coronoid process (MCP). The latter two are continuous across the radioulnar articulation. There is no articular contact at the medial aspect of the anconeus as well as the central trochlear notch. Neither the size nor the location of the contact areas is affected by the amount of axial loading.

The soft tissue structures surrounding and supporting the elbow joint are important for examination purposes as well as for surgical and arthroscopic procedures. The joint capsule encloses all three bones into one space; its cranial and caudal pouches are important for arthroscopy and arthrocentesis.[6] The lateral collateral ligament originates on the lateral epicondyle, splits into cranial and caudal crura, and inserts on the proximal radius and ulna, respectively. The medial collateral ligament originates on the medial humeral epicondyle, crosses the annular ligament, and also divides into cranial and caudal crura. The annular ligament of the radius encloses the cranial aspect of the radial head and inserts on medial and lateral extremities of radial incisure of ulna. Several important nerves surround the elbow joint. The ulnar and median nerves are on the medial aspect of the joint. The ulnar nerve is caudal and superficial, and can easily be palpated as it crosses the caudomedial aspect of the joint. The median nerve, on the other hand, is deeper and more cranial. It crosses the joint distal to the medial epicondyle, continues deep to the pronator teres muscle along the median artery, and may be seen during a medial arthrotomy. The radial nerve is on the cranial and lateral aspect of the elbow joint; a deep branch extends under the extensor carpi radialis muscle while two superficial branches course along the medial and lateral borders of the cephalic vein.

In small dogs the MCP and AP mature by 16 weeks of age, while in large dogs AP ossification is not completed before 14 weeks of age and MCP ossification is completed approximately 6 weeks later.[1]

Pathogenesis

Ununited anconeal process (UAP) is defined as the failure of the anconeal process to undergo normal bony fusion with the proximal ulnar metaphysis by 20 weeks of age.[4] The anconeal process may exhibit partial or complete separation or it may be fused in an abnormal location.[23] Several explanations for development of an ununited anconeal process have been proposed, including abnormal formation of the trochlear notch, osteochondrosis, and most recently, articular incongruency secondary to asynchronous growth of the radius and ulna.[34,39] In chondrodystrophic breeds, a shortened ulna relative to the radius occurs due most likely to growth retardation or premature closure of the distal ulnar physis. The resultant short ulna causes the radius to push upward on the humeral condyle during its continued growth, thereby forcing the ventral margin of the anconeal process against the humeral trochlea. This upward force leads to separation or lack of fusion of the physis, resulting in an ununited anconeal process. This theory has been supported by clinical evidence: in 15 of 18 dogs examined, the anconeal process was proximally displaced the same distance

as the radius relative to the ulna.[34] Though spontaneous fusion of an UAP has been reported, it is considered rare.[9,10,34] If an ununited anconeal process is left in situ, elbow osteoarthritis (OA) will progress leading to suboptimal limb function.[41]

Clinical Presentation

Ununited anconeal process occurs much less frequently than fragmented coronoid process (FCP) or osteochondritis (OC).[19,27] It is most commonly seen in large to giant breed dogs as well as chondrodystrophic breeds such as the Basset hound and Dachshund.[23,34] Of the large to giant breed dogs, German Shepherds are over-represented.[33,39] Breeds with a secondary center of ossification of the anconeal process are likely predisposed to UAP,[38] though asynchronous growth may play a secondary role (chondrodystrophic breeds). Males are affected approximately twice as commonly as females, and breeding of affected animals is not recommended.[3,9,34,36,42]

Radiographic Examination

Radiographs are indicated in any dog in which UAP or any other form of elbow dysplasia is a differential diagnosis for forelimb lameness. The diagnosis of a UAP can usually be made using a maximally flexed lateral radiograph of the elbow joint (Figure 56-21). The cranio-caudal view is indicated to document the degree of OA. Many patients will resist flexion of the elbow due to the discomfort associated with UAP and may require sedation to obtain diagnostic quality radiographs. Radiographs of both elbows are always indicated as this is considered a developmental disease. A definitive diagnosis of UAP can be made if a line of cleavage separating anconeal process from ulnar metaphysis is radiographically apparent. This line can be of differing widths and the anconeal process can be normal or abnormal in position, size, shape and radiographic density. The degree of osteoarthritis apparent radiographically depends on the chronicity of disease (Figure 56-22).

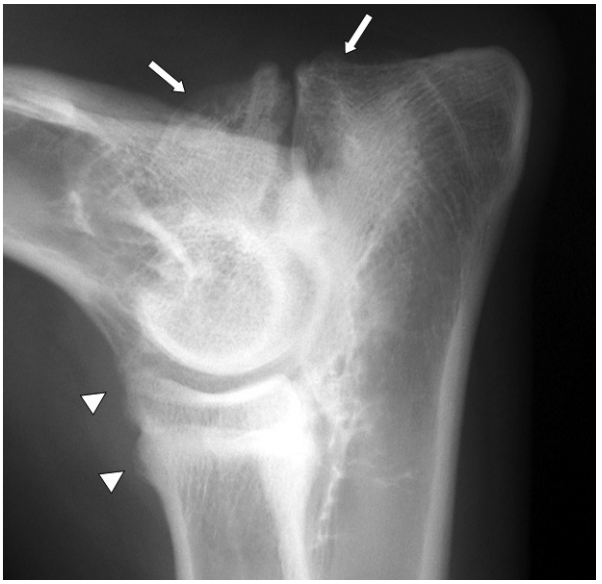

Figure 56-22. Severe OA secondary to UAP. Note the osteophytes on the dorsal aspect of the AP, surrounding the cleavage plane *(white arrows)* and on the radial head *(white arrow heads)*.

Treatment Options and Indications for Surgery

Surgical intervention is recommended for treatment of UAP.[38] If an ununited anconeal process is treated conservatively (left in situ), elbow OA will progress and likely cause less than optimal limb function.[41] Medical therapy includes weight management, controlled exercise, and appropriate medications (non-steroidal anti-inflammatories, osteoarthritis modifying supplements).[38] Conservative management is less successful than surgery and results in rapid progression of osteoarthritis.[4] The goal of treatment of an ununited anconeal process is the complete restitution of normal joint function.

Surgical options for UAP are its removal, reattachment to the ulna, and osteotomy/partial ostectomy of the ulna with or without surgical fixation of the anconeal process to the ulna.[7,8,11,13,17,25,29,30,32,33,34,37,39]

Surgical Removal of the Anconeal Process

(Table 56-1)

Initially, the recommendation was that all UAPs be surgically removed.[2,5,14,21,28,34] However, due to the inherent instability of the elbow following removal of the anconeal process,[41] the prognosis associated with this procedure has been variable. The lack of the anconeal process causes an unstable joint, reliably leading to a decreased range of motion of the elbow joint, increased osteoarthritis and a high incidence of post-operative clinical dysfunction.[9,10,18,21] One study reported that even though 70% of patients improved clinically following removal of the UAP, only 50% were free of lameness[9] whereas in another retrospective study, surgical removal resulted in good to excellent long term function.[29] Long-term results with excision are generally considered unsatisfactory because patients are not free of lameness. Removal of the anconeal process may still be an appropriate decision when it is misshapen and its preservation

Table 56-1. Published Outcomes of Anconeal Process Removal OA = Osteoarthritis, AP = Anconeal Process

Source	# joints	AP excision	Mean age (months)	Mean follow-up (months)	Change in osteoarthritis score
Sinibaldi 1975[32]	19	19		19.5	1 slight, 9 min, 5 mod, 4 severe
Parrisius 1985[21]	56	56		24.7	14% no change, 69% increase 1 grade, 17% increase 2 grades
Guthrie 1989[9]	19	19		6 to 72	7/7 re-evaluated progressed in OA
Meyer-Lindenberg 1991[18]	53	53		25	0 none, 8 minimal, 12 moderate, 7 severe (27 total)
Roy 1994[29]	7	7	8.7	73	all progressed in OA

would not restore joint congruity or if the dog has advanced osteoarthritis.

Reattachment of the Anconeal Process

(Table 56-2)

In an attempt to improve outcome, a technique was described whereby a compression screw is utilized to stabilize the ununited anconeal process.[10,25,26] This can be done from either the anconeal process into the ulna, or vice versa, though the latter is preferred because no implants are left within the joint. Results were encouraging and showed the stability afforded the joint by preserving the anconeal process.[7] Compression of the cleavage plane utilizing a screw placed in lag fashion stabilizes the anconeal process in a normal anatomic position and encourages bony fusion. By preserving the anconeal process, elbow joint stability is maintained, decreasing the potential for future development of osteoarthritis.[7] However, a complication encountered with any compression screw fixation is breakage of the screw.[31] This most likely occurs secondary to continued shear forces across the cleavage plane between the anconeal process and the ulnar metaphysis when the underlying elbow incongruity is not corrected. Stabilizing the anconeal process in an obviously incongruent joint may actually increase the forces acting on the articular cartilage of the anconeal process and the humeral trochlea, resulting in increased cartilage wear and potential screw failure. Continued incongruity will cause osteoarthritis to progress.

Reestablishment of Joint Congruity (Ulnar Osteotomy/Partial Ostectomy)

(Table 56-2)

An ulnar osteotomy or partial ostectomy is advocated to allow dynamic repositioning of the radius, relative to the ulna, thereby improving elbow congruity. It also lessens the pressure directed against the anconeal process, encouraging ossification of the cleavage plane.[20,33,34] Radiographic union of the anconeal process to the ulnar metaphysis has been variable with this technique,[34,39] but this appears to be dependent on the age of the dog at the time of surgery as well as whether or not the anconeal process is firmly attached to the ulna by fibrous tissue or is loose. Patients in whom the anconeal process is firmly fixed to the ulna appear to be more likely to proceed to bony union with only an ulnar osteotomy/partial ostectomy than those in which the anconeal process is loose at the time of surgery.[17] Failure to observe fusion of an ununited anconeal process after only an ulnar osteotomy/partial ostectomy is more prevalent when the age of the dog at the time of surgery is greater than seven to eight months.[11,39] These patients should have combination fixation (see below). A more favorable outcome is achieved with an ulnar osteotomy or partial ostectomy compared to surgical excision of the anconeal process.[34] Any time an intra-articular step with the ulna being shorter than the radius is evident within the joint at the time of surgery an ulnar osteotomy/partial ostectomy is indicated.

Overall, ulnar osteotomy or partial ostectomy alone should be performed in cases where the anconeal process is stable at the time of surgery or in animals 6 months of age or less. Additional fixation (lag screw) is indicated in any animal whose anconeal process is not stable at the time of surgery regardless of age.[17,38]

Combination Fixation Approach

(Table 56-2)

Combining both the ulnar osteotomy/partial ostectomy with lag screw fixation of the anconeal process has shown the most consistently promising results,[11,17] likely because it addresses the underlying cause (elbow incongruency) as well as the resultant pathology (UAP). The ulnar osteotomy improves the underlying elbow incongruency and relieves pressure directed against the anconeal process. Placement of the compression screw achieves the stability necessary to encourage fusion of the cleavage plane between the ununited anconeal process and ulna. In the long term, maintaining joint stability (preserving the anconeal process) and improving joint incongruency (osteotomy) should result in optimal clinical outcome.[11] Excellent long-term outcome with no to minimal OA progression has been achieved. Of 39 joints reported in the literature, radiographic fusion was achieved in over 97% of cases.[11,17] In another study, 13 of 20 dogs with UAP treated with the combination of an AP fixation and ulnar osteotomy/ostectomy were re-examined clinically and radiographically at a mean of two and a half years later. Nine (69%) had no lameness, four (31%) had no arthrosis, and 80% (16/20) of owners were satisfied with the outcome.[12] Best results are expected in dogs less than 6 months of age at the time of surgery.[16]

Surgical Techniques

Surgical options for UAP are its removal, reattachment to the ulna,

Table 56-2. Published Outcomes of Anconeal Process Fixation and/or Ulnar Osteotomy/Ectomy
OA = Osteoarthritis, AP = Anconeal Process

and osteotomy/ partial ostectomy of ulna with or without surgical fixation of the anconeal process to the ulna.[7,8,11,13, 17,25,29,30,32,33,34,39]

Anconeal Process Removal

Anconeal process removal can be performed via a caudomedial or caudolateral approach,[22] though the caudolateral approach is preferred due to the smaller size of the lateral humeral condyle making visualization, surgical manipulation, and fragment removal easier. Surgical removal using arthroscopy has also been described.[40]

Arthrotomy

The dog is placed in lateral recumbency with the affected limb up. During surgical manipulation, the elbow can be stabilized by placing a roll of towels or other padding underneath it. Two different surgical approaches have been described, one based on a procedure by Snavely and Hohn[35] (described here), and another based on a procedure by Chalman and Slocum.

Based on the procedure of Snavely and Hohn (Figure 56-23A-D): A curvilinear skin incision is made over the caudolateral aspect of the joint, centering over the lateral humeral epicondyle (Figure 56-23A). The incision extends from just proximal to the lateral epicondylar crest to several centimeters distal to the radial head. The subcutaneous fascia is incised along the same line, exposing the brachial fascia (Figure 56-23B). The radial nerve may be encountered if the incision is made too far proximally. The brachial fascia is then incised just cranial to the lateral head of the triceps brachii muscle where it inserts on the olecranon. The triceps brachii muscle is then elevated and retracted caudally to visualize the anconeus muscle underneath (Figure 56-23C). The anconeus muscle is incised at its periosteal origin at the lateral epicondylar crest and subperiosteally elevated (Figure 56-23D). Retracting the anconeus muscle caudally exposes the caudolateral joint compartment of the elbow and the anconeal process. Gelpi retractors can be used to maintain exposure. For closure, absorbable sutures are recommended in a simple interrupted or continuous pattern. The anconeus muscle is sutured to the origin of the antebrachial extensor muscles. The brachial and subcutaneous fasciae are closed in separate layers, followed by the skin closure.

Anconeal Process Removal

With the anconeal process exposed, the joint is placed in maximum flexion. The anconeal process can be removed with tissue or towel forceps. Usually fibrous attachments between the anconeal process and the ulna need to be severed.

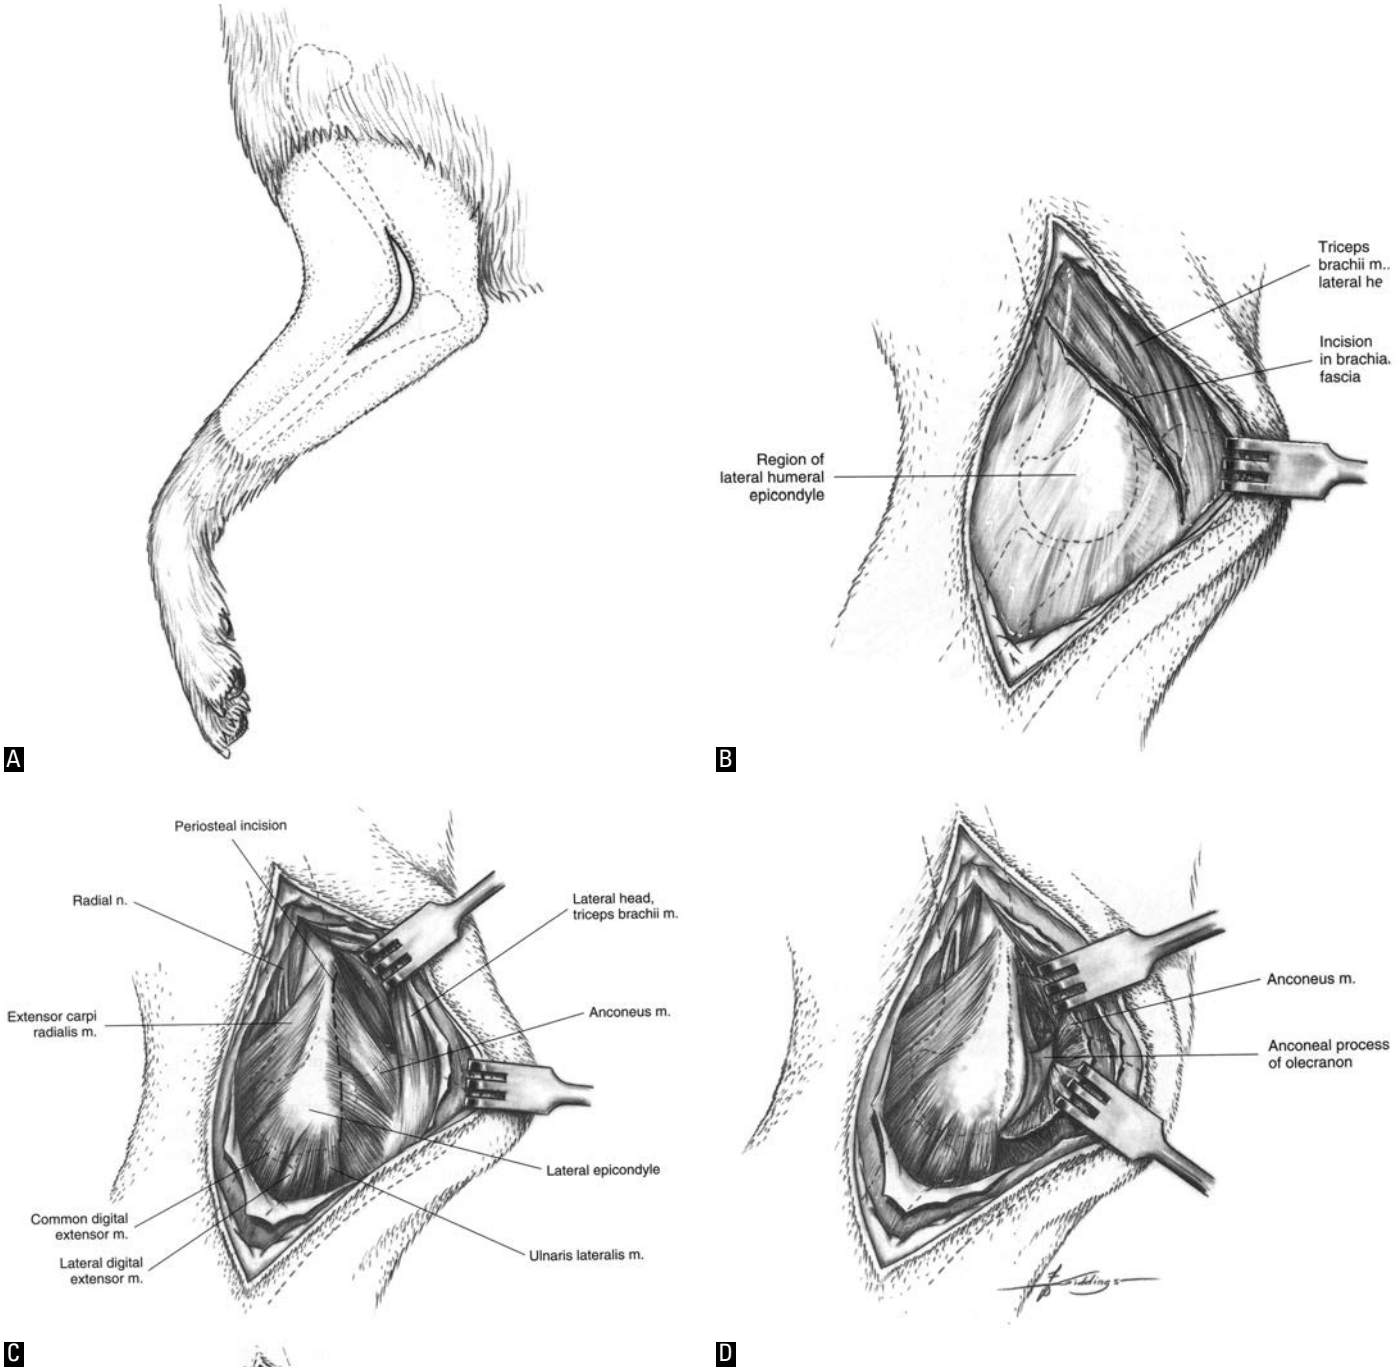

Figure 56-23A-D. Lateral approach to the elbow, see text for explanation. Reprinted from An atlas of surgical approaches to the bones and joints of the dog and the cat, 4th edition, Piermattei DL, Johnson KA. Approach to the lateral humeroulnar part of the elbow joint, 187-189, © 2004 Elsevier Copyright, with permission from Elsevier.

Ulnar Osteotomy

In chondrodystrophic and short-legged breeds, a distal ulnar ostectomy is recommended to prevent the creation of a painful nonunion that may occur after proximal or midshaft ulnar transection, while in long-legged dogs and non-chondrodystrophic breeds a proximal osteotomy or partial ostectomy is preferred.[15,38] Placing an intramedullary Kirschner wire is recommended for the fixation of proximal ulnar osteotomies or ostectomies to prevent caudal "kicking" of the proximal ulnar segment due to the pull of the triceps brachii muscle. Anconeal process removal or further fixation may be necessary if fusion is not observed 12 to 18 weeks after ulnar ostectomy and clinical signs remain.[38]

Proximal Ulnar Osteotomy/Partial Ostectomy

The skin is incised caudolaterally directly over the proximal ulna, followed in the same line by an incision in the underlying deep fascia. Periosteal incisions are then made in the origin of the flexor carpi ulnaris muscle medially and the ulnaris lateralis muscle laterally. The ulna is freed from its surrounding muscular attachments using a periosteal elevator. The ostectomy or osteotomy is performed 2 to 3 cm distal to the radial joint surface. The amount of dissection depends on whether a partial ostectomy or osteotomy is chosen. Hohmann retractors can be used to protect the soft tissues surrounding the ulna during the osteotomy. A sagittal saw is generally used for the ulnar cut(s). It is essential

to ensure that the osteotomy penetrates the entire ulna in order for joint congruity to be reestablished. The osteotomy may be straight or oblique at a 45° angle to the long axis of the ulna (caudoproximal to craniodistal) to minimize caudal angulation of the proximal piece and encourage rapid healing. In dogs in which this is the only method of UAP treatment, an ostectomy may be indicated as the oblique osteotomy may result in healing prior to restoration of joint congruence.[34] For the ostectomy, approximately 5 mm of bone and the surrounding periosteum are removed. The intramedullary pin can be applied normograde or retrograde. Normograde insertion is more difficult due to the small diameter of the target, but it will result in it exiting the ulna at a site amenable to surgical removal should that be needed. The surgical site is closed using absorbable sutures. The ulnaris lateralis and the flexor carpi ulnaris are sutured to each other over the caudal border of the ulna. The deep fascia, subcutaneous tissues and skin are closed routinely.

The intramedullary pin may cause discomfort, presumably due to interference with triceps muscle tendon of insertion. Once ulnar osteotomy or ostectomy site has healed, the intramedullary pin can easily be removed through a small incision.

Distal Ulnar Ostectomy

A skin incision is made directly over the distal lateral surface of the ulna, from the midshaft to the styloid process. Subcutaneous tissues are incised along the same line, exposing the underlying tendon of the ulnaris lateralis muscle over the distal ulna or slightly caudal to it and the tendon of the lateral digital extensor muscle is immediately cranial to the ulna. After identification of these tendons, the fascia between them is incised and retracted. The surrounding tissues, including part of the origin of the abductor pollicus longus if needed, are elevated from the ulna and protected from the sagittal saw using Hohmann retractors. The ostectomy is performed as above. Closure is routine: the fascia is closed, followed by the subcutaneous tissues and the skin.

Lag Screw Fixation of the Anconeal Process

The original procedure described screw placement from the anconeal process into the ulna, countersinking the screw head into the articular cartilage.[10] This has since been modified by placing the screw in the opposite direction, preventing the presence of an implant within the joint, creating a smaller hole in the anconeal process, and removal (if necessary) is easier and does not involve an arthrotomy.[25] A further modification is the addition of K-wires as a visual guide for screw placement and for anti-rotational purposes.[7]

The surgical approach to the joint for this procedure is as described above based on Snavely and Hohn (see Anconeal process removal). Once the anconeal process and the cleavage plane are visualized, a Kirschner wire (K-wire) is inserted into the anconeal process passing perpendicular to the cleavage line. It enters the caudal surface of the ulna, passes through the proximal quadrant of the anconeal process and exits 1mm beyond the articular margin. This allows visualization of the wire to assure its proper placement. A second K-wire and a compression screw are inserted sequentially using a drill guide. An aiming device can be used to facilitate proper K-wire and screw placement. The screw should be aimed towards the tip of the anconeal process. Either an appropriate length of partially threaded cancellous screw or a fully threaded cortical screw placed in lag fashion can be used. It is very important that there is no screw purchase within the ulnar metaphysis for both the lag screw and the partially threaded cancellous screw in order to ensure maximal compression of the cleavage plane. To achieve this with a fully threaded screw, a glide hole must be drilled through the existing thread (guide) hole to the cleavage plane. Its depth can be estimated by measuring the distance from the caudal aspect of the ulna to the cleavage plane along the line of the proposed screw placement. Screw sizes vary depending on the size of the anconeal process to be purchased, but 2.7 and 3.5 mm cortical screws and 4.0 mm partially threaded cancellous screws are most commonly used. After satisfactory screw placement, the initially placed K-wire is backed out until it is in the subchondral bone of the anconeal process, cut and bent in order to prevent migration into the joint. Its ideal position is 10 to 20 degrees divergent from the screw.[17] Post-operative radiographs are indicated (See Figure 56-24).

Proximal Ulnar Osteotomy and Lag Screw Fixation of the Anconeal Process

The combination of an ulnar osteotomy and lag screw fixation is used to address the underlying cause of the problem (elbow incongruity) and its resultant pathology (UAP). The procedure is performed as described above in the sections for lag screw fixation of the anconeal process and ulnar osteotomy/partial ostectomy. The general order of procedures is as follows: caudolateral arthrotomy, evaluation of the anconeal process and the tightness of its attachment, evaluation of joint incongruity, and lag screw fixation of the anconeal process followed by the ulnar osteotomy/

Figure 56-24. Post-operative radiographs using both lag screw fixation and proximal ulnar osteotomy.

partial ostectomy (Figure 56-24). It is thought that oblique ulnar osteotomy cuts may result in healing which is too rapid to allow for restoration of joint congruency.[34] This author concurs with that premise if the ulnar osteotomy is the only method of treatment for the UAP. If placing a lag screw in addition, the sliding oblique proximal ulnar osteotomy with an intramedullary pin appears to be adequate and comfortable for the patient. If in doubt, the joint should be evaluated for congruence after the ulnar osteotomy. If a large step remains, a partial ostectomy may be indicated. In dogs less than 6 months of age at the time of surgery that have minimal anconeal process instability, fixation using two K-wires is often sufficient.[16] This should always be combined with ulnar osteotomy or partial ostectomy in order to prevent continued incrongruency resulting in implant failure. In basset hounds, dachshunds and other chondrodystrophic breeds, a distal ulnar osteotomy/partial ostectomy is performed because the proximal procedure carries a higher risk of pseudoarthrosis formation in these breeds.[16] In dogs with longer legs, a proximal ulnar osteotomy/partial ostectomy is performed for better correction of joint incongruity, though it is associated with greater morbidity.[16]

Post-operative Care

Most surgeons recommend that the animal be placed in a soft support wrap for 2 to 5 days to decrease the immediate post-op swelling and minimize seroma formation. Exercise is generally restricted for 2 to 4 weeks[8,10,32] following anconeal process removal and until bony union has occurred in all other procedures. Passive range of motion exercise, heat and cold therapy, and non-steroidal anti-inflammatory drugs usually are implemented during the healing phase. Controlled walking on the limb is also encouraged. Removal of implants can be performed after bony healing is complete (Figure 56-25).

Figure 56-26. Failure on bony union of the UAP after treatment with a proximal ulnar osteotomy.

Complications

All surgeries described above carry a risk of infection, seroma formation, and bleeding. Osteoarthritis of the elbow may also continue after any of these procedures. Anconeal process removal itself does not carry any other major complications other than the probable increase in osteoarthritis. If only an ulnar osteotomy/partial ostectomy is performed, complications may include failure of the anconeal process and ulna to proceed to bony union, continued elbow incongruency, non-union of the ulnar osteotomy, chronic post-operative pain, and pin migration (Figure 56-26). Lag screw fixation of the ulna carries the possible complications of implant failure, failure of the anconeal process to undergo bony union with the ulnar metaphysis, and penetration of the joint surface with the screw or K-wire. When a combined treatment approach is used, all of the complications listed above are possible. Use of combined treatment does, however, appear to increase the likelihood of a positive outcome.

Figure 56-25. Radiograph of the dog in Figue 56-24 at three months after surgery. Note the lack of progression of OA.

Prognosis

Currently, there is no clinical trial definitively comparing all of the previously mentioned techniques, though some generalizations can be made based on the literature: Removal results in an increase of osteoarthritis in 93% of animals reported in the literature, though some lamenesses may temporarily improve, probably secondary to removal of the loose fragment. This procedure is likely indicated in those cases presenting as adults with severe osteoarthritis. The reported outcome with only lag screw fixation of the anconeal process has been disappointing with only 38% of reported cases achieving bony union. In one study, all dogs which did not achieve bony union had implant failure. Of the cases reported in the literature treated solely with an ulnar osteotomy, the overall rate of progression to bony union was 51%. Patient selection appeared to be important. If a fragment was firmly attached at surgery and the dog was less

than 7 months of age, it is reasonable to expect radiographic union and a good to excellent clinical outcome with only an ulnar osteotomy. If the animal is over 7 months of age or if the fragment is loose, combination fixation with a lag screw and ulnar osteotomy/ostectomy is recommended. Ninety-seven percent of cases which had this type of fixation continued to radiographic fusion (See Figure 56-26). Normal function even after strenuous exercise can be achieved in 82% of these dogs.

Surgical Treatment of Fragmented Coronoid Process

Ursula Krotscheck

Anatomy

See previous section on ununited anconeal processes.

Pathogenesis

In dogs, the medial coronoid process (MCP) develops exclusively by appositional ossification. The normal radioulnar articulation is a smooth transition between the ulnar trochlear notch and the proximal articular surface of the radial head.[58] During a dog's growth phase, the relatively early development of a trabecular pattern within the MCP reflects significant mechanical loading at an early age. It is loaded primarily in a direction perpendicular to the humeroulnar surface during normal weight bearing as evidenced by the primary axis of its trabecular orientation, while the tensile stress from the annular ligament forms a secondary axis.[62] Initially, a fragmented medial coronoid process (FCP) was believed to be a form of osteochondrosis (OCD),[39,40] but it has since been suggested that mechanical overload at an early age may lead to this condition.[17] The histologic and ultrastructural appearance of an FCP is more consistent with mechanical failure of the cartilage, its associated subchondral bone, and subsequent unsuccessful fibrous repair[17,22] than an osteochondrosis type of lesion. The characteristic osteochondral fissures or fractures associated with an FCP may be due to excessive loads experienced by the developing MCP secondary to conformational abnormalities, such as elbow incongruity.[17,58-60] Elbow incongruity is speculated to result from underdevelopment of the ulnar trochlear notch[8,15,58,59,61] or asynchronous growth of the radius and ulna (short radius, long ulna).[30,59,61]

In large, heavy-set breeds of dogs, the ulnar trochlear notch may not be large enough to accommodate the relatively big humeral condyle. When evaluating lateral radiographs of the elbow, the proximal ulna is significantly longer in breeds commonly affected with FCP compared to other breeds.[59,61] Additionally, heavy-set breeds have a slightly wider, larger, and less steeply sloping MCP than sight hounds.[58] When comparing the radius of the curvature of the ulnar notch in rottweilers and greyhounds, a significant and consistent difference was found, with greyhounds having a significantly greater mean radius of curvature at the end of the medial coronoid process, in comparison to rottweilers. The significance of these findings for dogs with FCP is unclear.[12]

As with an ununited anconeal process, the rate of growth of the radius and ulna in relation to each other is speculated to be part of the pathogenesis of FCP. Necropsies of dogs with FCPs have revealed that the MCP and the distal edge of the ulnar trochlear notch are often positioned slightly proximal to the adjacent articular surface of the radial head.[59,61] This incongruity then places excessive load on the developing MCP during weight-bearing and is implicated as the cause of fragmentation.[58-61] This agrees with the ultrastructural appearance of the FCP.[22] The most likely cause of this is a genetic predisposition to elbow incongruency leading to subsequent mechanical overload of the MCP.[18,50] Worsening of the phenotypic expression may be caused by caloric oversupplementation[58,61,65] and excessive calcium intake.[44]

Both osteochondritis dissecans and FCP have a polygenic mode of inheritance.[41] The heritability estimates vary from 0.27 to 0.7721,[48,49] and it is not recommended to breed dogs with this disorder, dogs producing offspring with this disorder, as well as phenotypically normal dogs with first degree relatives with this disorder.[41]

Clinical Presentation

FCP is one of most frequent canine developmental orthopedic disorders[8,26,34] and can occur in conjunction with OCD in the same joint. Often, the disease is bilateral.[30]

The age of presentation for clinical signs consistent with FCP in retriever-type dogs has two peaks: 5.9 months and 4.5 years.[31] Dogs bilaterally affected seem to present later because the lameness may be more difficult to recognize.[8] Male dogs account for 65 to 75% of cases in some studies,[19,28] while in a controlled breeding study to determine the inheritance of FCP and OCD males and females were equally affected.[41]

Clinical signs often consist of stiffness and a stilted gait or lameness occurring between four to seven months of age.[28,39] When the patient is standing, inward rotation of the elbow and external rotation, or supination, of the paw may be present. Pain on hyperextension or hyperflexion of the elbow is common and joint effusion of variable degree is usually present in more advanced cases. The development of osteoarthritis (OA) associated with FCP is influenced by the size of the fragment, its mobility, and the amount of time it has been present.[39] These fragments can be single or multiple and may involve only a small section of the MCP or its majority. It is interesting to note that the boxer is one of most frequently affected breeds presenting over 18 months of age, but radiographic evidence of OA in the affected joint is either absent or mild for unknown reasons.[34]

Diagnosis

Definitive diagnosis of FCP can be difficult. Techniques which have been used include plain film radiography, xeroradiography, linear tomography,[14] arthrography,[29] CT,[9,11] MRI and arthroscopy.[55,56]

Visualizing or definitively diagnosing an FCP using plain film radiography can be challenging. The MCP is a small ulnar projection obscured in normal dogs by the radial head and the ulnar shaft on standard views. The cleavage line cannot be seen if it is at all oblique to the x-ray beam. In young dogs radiographs can appear normal (Figure 56-27) while in older dogs only secondary OA changes are seen (Figure 56-28). Radiographic changes characteristic of secondary OA include periarticular osteophytosis of the dorsal aspect of the anconeal process (AP), the cranial articular margin of the radial head, the medial humeral epicondyle, and the MCP, as well as bony sclerosis of the ulnar trochlear notch.[5,28] The most significant radiographic lesion of FCP is osteophyte formation on the proximal margin of the AP.[24,36,57] Most osteophytes associated with FCP do not appear until the dog is 7 to 8 months of age.[2] Often, the radiographic diagnosis

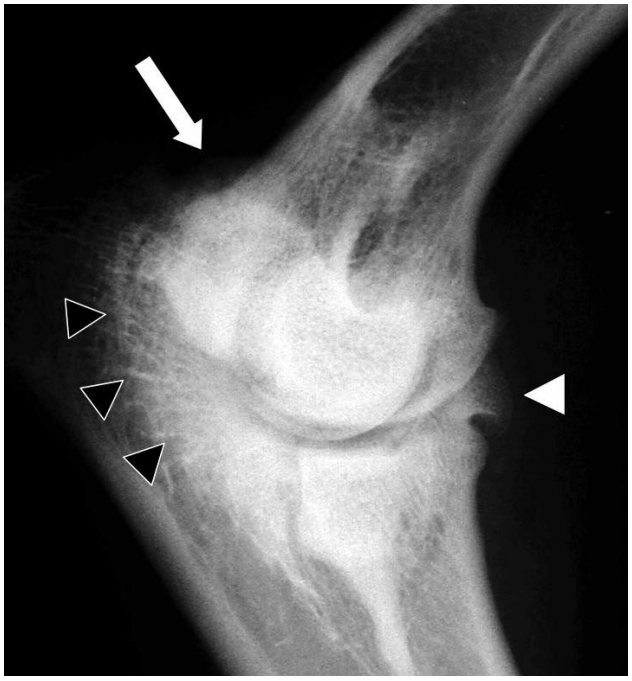

Figure 56-28. Radiographic changes consistent with osteoarthritis secondary to an FCP. Note the osteophytosis on the anconeal process *(white arrow)* and radial head *(white arrow head)*, and the sclerosis of the trochlear notch *(black arrow heads)*.

of FCP is based on these secondary OA changes.[4,6,18, 39,45,57] The accuracy and sensitivity of survey radiographs in detection of FCP is 56.7% and 23.5%, respectively.[11] Several alternative radiographic projections have been evaluated for their ability to definitively diagnose FCP. In one study, the MCP was best visualized on a mediocaudal-laterocranial 15° oblique (extended and supinated mediolateral) radiographic projection when compared to the standard mediolateral and flexed mediolateral views.[36,57] Another study agreed with these findings, stating that the Cr15L-CdMO provided greatest sensitivity (62%) for definitive identification of an FCP when it existed and the greatest agreement among evaluators.[64] A more recent study compared the Cr15L-CdM oblique and the Di35M-PrL oblique views (in addition to standard radiographic views) and found that a normal MCP was best identified on the Di35M-PrL oblique view, concluding that the Di35M-PrL oblique view enhances the identification of anomalies and fragmentation of MCP compared to other views.[23]

Because of the inherent difficulty with the definitive diagnosis of FCP on plain radiographs, other imaging modalities have been evaluated. Using arthroscopy as the definitive diagnostic method for FCP, computed tomography (CT) had the highest accuracy (86.7%) and sensitivity (88.2%) and negative predictive value (84.56%) when compared to standard radiographs, linear tomography, and xeroradiography.[11] Other advantages of CT are the ability to not only evaluate the MCP, but also other aspects of the articular surfaces for defects and incongruities (Figure 56-29A and B). Sagittal reconstruction of CT images can be helpful in evaluating joint incongruity. Magnetic resonance imaging (MRI) is also more accurate than conventional radiography for FCP detection in dogs.[46] Magnetic resonance arthrography permits classification of an FCP into 2 categories: completely loose fragments and fragmented processes that are still attached to the ulna by a cartilaginous bridge, but this did not provide substantial additional information about changes on MCP compared to MRI without contrast.[47] In general, CT and MRI have higher accuracy, sensitivity and specificity than plain radiographs.[11,46] Regardless, no noninvasive imaging modality currently available to veterinary medicine can make a diagnosis of an FCP with 100% certainty.[53] It was recently proposed that arthroscopy is the best diagnostic technique for determining the cause of elbow disease when there is no radiographic proof of FCP.[34] Comparison of standard radiographs, CT and arthroscopy in lame dogs elucidated that only arthroscopy allows consistent definitive diagnosis of elbow lesions before the development of OA.[56]

Treatment Options and Indications

Osteoarthritis is expected to progress in most dogs with FCP. Because of this, all dogs with FCP should be started on conservative medical management regardless of surgical intervention. This consists of dietary control of growth, weight management, exercise moderation, non-steroidal anti-inflammatory drugs, and chondroprotective agents. Early surgical removal of an FCP has been the treatment of choice.[31,42,43,54] This may have a better outcome than conservative medical management; especially if the dog is a companion animal and the surgery is performed prior to 2 years of age. According to owner questionnaires, 78% of dogs which had surgery at less than two years of age returned to apparent soundness.[31] Traditionally, in older dogs with severe OA secondary to FCP, medical management has been recommended over surgical FCP removal.[4,6,18,39] Evidence suggests that with only conservative therapy, elbow OA progresses significantly and the duration of lameness increases,[6,18,35,62] thus leading to the recommendation for surgery even in older patients with chronic OA.[33] Over half of patients followed radiographically after FCP removal did not increase in OA grade, suggesting that surgery may prevent worsening of the secondary OA.[19]

Figure 56-29. Computed tomography images of the dog in Figure 56-27. Note the normal left MCP **A.** and the area of chondromalacia on the right MCP **B.** *(white arrow).*

On the other hand, there are studies documenting a lack of positive influence of surgical intervention on the progression of secondary OA.[7] Part of the lack of improvement after surgical intervention and continued OA may be explained by remaining elbow incongruity. If present at the time of surgery, it can be addressed with an ulnar ostectomy/osteotomy.[30,37] It has been recommended that this surgery should be performed early to prevent changes to other ulnar structures. When combining FCP removal with a proximal ulnar osteotomy, the average time to improvement was 8.6 weeks. Nine of 10 dogs had a good to excellent clinical outcome with almost full range of motion (ROM), absence of pain and crepitation in the elbow, and no signs of lameness. Late follow-up radiographs showed mild caudomedial rotation of proximal ulna: 10 to 15 degrees caudally and zero to five degrees medially compared to the pre-operative images, with the author commenting that the fear of excessive rotation of the proximal ulnar fragment is unfounded.[38] OA did progress in most of these dogs. It has been recommended not to stabilize the osteotomy even though this might speed recovery and reduce callus formation. The risk of maintaining the fragment in an inappropriate location is minimized with an unstable osteotomy and optimizes the chance of achieving good functional elbow joint anatomy.[38] Along these lines, it has been hypothesized that with an early ulnar osteotomy/ostectomy, the removal of an FCP may be unnecessary because it could consolidate following relief of the excessive pressures it is subjected to in an incongruous elbow.

Several surgical approaches to the elbow for FCP removal have been described: triceps tenotomy,[6] olecranon osteotomy,[6] proximal ulnar diaphyseal osteotomy,[27] osteotomy of the medial epicondyle,[24] muscle separation with tenotomy of the pronator teres and/or in combination with tenotomy of the flexor carpi radialis,[16,32] muscle separation between the pronator teres and flexor carpi radialis muscles,[13,18,42] muscle separation between the flexor carpi radialis and flexor digitorum profundus muscles,[18] and longitudinal myotomy of the flexor carpi radialis muscle.[1] Adequate exposure to the medial compartment of the elbow joint for medial humeral condylar OCD and FCP evaluation and treatment can be obtained with either medial epicondylar osteotomy or a muscle separation technique with or without tenotomy of pronator teres or flexor carpi radialis muscle(s).[8] Significantly increased complications requiring additional surgery have been reported with the osteotomy approach and multiple authors suggest using one of the muscle separation techniques instead.[28,52] There are no other significant differences between the muscle separation and epicondylar osteotomy techniques in gait, range of motion, joint thickness or joint pain, but muscle mass measurements were significantly greater in the osteotomy group.[52]

Surgical Treatment by Arthrotomy

(Figure 56-30A-D)

The muscle separation approaches provide adequate exposure and a medial humeral epicondylar osteotomy is generally not needed. The approach described here is one of the more commonly used, varying from others only by which muscles are separated. The dog is placed in dorsal recumbency with the affected limb suspended for surgical preparation and draping. The limb is abducted once draped and the elbow is stabilized by placing a roll of towels or other padding underneath it.

A curvilinear skin incision is made over the medial aspect of the joint, centering on the medial humeral epicondyle and extending along the proximal ulna. The ulnar nerve crosses the medial epicondyle of the humerus just proximal to the origin of the humeral head of the superficial digital flexor and then continues on under the ulnar head of the flexor carpi ulnaris muscle. It should be protected during the fascial incision. The antebrachial fascia is incised along the same line as the skin and retracted, exposing the flexor muscle group. The muscular septum between the flexor carpi radialis and the deep digital flexor muscles or the pronator teres and flexor carpi radialis muscles is identified and bluntly separated (Figure 56-30A). The median artery and nerve will be visible in most dogs when dissection is complete. Hemostasis from intermuscular vessels is achieved with cautery and ligation. The muscles can now be separated by retraction, exposing the underlying joint capsule (Figure 56-30B). Desmotomy of the medial collateral ligament can be performed to increase exposure, though it is generally not needed for FCP removal. The joint capsule is carefully incised either along the same line as the muscles or horizontally along the joint line. It is then tagged and retracted to expose the articular surfaces of the humerus and ulna (Figure 56-30C). In order to completely visualize the MCP, the incision may need to be extended parallel to the ulnar trochlear notch, being careful not to sever the medial collateral ligament. Pronation and

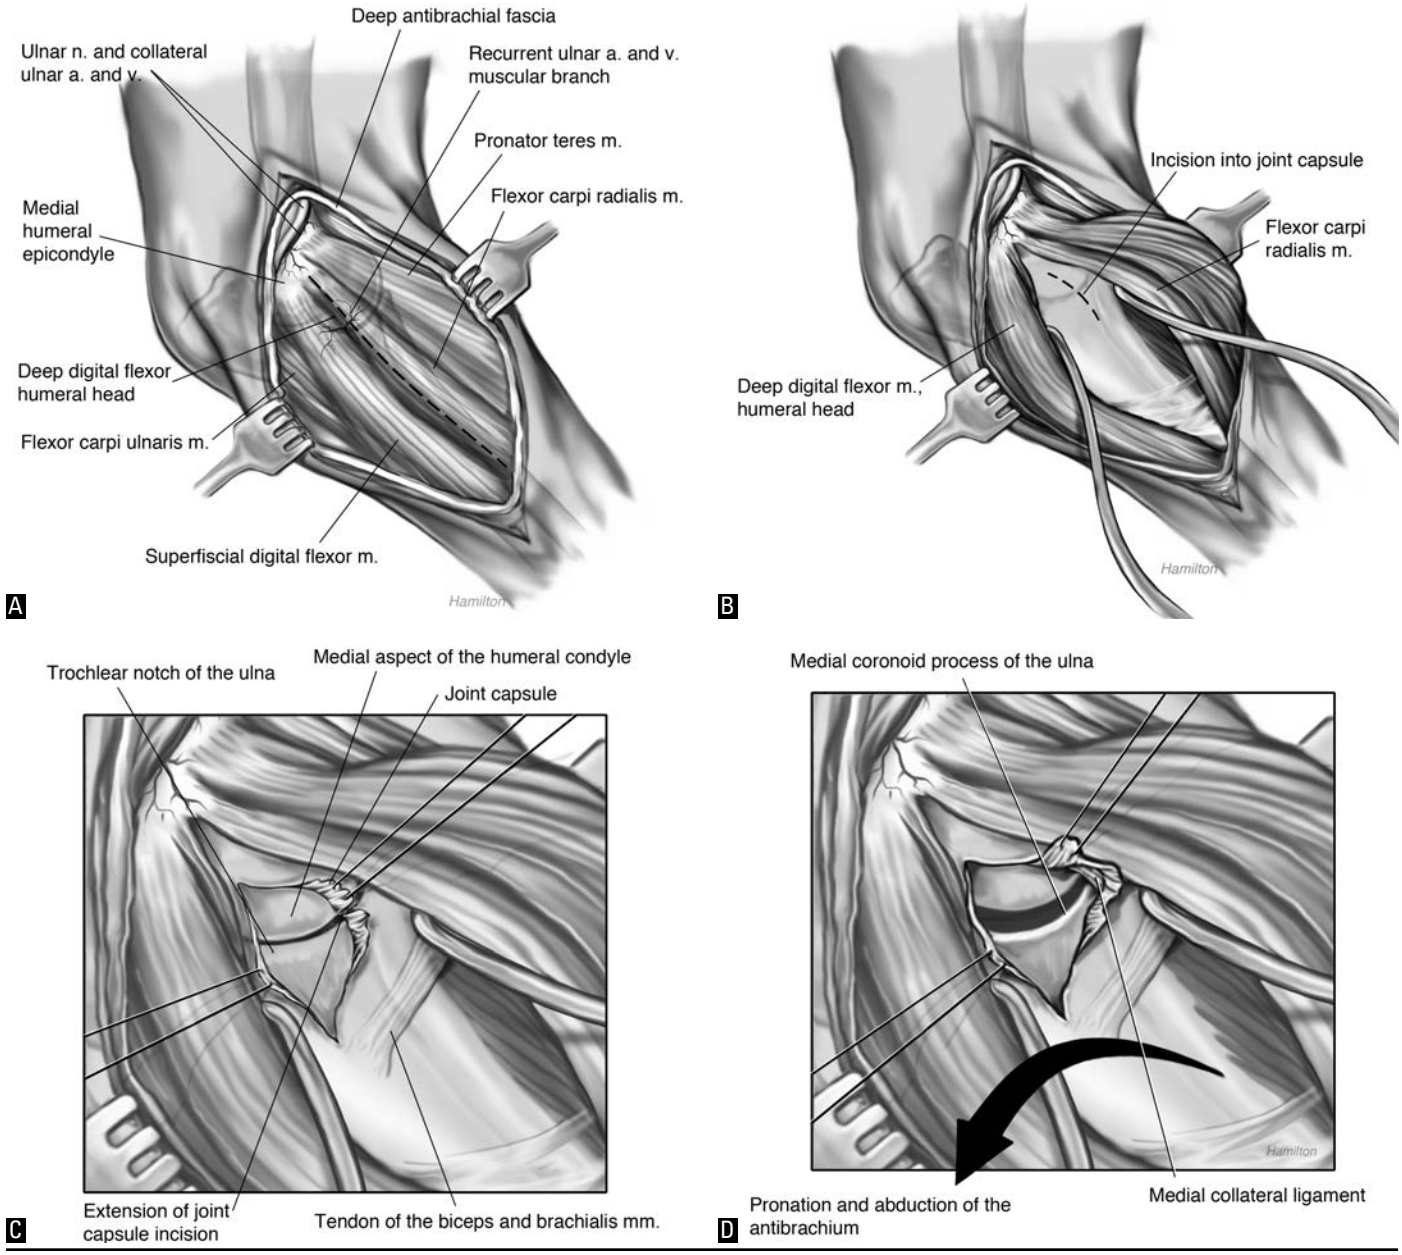

Figure 56-30. A-D. Medial approach to the elbow by an intermuscular dissection technique, see text for explanation.

abduction of the antebrachium opens the medial joint surface; the previously placed towels or padding under the elbow facilitate this maneuver (Figure 56-30D). A fair amount of pressure may be required for adequate visualization. The FCP can then be removed using rongeurs, curettes, or hemostatic forceps depending on its soft tissue attachments, size, location and remaining bony attachments. After fragment removal, the joint is flushed profusely and closed in a simple interrupted pattern using absorbable suture material. Following this, the intermuscular septum, brachial fascia, and subcutaneous tissues are closed in separate layers, followed by the skin closure.

Treatment by Arthroscopy

Arthroscopy is rapidly becoming a common method of FCP removal and joint exploration. Advantages include the minimally invasive approach, a greater area of visualization within the joint, and lower risks of complications usually associated with an arthrotomy. Its main disadvantages are the equipment requirements and the time needed to become proficient at arthroscopy.

The following is adapted from Beale et al,[3] and the reader is referred to this resource for a more in depth discussion. The arthroscopic procedure for evaluation of the elbow joint was originally described using a 2.7 mm, 30° rigid arthroscope. Beale et al recommend a 1.9 mm, 30° short scope because it causes less cartilage trauma in small joint such as the elbow.

Fluid inflow

For larger joints gravity inflow can be used, however small joints need a fluid pump due to higher pressures required to keep the joint open. It is recommend using 60 to 70 mm Hg pressure with a relatively low flow rate (10 to 20%) to avoid sudden surges.

Instrumentation

Power instruments are not required for elbow arthroscopy, but they can make surgery quicker, especially if large fragments are to be removed. An aggressive power shaver and a burr can be used. Arthroscopic cautery units or radiofrequency instrumentation are not recommended as they may pose a risk to the median and ulnar nerves.

Patient Preparation

The patient is prepared for open elbow surgery as if using the standard medial approach (see above) in case arthroscopy is unsuccessful and an arthrotomy must be pursued. The dog is placed in dorsal recumbency, especially if bilateral arthroscopy is planned, but can be placed in lateral recumbency with the affected limb down if only one side is affected. The surgery table, custom-made braces or towels can be used as a fulcrum for joint distraction.

Procedure

The assistant surgeon maintains the leg in a normal standing angle, positions the joint over the fulcrum, and places moderate downward (lateral) pressure on the antebrachium to open the medial compartment of the joint. Internal rotation also enlarges the joint space. For arthroscopic treatment of an FCP, 3 portal sites are generally used.

Egress

(Figures 56-31 and 56-33)

The egress is established first. Insert a needle craniodistal and slightly lateral, starting just proximal or adjacent to the anconeus, directing the needle so it sits in the joint pouch just proximal to the anconeus. A syringe is attached to aspirate joint fluid in order to ensure proper placement within the joint. If the needle is not within the joint space and fluid is injected, the difficulty of the procedure rises due to obscured landmarks, and external fluid pressure can cause the joint space to collapse. Lactated ringers solution may cause less damage to cartilage than saline. The joint is filled until moderate backpressure is felt in the syringe plunger. Underfilling makes scope portal establishment difficult and more traumatic, while overfilling may cause rupture of the joint capsule and loss of the fluid into the periarticular soft tissues. The assistant surgeon maintains pressure on the syringe to maintain joint pressurization during the arthroscope portal insertion.

Figure 56-31. Plastic bone specimen demonstrating ideal needle placement for egress establishment for arthroscopy of the elbow.

Arthroscope Portal

(Figures 56-32 and 56-33)

A blunt obturator is usually used within the arthroscope cannula. To determine the appropriate site for portal insertion, a line is drawn from the medial epicondyle distal to the level of the joint line, and then approximately 5 mm caudally. A needle is placed to ensure the appropriate location, after which a proximodistal incision is made through the skin and soft tissues. It is imperative not to incise into the joint capsule, otherwise joint distention is lost and fluid can extravasate. Having the assistant maintain the valgus force on leg, the scope cannula is inserted into the joint through this incision. Removing the obturator, fluid will rush out if the cannula is placed correctly.

Instrument Portal

Once the joint has been examined with the arthroscope, the instrument portal is established. A needle is inserted into the joint at the level of the medial collateral ligament at the same level and angle as the arthroscope. Triangulate the needle and arthroscope until the needle tip is visualized within the joint. Once the needle is visualized, use a blade to make an incision directly adjacent to the needle. Immediately remove the needle

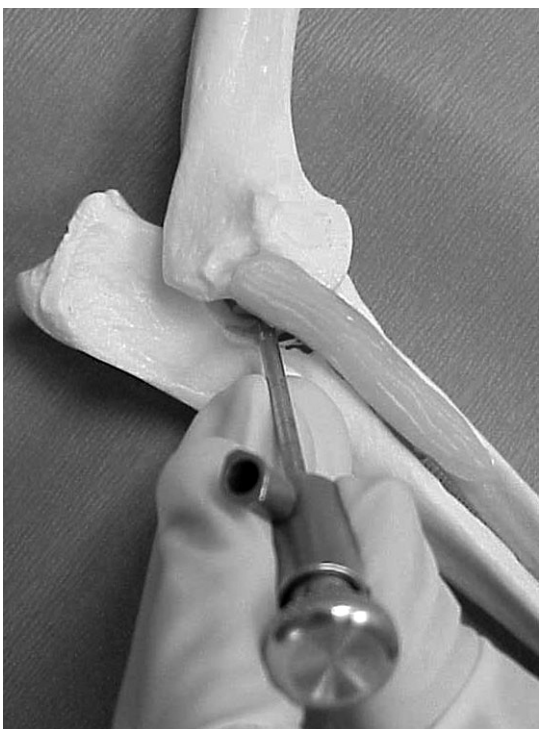

Figure 56-32. Plastic bone specimen demonstrating ideal arthroscope portal placement for arthroscopy of the elbow suspected of having an FCP.

Figure 56-33. Dissected cadaver specimen demonstrating arthroscope portal and egress placement for arthroscopy of the elbow suspected of having an FCP.

and insert a blunt trocar if planning to work through a soft tissue tunnel, or a cannula with trocar if planning to work through an instrument cannula.

FCP Assessment and Removal

(Figure 56-34A and B)

A probe can be used to assess the cartilage texture. If chondromalacia is present, the cartilage should be debrided and the underlying bone assessed. Removal of avascular bone is always indicated, even if it is palpably stable. Care must be taken not to injure the normal articular cartilage.

Ulnar Osteotomy

The use of an ulnar osteotomy has been reported both with and without fragment removal. The osteotomy is performed in a craniodistal oblique direction or transversely as described in the previous section of Chapter 56 (Surgical Treatment of Ununited Anconeal Process of the Elbow).

Postoperative Care

Most surgeons recommend that the animal be placed in a soft support wrap for 2 to 5 days to decrease immediate post-op swelling and minimize seroma formation. Exercise is generally restricted for 2 to 4 weeks following FCP removal. Passive range of motion exercise, heat and cold therapy, and non-steroidal anti-inflammatories usually are implemented during the healing phase. Controlled walking on the limb is also encouraged.

Prognosis

Surgical outcome is strongly dependent on several preoperative conditions. It tends to worsen with increasing age, a longer pre-operative duration of lameness, an increase in elbow incongruence, and an increasing OA grade. It is also negatively influenced by presence of a UAP and/or OCD lesions.[1,4,6,10,18,39,60,62] Other factors that affect prognosis are the age at which elbow dysplasia develops, the rate of disease progression, and the breed.[8] OA is expected to progress in all dogs, regardless of surgical intervention or not, though the severity seems less in operated patients.[33] Some studies do not show a difference between surgical and conservative medical management of FCP,[7,25] but most studies do. Surgical treatment of FCP seems to have a favorable result at both 6 weeks and 6 months post-operatively, despite progression of OA.[51] Interestingly, the severity of "kissing lesion" in the medial humeral condyle and the OA grade did not predict surgical outcome in one study.[51]

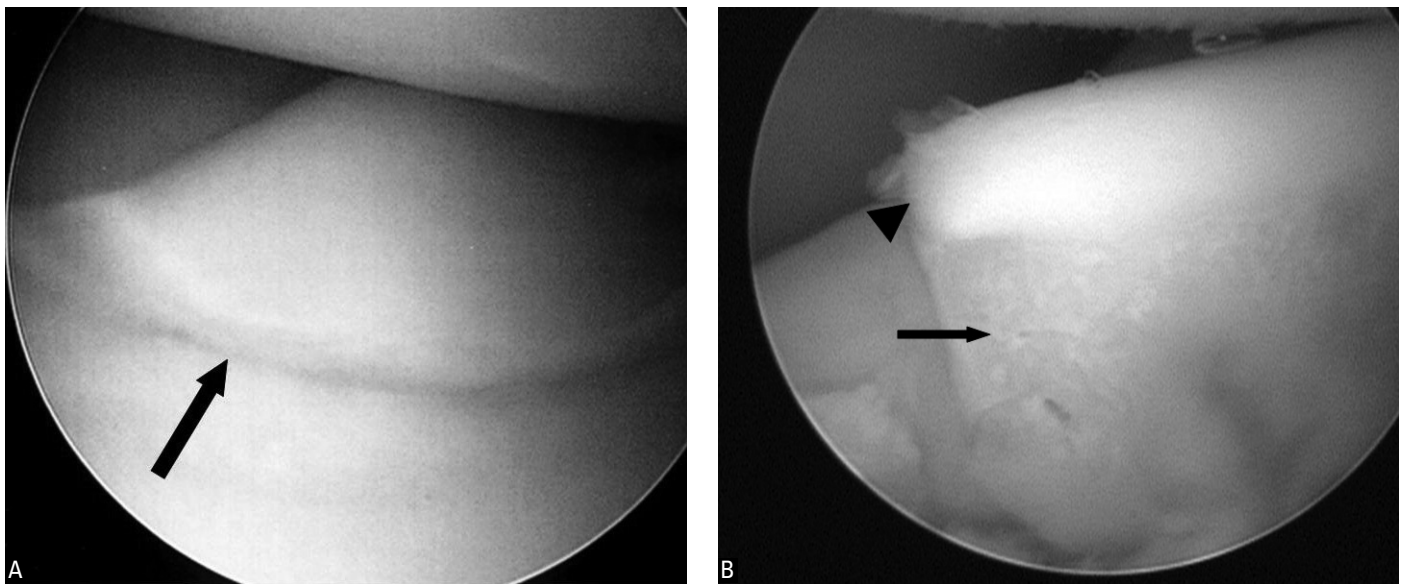

Figure 56-34. Arthroscopy images of two separate dogs with FCP. **A.** nondisplaced FCP. Note the fissure line in the articular cartilage *(black arrow)*. **B.** displaced FCP. Note the "wedding cake" appearance of the fragment: articular cartilage *(black arrowhead)* overlying yellow subchrondral bone *(black arrow)*.

A better outcome is expected with a lower pre-operative OA grade[10,18,19,61] and the progression of OA appears slower in dogs that are surgically managed (4.9 Guthrie points/month for FCP excision and ulnar osteotomy, 6.7 Guthrie points/month for FCP excision only) than those that received only conservative management (9.7 Guthrie points/month). It is important to note that these groups can not be directly compared due to variations in age.[20] Overall, a good outcome can be achieved in up to 75%of the cases operated at 4-6 months of age, decreasing to 42% in older dogs. Pre-existing OA seems to be the major determining factor: in one study animals without OA accounted for 60% of the cases with a good outcome.[10]

Total Elbow Replacement in the Dog

Michael G. Conzemius

The Causes and Frequency of Elbow Osteoarthritis

Elbow osteoarthritis (OA) secondary to fragmentation of the medial coronoid process (FCP), osteochondrosis (OCD), ununited anconeal process (UAP), intra-articular fracture, and elbow luxation is the most common cause of forelimb lameness in the dog.[1] Collectively, these conditions represent the cause of lameness for nearly 8% of all dogs that present to university hospitals for lameness.[1] The above conditions can be separated, based upon etiology, into either developmental (FCP, OCD, and UAP) or acquired (fracture and luxation) conditions. In addition, the developmental elbow abnormalities frequently occur bilaterally.

Treatment Alternatives and their Efficacy

The goal of nonsurgical and/or surgical management of the developmental abnormalities is to slow the progression OA in the joint and reduce lameness in the patient. Nonsurgical management includes using nonsteroidal anti-inflammatory medications (NSAIDs), weight reduction (if the patient is overweight), and moderate daily exercise. Surgical management is dependent upon diagnosis. Historically, FCP and OCD are treated with fragment removal via arthrotomy or arthroscopy. An UAP is treated by removal of the process, internal stabilization of the process, proximal ulnar osteotomy or by a combination of therapies. In addition to the surgical treatments listed, procedures to address cartilage defects, such as curettage of a subchondral defect, are commonly performed.

Unfortunately, nonsurgical and surgical management of developmental conditions of the elbow joint frequently lead to unsatisfactory results. Huibregtse et al. studied 22 dogs with forelimb

lameness caused by a FCP and provided evidence that elbow OA progressed radiographically in dogs following nonsurgical or surgical treatment.[2] In addition, they performed force platform gait analysis and found that there was no difference in limb function between groups and the pet owners reported a recurrence of lameness in 78% of dogs treated without and 69% of dogs treated with surgery.[2] Bouck et. al. studied 19 dogs diagnosed with FCP and/or OCD that were treated medically or surgically using physical, radiographic and force platform gait evaluations and found similar results: regardless of treatment, OA progressed radiographically and range of motion decreased over time.[3] Using force platform gait evaluations they did determine that dogs in both groups improved but there was no difference in the amount of improvement between treatments.[3] Read et al. studied the largest groups of dogs, reporting on 130 episodes of FCP in 109 dogs with 62 managed nonsurgically and 68 surgically.[4] In this retrospective study owners reported that the severity of lameness improved to some degree in 59% of dogs, regardless of treatment.[4] Lameness, however, persisted in 75.9% of all dogs studied.[4] Tobias et al. performed a long-term evaluation of 35 dogs that had surgery for FCP.[5] After evaluating an owner questionnaire, physical and radiographic findings they concluded that nearly 65% of dogs still had lameness, 80% had joint pain, and over 95% had joint thickening and a reduced range of motion at follow-up examination.[5] In addition, OA significantly increased in 100% of the cases.[5] Caplan et al. studied the radiographic progression of OA in 24 dogs treated non-surgically and 26 treated surgically for lameness because of a FCP provided and reported that, regardless of treatment, OA progressed in 100% of cases and that the progression of OA was similar regardless of treatment.[6] How prognosis is affected by a growing list of more recent procedures (arthroscopy, medial coronoidectomy, radial head lengthening, humeral osteotomy, etc.) will only be known after thorough investigation and speculation is beyond the scope of this chapter.

The goal of treatment of the acquired conditions is to restore normal anatomy. Conditions that frequently cause elbow OA include intra-articular fracture and luxation.[1,7-11] In addition, fracture of the radius or ulna can lead to OA in the elbow by two mechanisms. First, fracture of the one of the growth plates of the radius or ulna can cause asynchronous growth between the two bones leading to incongruity in the elbow.[12] Second, fracture and subsequent callus formation can cause synostosis between the radius and ulna which, in a growing animal can lead to incongruity in the elbow.[13] Although, treatment for these conditions can lead to a good prognosis, long-term complications are common. In one study, 45% of all cases that had surgery for traumatic luxation had an unacceptable clinical outcome.[11] Similarly, Gordon et al. reported that following surgery for humeral condylar fracture 50% of dogs had visible lameness and 100% had developed OA.[14]

Treatment Alternatives for Dogs with established OA

Treatment alternatives for dogs with moderate to severe elbow OA include nonsurgical management, debridement arthroplasty (removing loose bodies and osteophytes from the joint), and arthrodesis.[8,15,16] In a clinical report, one dog with severe elbow OA had surgery to remove fragmented medial coronoid processes and a fractured anconeal process; this dog returned to near normal function after surgery.[8] This case may be the exception, however, because the dog became acutely lame because of an intra-articular fracture. There are no reports in the peer-reviewed literature addressing debridement arthroplasty for moderate to severe OA in dogs. However, in one abstract it was suggested that this procedure provided good long-term results.[15] deHann et al. retrospectively investigated results after arthrodesis of the elbow and found that although pain in the joint was eliminated, function of the limb was limited.[16] In a review article addressing the surgical treatment of OA, it was stated that debridement was the primary and arthrodesis the secondary option for OA in the elbow. They also stated that total elbow arthroplasty was likely to be the best future option.[17]

Total Elbow Arthroplasty as an option in the Dog

Improvements in implant design and surgical techniques have made total elbow arthroplasty a satisfactory treatment for arthritic disorders of the elbow in man since the mid-1970s.[18] In two separate evaluations, 91% of total elbow arthroplasty cases had excellent long-term (~4 years) outcomes.[19,20] It is important to note that limb use in man after successful total elbow arthroplasty is far from normal. Limb functions that are possible include such activities as opening a door, using a fork, and bringing the hand to the back of the head.[19,20] The success that veterinarians have had in total joint replacement has mirrored that of physicians when it comes to hip and knee. In the dog, 90 to 95% of patients will have a good or excellent outcome after total hip replacement.[21] Current implant designs and surgical techniques for total knee replacement in man are commonly developed in canine models.[22] The similarities in implant design and surgical success found in the hip and knee are likely because of similarities in anatomy and joint mechanics.

The anatomy and mechanics of the elbow joint, unfortunately, are dramatically different between man and dog. The first and most obvious difference is that the dog is a quadruped, and the elbow is a load bearing joint during motion. In fact, the forelimbs have ground reaction forces (GRF) that are 75% greater than the rear limbs at a trot (velocity of 1.5 to 2.0 m/s).[23] Anatomically, the radius is the primary load bearing bone in the dog. In contrast, the ulna seems to be the primary load bearing bone in man. The difference is most likely explained by the fact that dogs almost exclusively load the elbow when in extension, whereas man generally loads the elbow when in flexion.[24] These differences in mechanical demands have led to differences in anatomy. The ulna of the dog is comparatively smaller and the radial head larger. These differences are reflected by the fact that radial head excision arthroplasty can be successfully performed in man.[25] Given an understanding of canine anatomy and joint mechanics, it is easy to understand why radial head excision is not even reported in the dog. This point is further reflected in designs of total elbow components for humans. Many currently used total elbow designs (Coonrad/Morrey elbow replacement prosthesis, GBS II design, Capitello-Condylar design, HSS-Osteonics Linked Semicon-

strained Total Elbow Prosthesis, etc.) utilize a humeral and an ulnar component. The radial head is removed during the surgical procedure.[18-20,25,26] These design concepts, although successful for the human elbow, seem inadequate for the canine elbow.

Total elbow arthroplasty has been reported in the dog. To the author's knowledge, Dr. Ralph Lewis was the first to report on experience with total elbow arthroplasty in the dog.[27] He used constrained (hinge-like) components and although he had some successful outcomes he concluded that because of a high complication rate the system needed to be redesigned. Vasseur et al., at the University of California at Davis designed a nonconstrained system and tested it in three dogs with naturally occurring elbow OA. Although their results are not reported it was suggested, via personal communication, that the dogs in that study had poor short-term and long-term results and the project was abandoned.

Conzemius et al. designed and reported on a semiconstrained, two component (humeral and radioulnar) system, based on a morphometric study in Greyhounds and tested it in six Greyhounds.[28] (Figure 56-35) The design was based on the rationale that a total elbow replacement for the dog should reflect the anatomy of a breed that is not predisposed to developmental elbow diseases. A semiconstrained design was selected because constrained (hinge-like) designs do a poor job of sharing load with intact ligamentous structures. Load is principally absorbed by the implant and concentrated at the implant-bone interface. This type of design has not withstood the test of time in load bearing joints; the best example being the human knee. Constrained total knee designs have a comparatively high rate of aseptic loosening and are reserved for use in revision surgeries of the knee when no ligamentous structures remain intact.[29,30] In addition, semiconstrained and nonconstrained designs can include shorter stem lengths relative to constrained designs. A feature that was appealing because of assumed anatomic differences that would be present amongst dog breeds. Cement fixation was used because it allows for a greater variability in implant design and positioning (Figure 56-36). Cement fixation allows the stems of the implant to be virtually anywhere within the confines of the medullary canal as long as there is room remaining for a cement mantle with a thickness of at least 2.0 mm.[31] Press-fit and porous in-growth designs require a near perfect fit between existing bone anatomy and implant. A two piece design was used to limit the number of working pieces. This minimizes manufacturing costs and makes it technically simpler for the surgeon. For

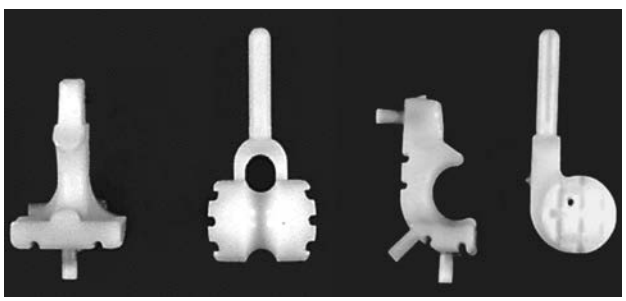

Figure 56-35. Photographs of the initial total elbow implant system evaluated by Conzemius et al.The photographs are oriented from cranial to caudal (left images) and lateral (right images).

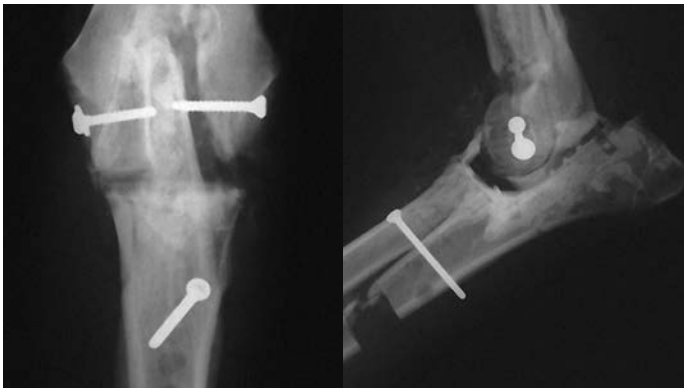

Figure 56-36. Postoperative radiographs of the initial total elbow arthroplasty system tested by Conzemius et al.

example, the radial and ulnar components were made as a single component instead of two or three. Although post-operative complications occurred in 4 of 6 dogs many beneficial things came from this study. First, two dogs had a fair outcome with peak vertical force (PVF) reaching 82% four months after surgery (Figure 56-37). Thus, it was concluded that elbow replacement was possible, just not with the exact design and technique used. In an evaluation of limb use in normal Greyhounds after femoral head and neck excision and total hip replacement limb function improved for the first six months after surgery.[32,33] Second, it was apparent that lateral luxation occurred in two dogs from lateral instability after transection of the lateral collateral and insufficient stabilization. An alternative approach needed to be considered. Third, the cement-bone interface of the radioulnar component was loose in all dogs (See Figure 56-37). This was likely because the snap fit components were too constrained and the 1 cm pegs of the radioulnar component (designed so it could be used in either the left or right limb) were too short. These short pegs provided limited surface area for the cement interface thus increasing stress. Fourth, the humeral component was consistently stable even after a stabilization screw was removed. Finally, radio-ulnar synostosis was incomplete in all dogs and the screw placed between the radius and ulna was loose in 5 of 6 dogs. Radio-ulnar synostosis is necessary when a single component has stems that enter the medullary canal of multiple bones. It was concluded that the ulnar osteotomy was too proximal, the radio-ulna screws were insufficient and that cancellous autograft should be used to encourage fusion.

This was followed by an in vivo study evaluating the efficacy of a modified system in six normal dogs.[34] The system and surgical technique evaluated included several modifications as compared to the initially reported design.[28] The humeral component had been angled in a cranial direction by 5° to reduce the probability of bone contact, dove-tail grooves in the sides of the component were included that were deeper and did not communicate with the load-bearing surface of the humeral component and all articulating surfaces were made with a larger radius. The radioulnar component now had two, 3 cm stems (radial and ulnar), it was designed for either left or right limbs with stem angles and an inter-stem distance that matched that of the anatomy of the a Labrador retriever and the proximal aspect of the component was removed and all articulating surfaces were made with a larger radius. Changes in surgical technique included removal

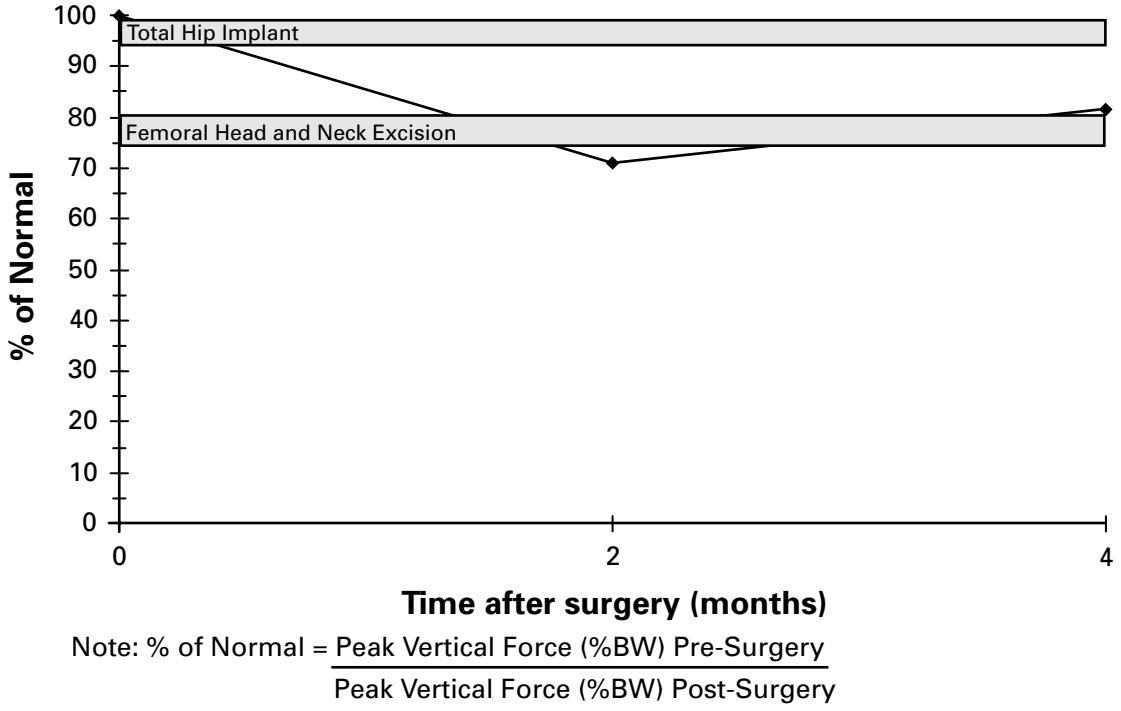

Figure 56-37. A graph of PVF of the operated limb as a percent of body weight at all time periods. The shaded areas in the graph demonstrate limb use in normal Greyhounds after femoral head and neck excision and total hip implantation.

of the lateral collateral ligament at its insertion from the radius, distal ulnar ostectomy (~1 cm of bone), no screws were used with the humeral component or between the radius and ulna and a generous amount of autogenous cancellous bone graft was placed between the radius and ulna just distal to the radioulnar component on the lateral side. Six, healthy, adult medium and large breed dogs ranging from 25 to 38 kg were used in the study. Each dog underwent an orthopedic, radiographic, and force plate gait evaluation before surgery and surviving dogs were reevaluated at 8, 16, 24 and 52 weeks after surgery. Dogs were sacrificed 6, 10, and 20 weeks after surgery, leaving three dogs for long-term evaluation. Treated limbs from the sacrificed animals were harvested and the components were examined. The results from this study were mixed. Post-operative complications occurred in 3 of 6 dogs and included one dog that never used the operated limb, a dog that developed proximal ulnar fracture 9 weeks after surgery and a dog that developed osteomyelitis. Limb function in the remaining 3 dogs consistently improved over the course of the 52 week study to the point that PVF and vertical impulse (VI) were the same as the unoperated, normal limb at 1 year. These dogs were adopted and continue to do well over 5 years after surgery. Important conclusions from this study were that the components could be made even less constrained, a corner on the caudal aspect of the radioulnar component needed to be removed, a hole in the humeral component to simulate a foramen needed to be removed, synostosis between the radius and ulna could be achieved using only the distal ostectomy and bone graft, multiple component sizes were needed and that limb function could return to normal when elbow replacement was performed in a normal dog.[34]

Although that study did not demonstrate that total elbow arthroplasty could yield consistent results or that it would be successful in naturally occurring elbow OA, it provided evidence that it would likely be successful in at least some cases.

Given the frequency of elbow OA in the dog, the poor prognosis provided by other available treatments, and the encouraging preliminary data it was thought to be reasonable to attempt total elbow arthroplasty in severely affected cases. Prior to clinical use, several design changes were made to enhance the nonconstrained total elbow arthroplasty components. First, the corners at the articulating surface of the humeral and radioulnar component were softened. This made the articulation less constrained which should reduce the formation of particulate wear debris. Second, the hole in the humeral component was eliminated. Third, the surface area for the component-cement interface was increased. Fourth, the caudal peg of the radioulnar component was angled to better fit the ulnar metaphysis. Fifth, the caudal non-articulating surface that rests on the ulna was made semicircular. This will preserve ulnar bone stock and reduce the chance of ulnar fracture. Finally, three were made available, with a 10% increase in size from small to medium to large.

This implant system was tested in twenty, adult, client owned dogs with elbow OA that were treated with nonsurgical management unsuccessfully for at least 1 year.[35] Following inclusion into the study dogs were evaluated clinically, radiographically and by force platform gait analysis before surgery and at 3, 6, and 12 months after surgery. At 1 year it was concluded that 16 of the 20 dogs had a satisfactory outcome, as defined by an improvement in quality of life and a reduction in pain and lameness. On average, 1 year ground reaction forces were 25% greater on the operated limb when compared to preoperative function. Unsatisfactory outcomes were associated with infection, lateral luxation and an iatrogenic humeral condylar fracture. Similar to

previous investigations potential improvements in component design and surgical technique were identified. The humeral component had large proximal shoulders that required removal of an unnecessarily large amount of bone. These shoulders have been removed. It was nearly impossible to establish a good cement mantle at the interface between the sides of the humeral component and the remaining bone of the humeral condyle. The sides of the humeral component have been beaded for porous ingrowth fixation. Although no problems were identified with the articulating surface in this 1 year study, it was thought that a surface that was similar to that or a human knee component would be ideal. Technical challenges that remained were development of drill and cutting guides that would allow for a more reproducible outcome and provision for lateral stabilization to reduce the probability of lateral luxation. These changes and an additional component have been implemented into a total elbow replacement system (Figure 56-38) that is commercially available and taught to surgeons in training courses.

Figure 56-38. Photograph of the two components currently used for total elbow replacement in the dog. In this photo cranial is left and caudal is right.

Surgical Procedure

Dogs are placed in lateral recumbancy and standard aseptic preparation of the affected forelimb is performed. A caudolateral approach to the elbow through the anconeus muscle that is extended proximally along the triceps and distally along the ulna is made. The insertion of the lateral collateral ligament on the radius is identified and removed close to its bony attachment. The elbow is luxated laterally (this can be difficult in many cases that have severe periarticular fibrosis or a large osteophyte on the cranial aspect of the radius). A 5 mm access hole is made in the humeral diaphysis. The humeral mounting pin is placed into the humerus and the humeral cutting guide mounted. The arthritic, articular aspect of the condyle is removed using the cutting guide and a trial component is implanted. (Figure 56-39) A 3.5 mm hole is drilled from proximal to distal down the radius diaphysis. The radial cutting guide is mounted and the cut started on the radius. The radial cutting guide is removed and the radial cut completed. The ulnar cutting guide is then mounted and used to drill multiple holes along the proximal ulnar metaphysis (Figure 56-40). The cutting guide is removed and the drill holes are connected with a high speed bur which results in removal of the ulnar trochlea and the medial and lateral coronoid processes. The diaphysis of the radius and ulna are then prepared to accept the component and cement. A trial radioulnar component is positioned and the joint is reduced to ensure that both components are positioned correctly. A distal ulnar ostectomy (1 cm) is performed. The components are cemented in position and the joint is reduced. As the cement polymerizes an autogenous, cancellous bone graft harvested from the removed bone is placed between the proximal aspects of the radius and ulna just below the body of the lateral aspect of the radioulnar component. Prior to closure, two suture anchors are placed (one in the lateral aspect of the humeral condyle and one between the proximal radius and ulna) to provide additional lateral stability during the early postoperative period. Following closure a splint is applied and postoperative radiographs are taken (Figures 56-41 and 56-42). Postoperative management generally should include removal of the splint 2 to 3 days after surgery, restriction to short leash walks for 8 weeks and a re-exam at 8 weeks. At this time more aggressive postoperative rehabilitation for the joint can be considered.

In the author's experience with this commercially available system, an outcome that is satisfactory to the surgeon and owner(s) can be expected 80 to 85% of the time. The most common complications that can be expected include infection, luxation, and fracture of the ulna. In 5% of humans undergoing total elbow replacement, fracture of the olecranon has been reported as a major complication.[36] Since perpendicular bone cuts create a stress riser in the ulna and have been identified as a predisposing factor for an olecranon fracture,[37] it is hoped that the technical modifications in place will reduce this problem. Again, in the author's experience, the majority of complications occur in the first 8 weeks after surgery.

Elbow Arthrodesis

Arnold S. Lesser

Indications

Arthrodesis of the elbow or any midlimb joint is some what controversial. There are some surgeons that believe that the result after fusion of the elbow or stifle is not good enough to warrant the procedure. Certainly pancarpal or pantarsal arthrodesis gives better and more consistent results but there are dogs that can function fairly well after fusion of the elbow, especially smaller patients that tend to walk with a stiff gait. The decision to fuse a joint is only made when other alternatives are not feasible or successful. The indication for arthrodesis of the elbow is any condition that leaves the elbow chronically painful and nonfunctional. These can be divided into traumatic and developmental. Traumatic includes fractures that cannot be repaired or that have failed to heal or healed as painful malunions. The elbow's configuration can make primary repair difficult especially in miniature breeds. Highly comminuted articular fractures or gun shot trauma with bone loss are examples of fractures that may not be repairable or lead to painful malunions. In the majority of cases a primary repair should be attempted first but there may be situations where finances allow only one procedure to be performed and then it is the surgeon's judgment whether to go right to the arthrodesis or attempt the repair. With non unions the question also arises as to whether to attempt another osteosynthesis or go right to an arthrodesis. If a malunion cannot be revised to allow for good function or has led to severe DJD and the patient is not using the limb then fusing the elbow is indicated. Also the elbow joint is especially susceptible to loss of motion after difficult fracture repair and if the joint becomes ankylosed in too flexed a position the dog will not use the leg due to the physiologic shortening. Arthrodesis of the joint at the proper angle is then indicated.

The other major indication for elbow arthrodesis is severe arthritis, most commonly secondary to elbow dysplasia (ununited anconeal process or fragmented coronoid process). When conservative therapy is no longer giving sufficient relief then surgery is indicated. Recently a Total Elbow prosthesis has become available and where applicable would be the first choice. There are size restrictions and the presence of infection affects the use of a prosthesis more than arthrodesis, but this is a promising alternative and further clinical use will be needed to fully evaluate its potential.

Procedure

Plate fixation along the caudal aspect of the humerus and ulna is by far the best method (Figure 56-43). This places the plate on the tension band side. It is necessary to perform an olecranon osteotomy to provide a smooth transition and bed for the plate. Part of the olecranon can be sacrificed for graft (all fusions should be grafted) and the remainder reattached to the bone next to the plate. The angle of the cut can be determined by placing the leg in the desired angle (reported from 110 to 130 degrees) and running a line off the caudal edge of the humerus onto the ulna (Figure 56-44). The lateral collateral ligament is transected and the extensor muscles are elevated to provide exposure for the removal of cartilage from the radial head, coronoid process and

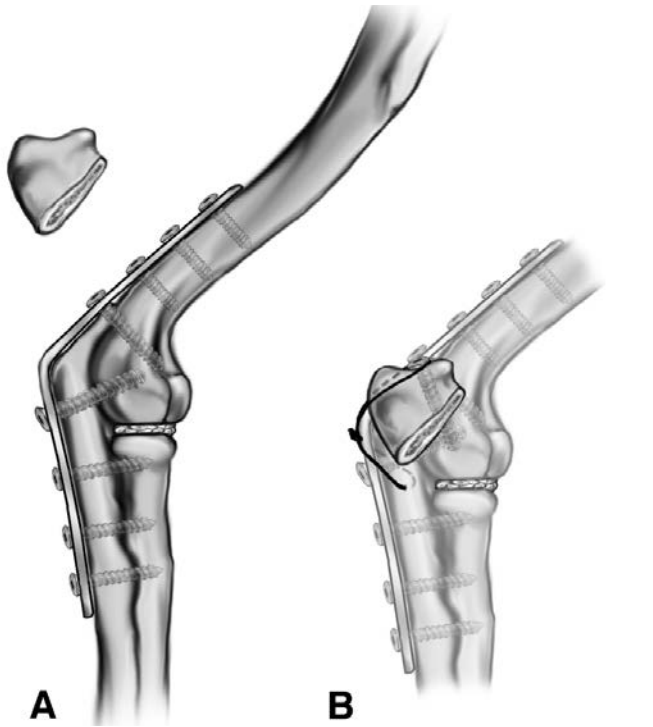

Figure 56-43. A. The plate is paced on the caudal aspect of the elbow with a minimum of 3 screws in both the humerus and the ulna. Screws crossing the arthrodesis should be placed under compression. **B.** The olecranon can be sacrificed as graft and the triceps sutured down, or it can be attached to the humerus adjacent to the plate with a screw and tension band wire.

humeral condyle. These surfaces should be shaped to create good contact. The ulnar and median nerves should be identified and protected on the medial aspect of the joint. Once the angle has been determined from the standing angle of the normal leg, the joint is held with a pin driven from the ulna into the medial humeral condyle. A goniometer or an old plate prebent can be used to measure this angle at surgery. If there has been bone loss then the angle is increased (straighter). However, there is more of an acute angle at the elbow than appears from looking at the leg because of the thick muscle caudal to the humerus and the curvature of the radius, so there is a tendency to make the leg too straight. Be sure to measure the bone and not the leg when determining the angle of arthrodesis (Figure 56-45). A sterile preparation of the controlateral leg provides a quick reference. The triceps muscles can be elevated to allow placement of the plate. A minimum of 3 screws are used in the humerus and ulna respectively, with additional intervening screws crossing the joint under compression. A 9 or 10 hole, self compressing or locking plate is sufficient for a 30 kg dog.

Screw fixation has been advocated for elbow arthrodesis and may have a place in smaller patients when combined with an external skeletal fixator(Figure 56-46), With the availability the small 2.0 mm cuttable plates, I would recommend staying with plate fixation. These plates can be doubled for greater stiffness. External fixators can be used but are more difficult to adapt in this area due to the presence of the body wall medial to the humerus. Modified type 1b fixators can be used but are more complicated to construct. Fixators can also be used as a secondary fixation rather then a bulky spica where the primary fixation is suspect. If the plate fixation is sufficient only a padded bandage is used for a few weeks.

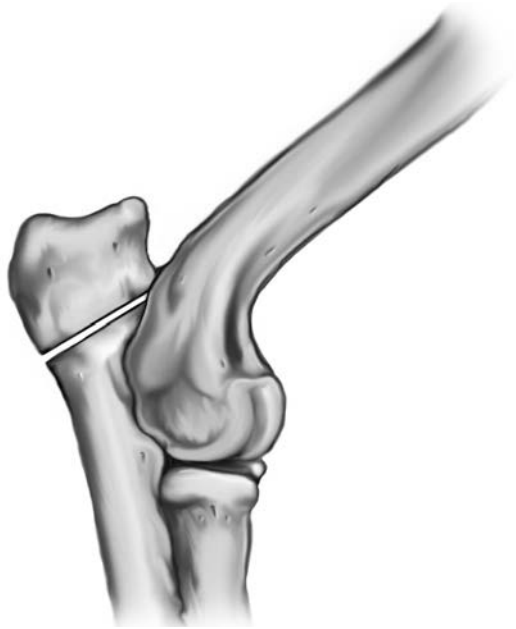

Figure 56-44. The olecranon is osteotomized at an angle parallel to the caudal aspect of the humerus to facilitate plate placement.

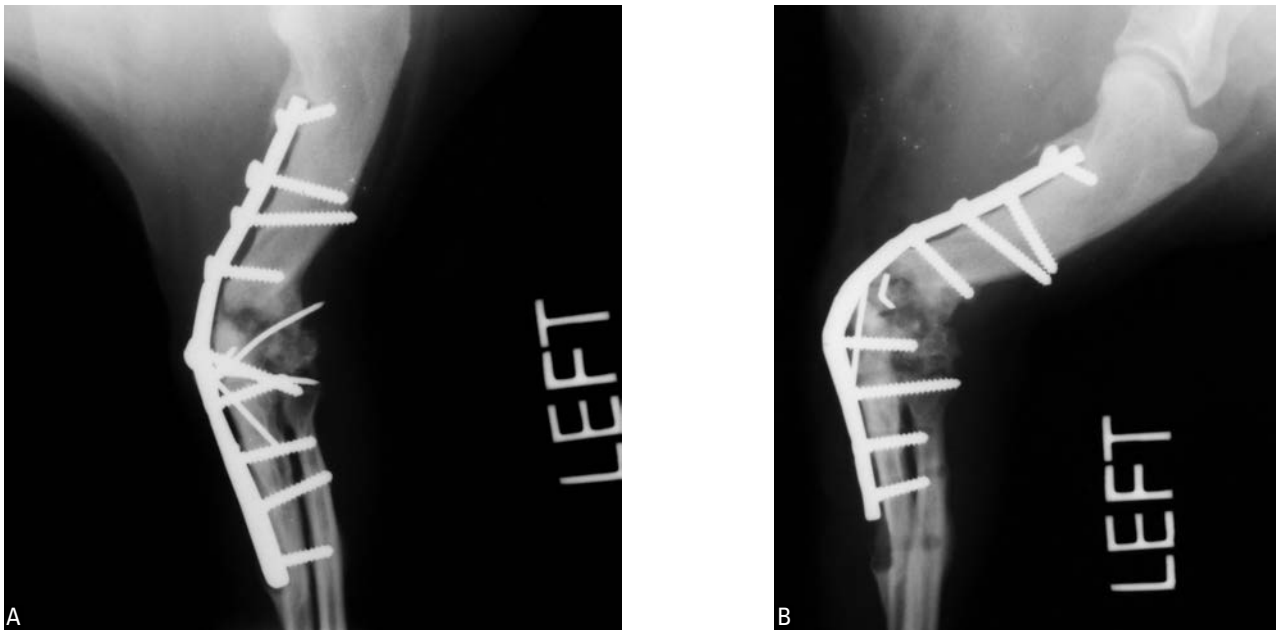

Figure 56-45. The angle made by the bones of the elbow joint is more acute (flexed) than appears from looking at the leg because of the asymmetry of the brachial musculature. In this case what appeared as the proper angle **A.** was too obtuse and had to be revised. **B.** The plate is bent at approximately 120 degrees.

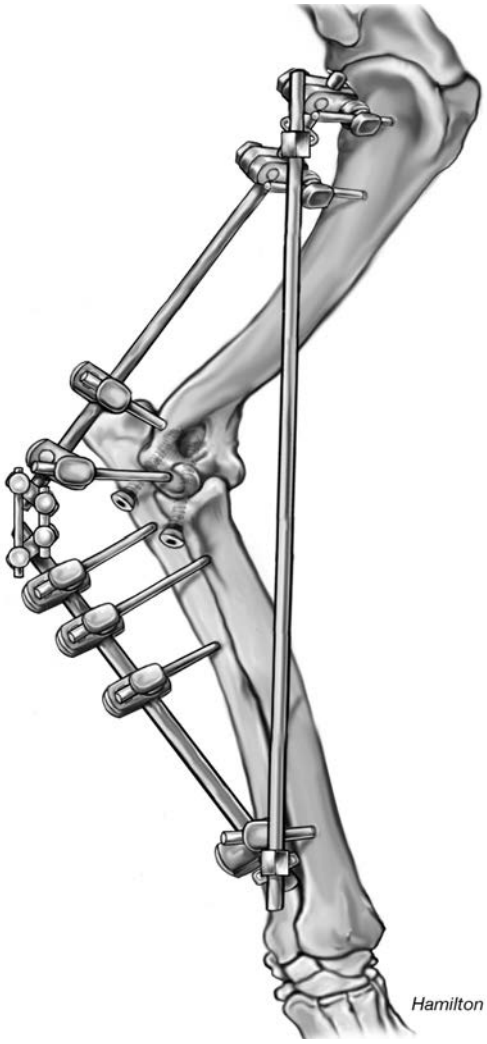

Figure 56-46. An alternate method is the use of an external skeletal fixator and a compression screw spanning the arthrodesis from the olecranon into the humerus.

Chapter 57

Radius and Ulna

Repair of Fractures of the Radius and Ulna

Curtis W. Probst

Introduction

Radial and ulnar fractures are seen frequently in small animal practice. These fractures often, but not always, involve both bones. Most fractures are the result of automobile trauma; however, fractures in toy breeds often result from jumps or falls.

As with all traumatized animals, the first step in managing patients with radial and ulnar fractures is to perform a complete physical examination. The surgeon should pay particular attention to the cardiovascular and respiratory systems. Approximately 40% of animals that have been hit by a car have some type of respiratory system damage; therefore, thoracic radiographs are advisable. One should also carefully assess the patient for the presence of cardiac arrhythmias that may result from traumatic myocarditis. Once the patient's condition has been stabilized, the surgeon can attend to the fracture.

Radiographs (at least two views) of the radius and ulna are essential to define the fracture properly. The fractured limb should be protected by applying a Robert Jones bandage until definitive treatment can be performed. This bandage should extend from the toes to well above the elbow. Half circumference splints applied distal to the elbow joint are ineffective in immobilizing radial and ulnar fractures.

Fractures of the radius and ulna may be associated with a higher complication rate than fractures of other long bones. Because of the potential complications, which include delayed union, nonunion, joint stiffness, and growth deformities, one should not dismiss these fractures lightly.

I prefer to group radial and ulnar fractures into several categories because of the difference in principles of treatment. These categories include olecranon fractures, Monteggia fractures, isolated ulnar or radial diaphyseal fractures, radial or ulnar styloid fractures, radial head fractures, combined radial-ulnar diaphyseal fractures, and radial physeal fracture-separations.

Olecranon Fractures

The olecranon,the proximal portion of the ulna, serves as a fulcrum for the extensor muscles of the elbow joint. Fractures of the olecranon can occur proximal to the trochlear notch (i.e., extra-articular fractures) or through the trochlear notch (i.e., intra- articular fractures). These fractures can be simple two-piece fractures or complex comminuted fractures. Regardless of the type of fracture, the proximal fragment usually is severely displaced because of the pull of the triceps muscle

(Figure 57-1). Open reduction and internal fixation of these fractures are required because external coaptation (e.g., a cast or splint) is unable to counteract the distractive force of the triceps muscle.

Generally, olecranon fractures are exposed through a caudal approach in which the extensor carpi ulnaris and flexor carpi ulnaris muscles are subperiosteally elevated, thus exposing the ulnar diaphysis and olecranon. The skin incision is made slightly lateral to rather than directly over the caudal surface of the olecranon.

With an intra-articular fracture, the anconeus muscle and joint capsule must be incised so the surgeon can see the articular surface. Perfect reduction of articular fractures is essential to minimize the development of secondary degenerative joint disease. Extension of the elbow relaxes the triceps pull, thus facilitating fracture reduction. After reduction, olecranon fractures can be stabilized with pins and tension band wire or bone plates and screws.

Tension Band Fixation

The preferred technique for repairing extra-articular olecranon fractures and transverse or short oblique intra-articular fractures involves pinning and placement of a tension band wire. After exposure of the fracture and removal of blood clots and fibrous tissue the elbow is extended, and the fracture fragments are reduced. Reduction usually can be maintained with digital pressure or a bone clamp.

The reduced fracture is initially stabilized by driving two Kirschner wires or Steinmann pins across the fracture. The pins are driven in a normograde fashion through the proximal

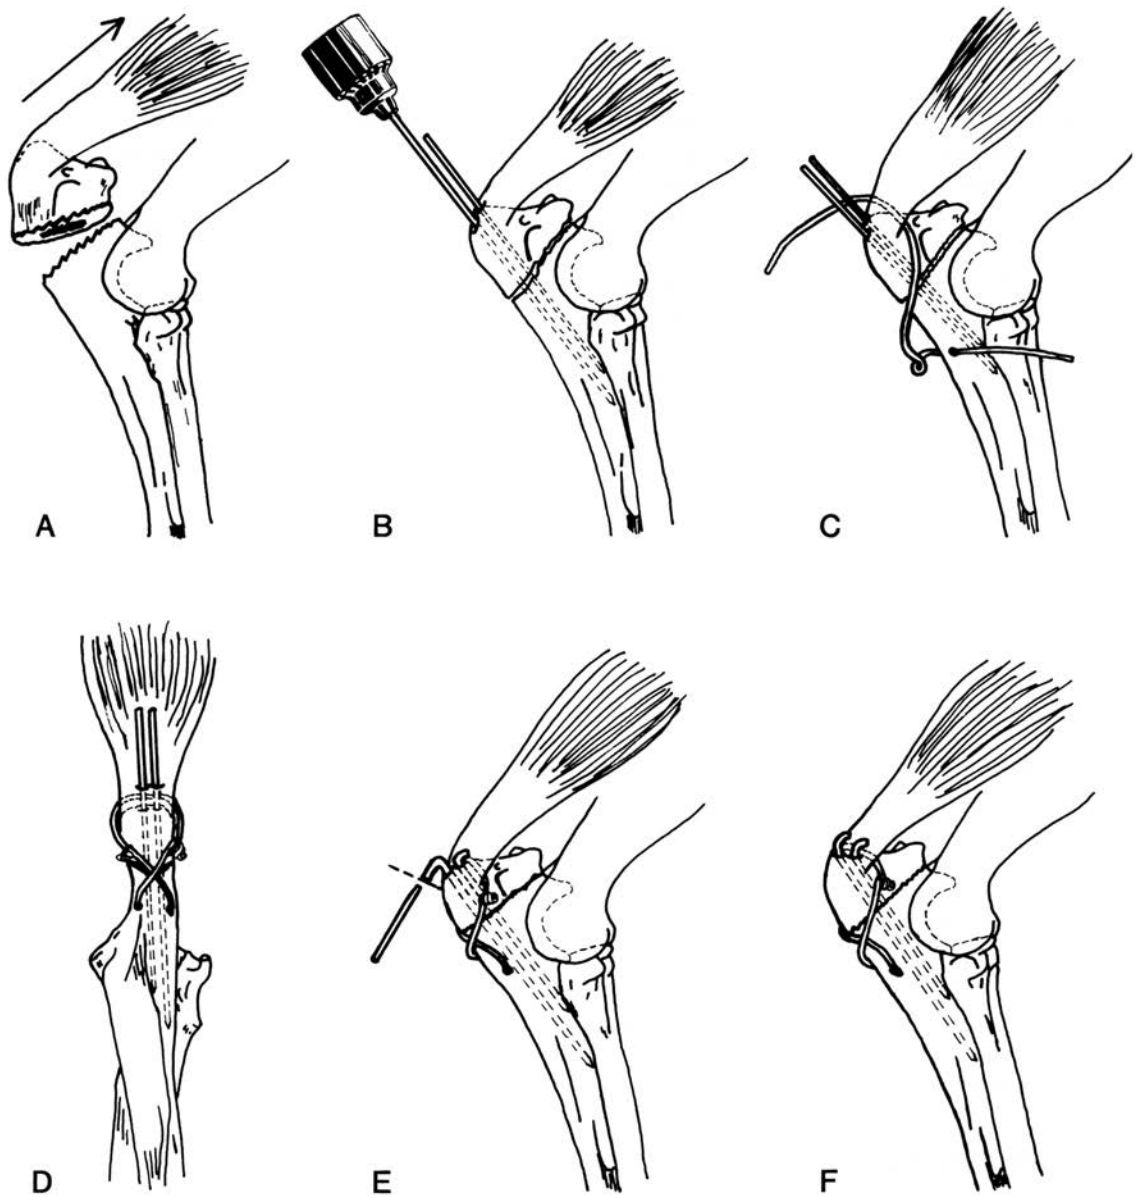

Figure 57-1. Fixation of extra-articular olecranon fracture with a tension band wire. **A.** Typical fracture location proximal to the trochlear notch. **B.** Placement of two Kirschner wires or Steinmann pins across the reduced fracture in a normograde fashion. **C.** Insertion of orthopedic wire through a hole in the distal fragment. **D.** Figure-of-eight tension wire in place. **E.** Trimming of bent pin ends. **F.** Completed repair with pin ends lying flat against triceps tendon. See text for details.

fragment, across the fracture, and into the distal fragment with a Jacob's pin chuck. The proximal olecranon is quite dense bone, so it may be helpful to pre-drill pilot holes of a slightly smaller diameter than the pins. The pins should be parallel to each other to allow compression of the fracture with the tension band wire. The pins should be directed so they engage the cranial cortex of the distal ulnar fragment, rather than extending directly down the medullary cavity, because the latter placement may not counteract rotation effectively (Figure 57-1B); similarly, a single pin does not counteract rotation. A hole is then drilled transversely in the caudal aspect of the distal fragment. The hole should be large enough to accept 18-gauge orthopedic wire (20-gauge wire in small dogs and cats) and should be placed roughly the same distance distal to the fracture as the length of the proximal fragment. A single tightening twist is made in the center of an appropriate length of wire, and one end is then passed through the hole. The other end of the wire is then passed underneath the triceps tendon and cranial to the pins (Figure 57-1C). The free ends of the wire are twisted together, thus forming a figure-of-eight (Figure 57-1D). The two twist points on the medial and lateral portions of the figure-of-eight wire are alternately tightened until the fracture is compressed. The wire should not be over-tightened because this may cause a gap to form in the cranial aspect of the fracture. The excess wire is cut, leaving three or four twists, and the two ends of the wire are bent so they lie flat against the bone. The pins are bent in a caudal direction and are cut to leave 4 to 5 mm's of pin; the ends are then turned cranially so they lie flat against the triceps tendon (Figure 57-1E and F). If the pins are initially bent in a cranial rather than a caudal direction, the cut ends will not lie flat against the triceps tendon.

If properly applied, the tension band wire is strong enough that no postoperative support is needed. The wound is covered with a sterile dressing, and the limb is placed in a light support wrap for 48 hours postoperatively. The animal's activity should be limited to leash walks for 6 to 8 weeks after surgery. The implants are not removed unless they loosen, break, or cause soft tissue irritation.

Bone Plating

I prefer to use a bone plate and screws to repair comminuted olecranon fractures and olecranon fractures in large and giant breed dogs. A plate applied to the caudal aspect of the ulna acts as a tension band, provided no cortical fragments are missing from the cranial cortex. Screws can be applied through the plate using the lag principle, thus achieving interfragmentary compression in comminuted fractures (Figure 57-2A and B). Screws must not be placed through the articular surface of the trochlear notch. With fractures that are sufficiently proximal to require plating up to the most proximal aspect of the ulna, pressure sores frequently develop over the olecranon if the plate is applied caudally. The plate should be applied to the lateral aspect of the ulna and inter-fragmentary lag screws may be used as necessary (Figure 57-2C).

Monteggia Fractures

Fractures of the proximal half of the ulna with luxation of the radial head are known as Monteggia fractures. The radial head usually luxates cranially, and the ulna may be fractured anywhere from the middle of the diaphysis to the trochlear notch. The proximal annular and interosseous ligaments may be torn (Figure 57-3A) or may remain intact, as is common when the ulnar fracture is at the base of or into the trochlear notch (Figure 57-3B). Early treatment is helpful for ease of reduction of the luxation and fracture.

A caudal approach usually provides adequate exposure to allow reduction of both the radial head luxation and the ulnar fracture. A craniolateral approach can be used in addition to the caudal approach if the luxation cannot be reduced.

If the proximal annular ligament is torn, as occurs when the ulnar fracture is distal to the annular ligament (See Figure 57-3B), one must not only stabilize the ulnar fracture but also secure the radial head in its normal relationship with the ulna. Although suture repair of the annular ligament has been described, this is seldom possible. I prefer to secure the radial head to the ulna with lag screws alone or in conjunction with a bone plate. If the ulnar fracture is oblique enough, lag screws alone are sufficient

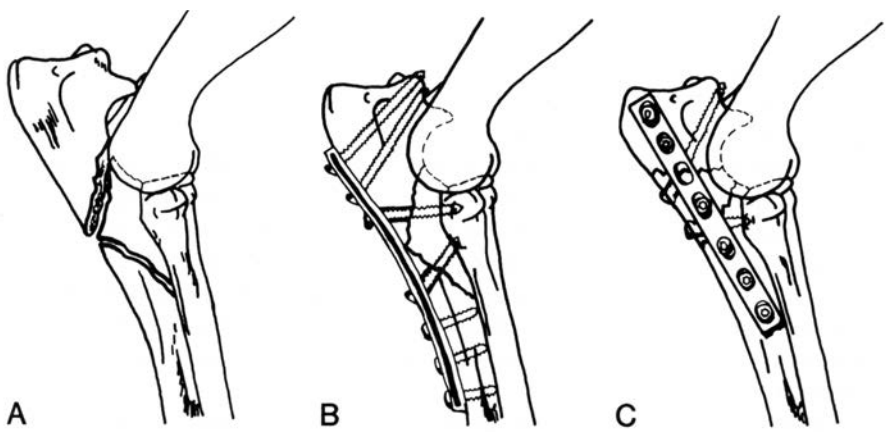

Figure 57-2. A comminuted intra-articular olecranon fracture **A.** repaired with a bone plate applied to the caudal aspect of the ulna. **B.** Screws have been applied through the plate in lag fashion, thus achieving interfragmentary compression. With more proximal fractures **C.** that must be plated to the most proximal end of the ulna, the plate is applied on the lateral surface. Lag screws can be applied in a caudal to cranial direction if necessary.

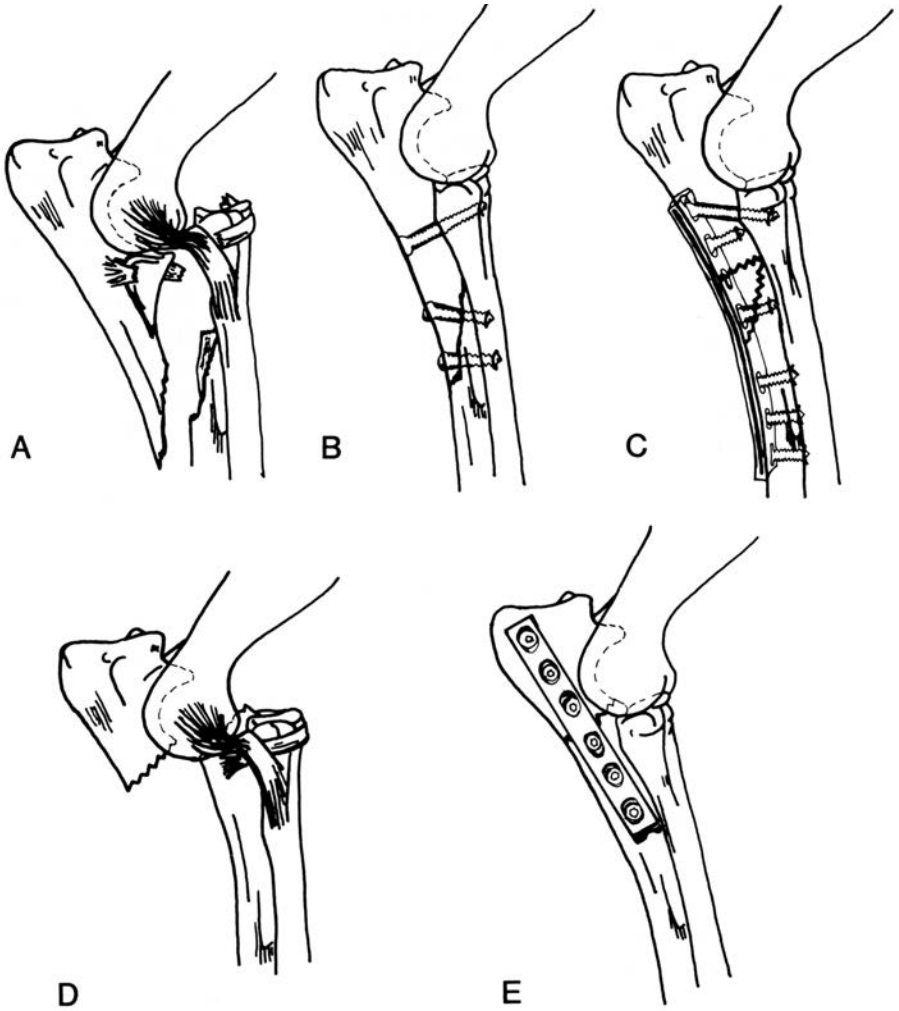

Figure 57-3. Stabilization of Monteggia fractures. An oblique fracture with ruptured proximal annular ligament **A.** can be repaired with three lag screws **B.**; if the fracture is comminuted, a bone plate is applied to the caudal aspect of the ulna. **C.** In both cases, the most proximal lag screw holds the radial head in its normal position. A Monteggia fracture with an intact proximal annular ligament **D.** can be repaired with a bone plate applied to the lateral aspect of the ulna. **E.**

to repair the fracture (See Figure 57-3A) (Figure 57-3C). If the ulnar fracture is comminuted, I prefer to use a bone plate and place one or two screws through the plate into the proximal radius (Figure 57-3D).

If the proximal annular ligament is intact, reduction of the ulnar fracture can be accomplished only with concurrent reduction of the radial head luxation. Because the intact annular ligament maintains the normal relationship between the radial head and the ulna, the surgeon only needs to stabilize the ulnar fracture. I prefer to use a bone plate and screws to stabilize this type of ulnar fracture (Figure 57-3E and F), although repair with pin(s) and tension wire has been described.

Postoperatively, the incision is covered with a sterile dressing, and the limb is placed in a modified Robert Jones bandage. The bandage helps to minimize postoperative swelling and is left in place for several days. The animal's activity should be limited to leash walks only for 10 to 12 weeks after surgery, but early movement of the elbow is encouraged to minimize stiffness.

Isolated Ulnar or Radial Diaphyseal Fractures

Isolated radial or ulnar fractures generally are the result of falls, gunshot wounds, or the patient being kicked by a horse, for example, rather than automobile accidents. Isolated ulnar diaphyseal fractures occur more frequently than isolated radial diaphyseal fractures. These fractures usually are minimally displaced because the intact companion bone acts as an internal splint. Radiographic diagnosis of these fractures may be difficult because of the minimal displacement; therefore, one should obtain two radiographic views of diagnostic quality.

Most isolated radial or ulnar fractures can be stabilized with a properly applied fiberglass cast. The joints proximal and distal to the fracture must be immobilized to stabilize a fracture properly with external coaptation. Half circumference splints, although used frequently, are an unacceptable means of stabilizing radial or ulnar fractures because they do not immobilize the elbow joint adequately.

A cast should be applied with the patient under general anesthesia. The fracture is manually reduced. The reduced fracture should have at least 50% purchase (i.e., contact between fracture ends)

before the reduction is considered adequate. One should avoid casting the limb with a varus or valgus angulation at the fracture. This type of angulation can lead to secondary arthritis because of abnormal stresses placed on the joints during weight-bearing. The cast should extend from the midshaft of the humerus to the digits, with only the distal phalanx of the third and fourth digits left exposed distal to the cast.

External coaptation is not without complications, but many problems can be avoided by applying the cast properly. Pressure sores over the accessory carpal bone and olecranon are common. They can be avoided by applying "donuts",layers of cast padding with a hole cut in the center,over these pressure points (Figure 57-4A). Donut pads placed around a pressure point alleviate the pressure directly on the bone. Simply adding more padding directly over a pressure point actually increases the pressure and should be avoided. The distal end of the cast can cause severe erosions to the dorsal aspect of the protruding toes as the animal walks. Adding extra padding and applying a walking bar (i.e., aluminum rod) to the distal end of the cast helps prevent damage to the dorsum of the protruding toes (Figure 57-4B). The walking bar can be incorporated into the cast or can be secured to the dried cast with adhesive tape. A cast also may not immobilize the elbow joint properly. This problem usually occurs because the cast is not applied as far proximal to the elbow as it should be or because the cast is applied too loosely proximal to the elbow.

Diaphyseal fractures of the radius or ulna that are the result of gunshot wounds may not be amenable to treatment by external coaptation. Because such fractures frequently are severely comminuted, restoration of cortical continuity may be difficult, if not impossible. Fractures involving only the radial diaphysis are best treated with an external fixator (Figure 57-5). The external fixator provides direct skeletal fixation and allows treatment of open wounds. Generally, the major segments of the radius are not severely displaced; therefore, the external fixator can be applied after closed reduction. This technique minimizes further disruptions of the blood supply to the fracture fragments. If the major fracture segments are displaced, or if one chooses to use a cancellous bone graft, then open reduction is required. It is best to use a minimal approach and avoid handling the fracture fragments (i.e., the "look but don't touch" method) to avoid further iatrogenic disruption of blood supply. The application of external fixators is described later, in the discussion of combined radio-ulnar diaphyseal fractures.

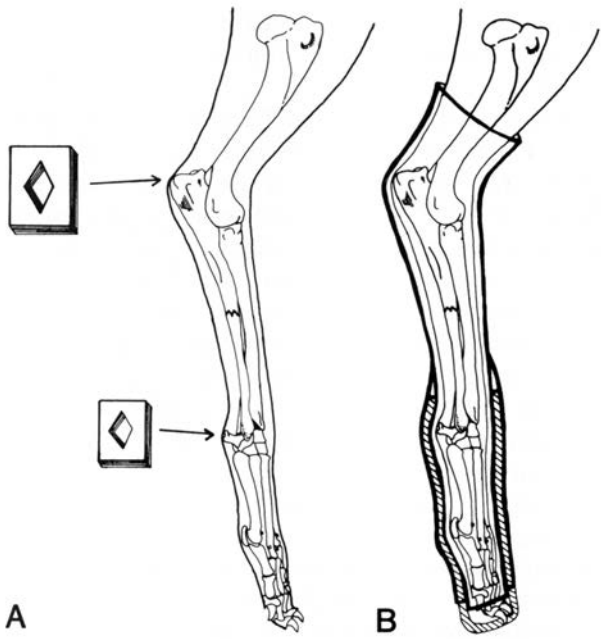

Figure 57-4. Isolated ulnar and radial diaphyseal fractures can be treated with external coaptation. **A.** Cut-out "donut" pads are applied over accessory carpal bone and the olecranon to relieve pressure from the cast. **B.** A walking bar incorporated into the distal aspect of the cast prevents damage to the dorsal surface of the protruding toes.

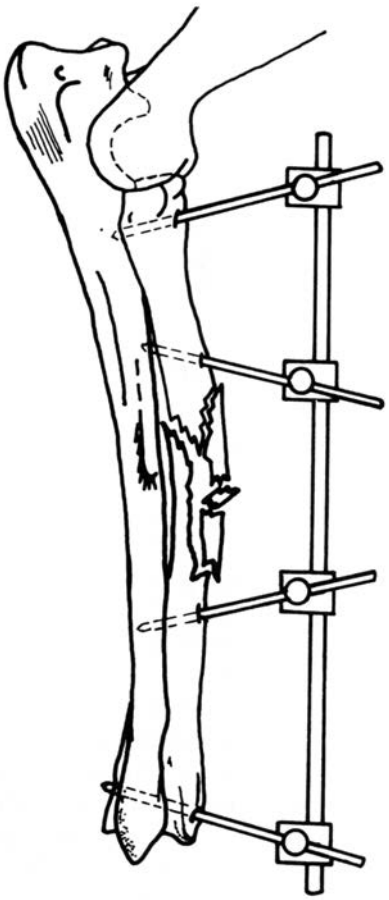

Figure 57-5. A severely comminuted isolated radial fracture stabilized with a Type I external fixator.

Isolated ulnar diaphyseal fractures resulting from gunshot wounds can be treated with a cast, provided no extensive open wounds are present. Such fractures usually do not require rigid fixation because the radius is the major weight-bearing bone. The limb can be immobilized temporarily in a Robert Jones bandage until any swelling subsides or the open wounds begin to heal before applying a cast.

Radial and Ulnar Styloid Fractures

The radial and ulnar styloid processes serve as the origins of the medial and lateral collateral ligaments of the antebrachio-carpal joint. The styloid processes also extend distal to the proximal row of carpal bones, thus providing a buttress for medial and lateral stability. Because carpal instability results

from fracture of one or both styloid processes, internal fixation of these fractures is required.

The styloid processes are exposed by incising directly over the process taking care to avoid iatrogenic laceration of the collateral ligaments. Fixation of radial styloid fractures usually is accomplished with tension band wire or lag screws (Figure 57-6A-C). It may not be possible to place two pins into the distal ulna in small dogs; therefore, ulnar styloid fractures may not be completely rotationally stable (Figure 57-6D and E).

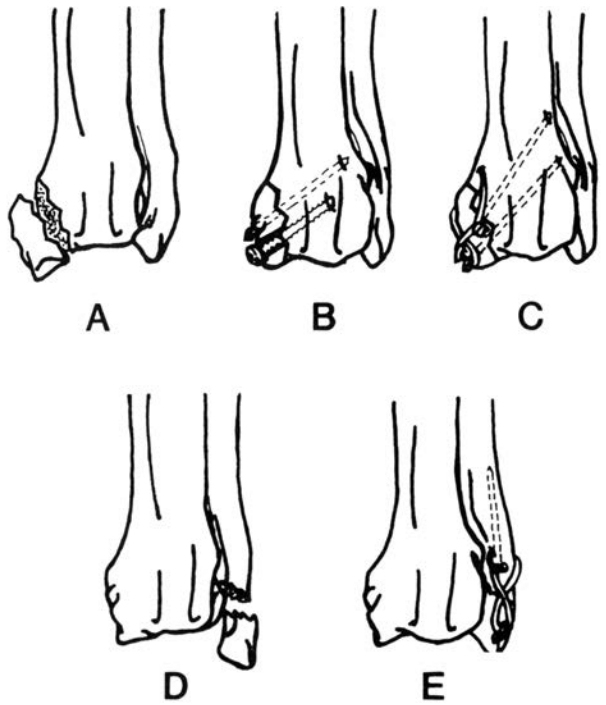

Figure 57-6. A radial styloid fracture **A.** can be repaired with a lag screw and Kirschner wire (to prevent rotation of the fragment) if the fragment is large enough **B.** or with two Kirschner wires and a tension band wire **C.** An ulnar styloid fracture **D.** can be repaired with a pin and tension band wire **E.**

Because uncomplicated healing of these fractures is necessary to prevent carpal instability, supplemental external coaptation is necessary. A fiberglass half-cast or Mason metasplint provides satisfactory support. External coaptation can be discontinued after 6 to 8 weeks. The animal's exercise should be restricted until fracture healing is complete.

Radial Head Fractures

Radial head fractures, which are uncommon, may or may not involve the articular surface. If the articular surface is involved, perfect reduction and rigid fixation are required to minimize secondary arthritis and joint stiffness.

The radial head is most easily approached through a lateral skin incision. A fascial incision is made between the common and lateral digital extensor muscles near their origin. These muscles are separated to expose the supinator muscle, deep branch of the radial nerve, branches of the dorsal interosseous artery, and part of the radius. One should protect the radial nerve during the surgical procedure. Incision of the supinator muscle along its insertion on the radius exposes the lateral collateral ligament annular ligament and joint capsule. The annular ligament and joint capsule are incised along the cranial border of the collateral ligament thus exposing the radial head. After the fracture is repaired, the joint capsule and annular ligament are re-apposed. The supinator muscle may be sutured to the radial periosteum. The remainder of the closure is routine.

Extra-articular radial head fractures can be repaired with a T-plate or crossed Kirschner wires (Figure 57-7A and B). The latter method is used in cats and small dogs in which T-plate fixation often is not feasible. Intra-articular radial head fractures can be repaired with lag screws or divergent Kirschner wires, depending on the size of the fragment. Lag screw fixation is ideal because it provides interfragmentary compression. A small Kirschner wire should be used in conjunction with the lag screw to counteract rotation of the fragment around the screw (Figure 57-7C). If the fragment is too small for lag screw fixation, then multiple divergent Kirschner wires can be used. Because

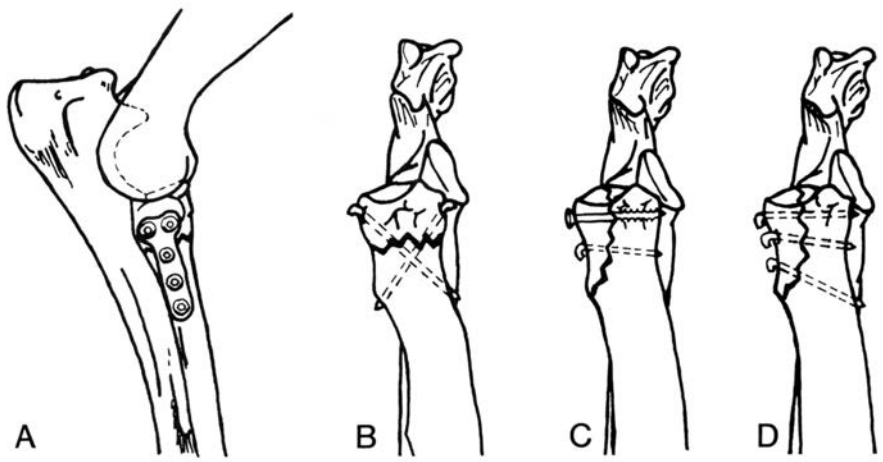

Figure 57-7. After reduction, an extra-articular radial head fracture can be stabilized with a small T-plate **A.** or crossed Kirschner wires **B.** in the case of small animals. Intra-articular radial head fractures are stabilized with a cancellous screw placed in lag fashion and a Kirschner wire to counteract rotation **C.** or with multiple Kirschner wires placed a divergent angles **D.**

interfragmentary compression is not achieved with Kirschner wires, the fracture should be reduced and compressed as much as possible with a bone clamp before the Kirschner wires are placed. At least two, and preferably more, Kirschner wires should be driven at maximally divergent angles across the fracture and through the opposite cortex (Figure 57-7D). The divergence of the wires prevents the fragment from loosening and sliding along the wires.

Preventing the animal from bearing weight on the radial head for several weeks postoperatively may be advisable, depending on the stability of the repair. This goal may be accomplished by placing the limb in a carpal flexion bandage, Velpeau bandage, or cast.

Salvage procedures such as elbow joint arthrodesis or excision of the radial head can be considered for treatment of severely comminuted radial head fractures.

Combined Radioulnar Diaphyseal Fractures

Most fractures of the antebrachium involve both the radius and ulna, and many of these fractures occur in the middle or distal third of the diaphysis. These fractures can be managed in several ways, depending on the fracture type, patient, client cooperation, facilities available, and the surgeon's capabilities. The methods of managing these fractures include closed reduction and external coaptation, open reduction and bone plating, open reduction and pinning, and closed or open reduction and external skeletal fixation. Each method is described here.

Closed Reduction and External Coaptation

Some combined fractures of the radius and ulna can be managed adequately with external coaptation after closed reduction. This method should be reserved for treatment of incomplete or transverse midshaft fractures in young, medium-sized dogs and in cats. External coaptation of radial and ulnar fractures should be avoided in toy breeds and in large, active dogs. There is a high incidence of delayed union or nonunion in distal radial and ulnar fractures in toy breeds treated with external coaptation. This may be due, in part, to a decreased interosseous blood supply in the distal radius of toy breed dogs compared to large breed dogs. Bone plates and screws should be used to treat radius and ulnar fractures in toy breed dogs.

When performing closed reduction of transverse midshaft radial and ulnar fractures, reduction is considered adequate only when a 50% or more purchase is achieved. The limb should not have a varus or valgus angulation when it is cast. (See the earlier discussion of isolated ulnar or radial diaphyseal fractures for guidelines and complications of external coaptation.)

Open Reduction and Bone Plating

The radius is an ideal bone to plate because the approach to it is straightforward, its cranial surface is the tension side of the bone, and little bending is required to contour the plate properly to the bone. Open reduction and bone plating are the treatments of choice for combined radioulnar fractures in toy breeds, in large or giant breeds, and in animals with multiple limb fractures. In toy breeds, distal radial and ulnar fractures seem to have an unusually high incidence of delayed or nonunion when treated conservatively; plating these fractures provides the rigid fixation necessary for healing. Properly applied bone plates are better than other methods of fracture repair in withstanding the tremendous stresses placed on fracture repairs by active large and giant breed dogs. Similarly, the rigid fixation provided by bone plates permits earlier return to function in the patient with multiple limb fractures than when more conservative treatment methods are used.

Usually, only the radius needs to be plated, although plating both the radius and ulna may be advisable in large or active dogs. The radius is exposed through a craniomedial approach; the ulna can be exposed through a caudal or caudolateral approach if it is to be plated also. The most proximal and distal aspects of the radius are more difficult to expose than the diaphysis because of proximal muscular insertions and tightly adherent extensor tendons distally. The plate is applied to the cranial surface of the radius and, if necessary, the caudolateral surface of the ulna (Figure 57-8A). One must be certain that a plate applied to the radius is beneath the extensor tendons. Failure to do so results in entrapment of the extensor tendons and limited function of the carpus or digits.

With proximal radial fractures, screws can be placed through the radial plate into the ulna. This procedure may increase

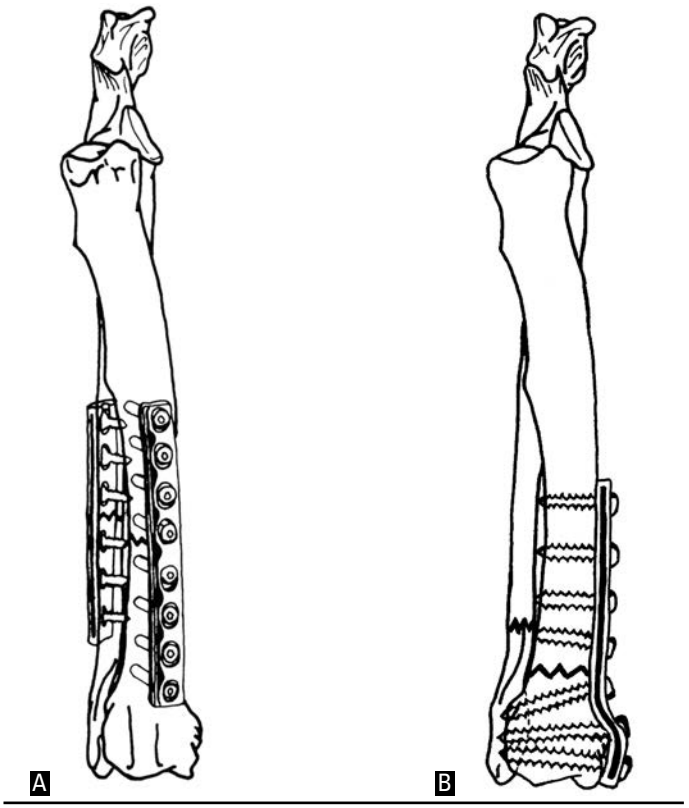

Figure 57-8. Combined radius and ulnar diaphyseal fractures repaired with two bone plates **A.** Usually, only the radius needs to be plated except in very large dogs or in dogs with multiple limbs fractured. When dealing with distal radial and ulnar fractures, a bone plate can be applied to the medial aspect of the radius thus facilitating the placement of more screws into the distal fragment **B.**

fracture stability, but it prevents supination and pronation of the antebrachium. Therefore this technique should be used only when there is a short proximal segment and additional screw purchase is warranted. Screws should never be placed through the radius into the ulna in a growing animal because doing so causes the animal to develop an angular limb deformity.

Plating the medial aspect of the radius is advised for treating distal radial and ulnar fractures where three screws cannot be placed into the distal fracture segment using a dorsally applied bone plate (Figure 57-8B). Because the plate can be applied along the radial styloid process, additional screw purchase can be achieved in the distal radial epiphysis. Additionally, the screws engage the thicker medial and lateral radial cortices, and the extensor tendons are avoided. Generally, a narrower plate is chosen for the medial radius compared to the plate that would be chosen for the dorsal radius. The radius is narrower in a craniocaudal direction than it is mediolaterally, therefore accurate aiming of the screws is necessary to capture the entire width of the radius. Care must be used to avoid placing the most distal screw into the antebrachiocarpal joint.

A cancellous bone graft is recommended for comminuted fractures and for fractures in older animals. The proximal humerus is a convenient site to harvest cancellous bone for radial and ulnar fractures. The cancellous graft can be placed around the fracture site as it is removed from the humerus, or the graft can be put into a stainless steel bowl until enough cancellous bone has been harvested. The fracture site should not be lavaged after the graft has been placed.

A padded bandage is applied to the limb after wound closure. The bandage is applied snugly from the toes to the midshaft of the humerus. The bandage minimizes postoperative swelling of the limb and keeps the incision clean. The bandage can be removed in 48 hours. The dog's activity should be restricted to leash walks only for 10 to 14 weeks postoperatively. Although not routinely done, the plate may be removed 10 to 12 months after the fracture has healed.

Open Reduction and Intramedullary Pinning

The radius is not as amenable to intramedullary pinning as the other major long bones for several reasons. Because the radius is relatively straight and both ends are completely covered with articular cartilage, retrograde pin placement causes the pin to enter either the elbow or the carpal joint. The oval cross-sectional shape of the medullary cavity limits the size of the pin that can be used. Furthermore, many toy breed dogs do not have a distinct medullary cavity in the radius, making it difficult or even impossible to pin. A single medullary pin does not provide stable fixation of a radial fracture even if the ulna is also pinned. Therefore, treating radial fractures with an intramedullary pin is not advised and should be avoided.

Pinning of the ulna may be performed in conjuction with other types of radial fracture fixation (e.g., bone plate and screws, external fixator) to facilitate alignment of the ulna. One may wish to use this auxiliary fixation in large or active dogs. Retrograde placement of the pin is more easily accomplished than normograde placement. It is advisable to insert the pin into the proximal ulnar fragment before stabilizing the radial fracture if one wishes to use retrograde placement. The pin should be aimed toward the caudal ulnar cortex to avoid the pin exiting the ulna through the dorsal aspect of the anconeal process. If normograde placement is chosen, the pin is inserted at the medial aspect of the olecranon and directed slightly laterally to insure the pin enters the medullary canal.

Closed or Open Reduction and External Skeletal Fixation

External skeletal fixation is a versatile and useful method of managing many combined radioulnar fractures. An external fixator can be applied after open or closed fracture reduction. If open reduction is chosen, the approach should be limited in length to what is necessary to see the fracture site. I prefer to use a limited craniomedial approach. The open approach offers the advantages of seeing the fracture during reduction and allowing application of a cancellous bone graft. However, open reduction also has disadvantages of causing further trauma to the blood supply of the fracture fragments and exposing the fracture to the outside environment.

Several different external fixator configurations are applicable to the radius. Stable transverse or short oblique fractures in medium-sized dogs can be treated with a Type 1-a fixator consisting of four half- pins and a single connecting bar (Figure 57-9C). A similar configuration with six pins and a single connecting bar is used for similar fractures in larger dogs (Figure 57-9D). The fixator is applied on the cranial or craniomedial aspect of the radius. Driving the pins in a true medial to lateral direction across the radius is difficult and may result in iatrogenic fracture because of the oval shape of the radius. If one chooses to apply a Type II fixator, smaller diameter pins should be used in the proximal portion of the radius to minimize the risk of iatrogenic fracture.

Depending on the system used, the pins must be inserted in a particular order during application of an external fixator with only one connecting bar. The fracture is reduced, and the most proximal and distal pins are inserted first. These pins should be inserted as far away from the fracture as possible and at a 45 to 60° angle to the long axis of the bone (Figure 57-9A) if smooth pins are used. If positive profile threaded pins are used, they should be applied perpendicular to the long axis of the bone. A connecting bar with four clamps is attached, and the two outermost clamps are tightened on the pins. The middle two pins are placed through the clamps and then are driven into the bone (Figure 57-9B). These pins should be 1 to 2 cm from the fracture. The greatest biomechanical stability is achieved when there is maximal distance between the two pins on each side of the fracture (Figure 57-9C). All clamps are then completely tightened, and postoperative radiographs are obtained. Minor adjustments in fracture reduction can be made if the clamps are loosened. Because use of a single connecting bar precludes major adjustments in fracture reduction once all the pins have been placed, one should reduce the fracture properly before applying the external fixator.

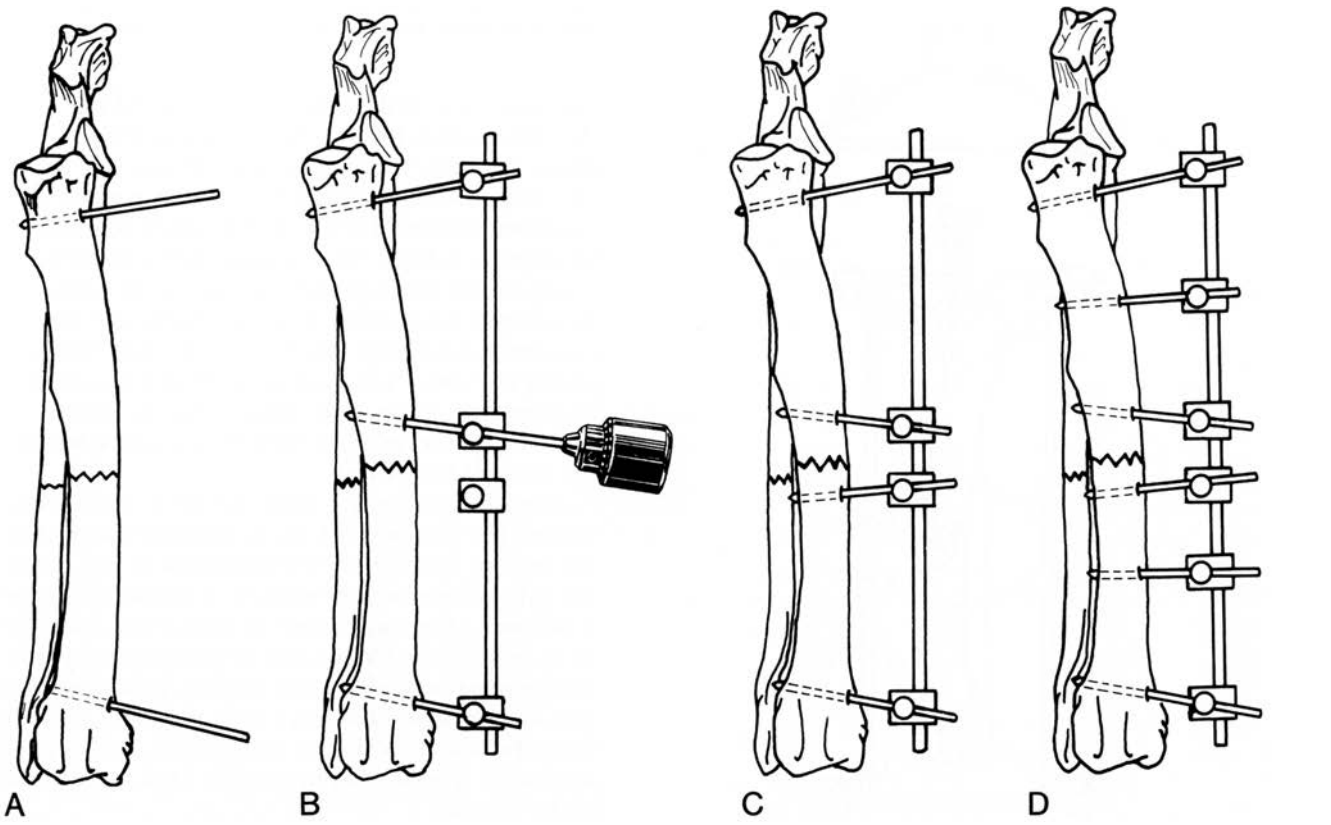

Figure 57-9. External skeletal fixation of combined radial and ulnar diaphyseal fractures. **A.** Insertion of most the distal and most proximal pins. **B.** Attachment of t he connecting bar with clamps and placement of middle two pins. **C.** Completed four-pin, single-bar (Type I) fixator in place. **D.** Six-pin single-bar fixator in place.

A six-pin, single-connecting bar fixator is applied similarly to a four-pin, single-bar fixator. Six clamps are placed on the bar instead of four. The middle pins on either side of the fracture are placed last (See Figure 57-9D).

A quadrilateral frame (Type I-b) external fixator is useful for unstable comminuted fractures and open fractures with missing bone fragments (Figure 57-10). This configuration is also particularly useful for proximal or distal fractures in which one segment is short. A quadrilateral frame allows pin fixation in two planes, thus providing stable fixation of short fragments that would not be possible with other configurations. A quadrilateral frame, like other external fixators, can be applied after open or closed reduction. If reduction is not possible (i.e., if cortical fragments are missing), the bone is anatomically aligned before the fixator is applied. The first row of pins is applied from the craniomedial aspect of the radius toward the caudolateral aspect in the same way as described for a four-pin, single-bar fixator. Once the first row of pins is placed and the connecting bar is applied, the second row of pins is placed. The second row of pins is placed identically to the first, except it is applied from the craniolateral aspect of the radius toward the caudomedial aspect. The second connecting bar is then applied. The two rows of pins are connected to each other by applying a connecting bar to the two most proximal and another to the two most distal pins (Figure 57-11). Alternatively, a diagonal connection can be made (i.e. from the most proximal pin on the lateral side to the most distal pin on the medial side) which has been shown to be stronger than the proximal and distal connections previously described.

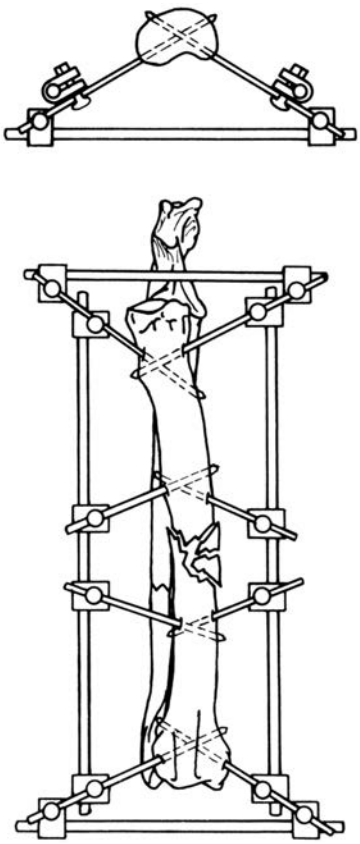

Figure 57-10. A quadrilateral frame (Type IB) external fixator is useful for unstable comminuted radial and ulnar fractures, especially those that occur in the distal third of the diaphysis.

Figure 57-11. Proximal and distal radial physeal fractures can be stabilized with two small Kirschner wires. External coaptation may also be necessary, especially with distal physeal fractures.

Other fixator configurations may be used depending on the nature of the fracture. Generally, the more unstable the fracture or the longer the expected healing time, the more stable the configuration should be. Positive profile threaded pins provide greater bone holding power and are less likely to loosen prematurely. Pre-drilling technique is recommended with these pins. Some of the newer systems allow placement of threaded pins through the clamps and permit clamps to be tightened on the pins after they have been inserted into the bone. These systems provide the flexibility of adding additional pins after the connecting bar and initial clamps have been applied. Regardless of the configuration chosen, the points of the pins should protrude slightly beyond the second cortex. The pins should be driven by hand or with a low-speed power drill. The clamps should not touch the skin; rather, they should be approximately 1cm above the skin. The pins are cut off near the clamps after any necessary adjustments have been made.

Circular ring fixators may be used to stabilize radius and ulnar fractures. These devices require some preoperative assembly of the rings to facilitate application during surgery, and may require more time to apply than conventional external fixators. Ring fixators offer the advantage of placing small wires (e.g., 1.6 mm diameter) through the fracture fragments. These wires are attached to the rings and tension is applied which dramatically increases the stiffness of the wires. Therefore these small wires can be used instead of larger pins (see Chapter 53 – Circular External Skeletal Fixation). Using small wires allows one to stabilize short bone fragments that occur with distal radial fractures because they do not require as much bone length as larger pins. I believe circular ring fixators offer the greatest advantage when attempting to repair fractures with one main fragment is very short. Hybrid fixators utilizing a ring and wires to capture the short segment and linear fixator elements to immobilize the long segment have also been used successfully (see Chapter 53 – Circular External Skeletal Fixation).

Post-operative placement of a compression bandage is helpful. The bandage helps to minimize postoperative swelling and is left on for 48 hours. The fixator is wrapped with cotton and elastic tape after the compression bandage has been removed. This wrap covers any sharp pins and prevents the fixator from catching on carpet and similar objects. The client should limit the animal's exercise to leash walks until the fracture has healed.

Fixation pins may loosen before a fracture has healed. The likelihood of this complication depends on the type of fracture, the configuration of the fixator, the number and type of fixation pins used and the techniques used to place them, the animal's age, and the amount of activity the animal is allowed. One may choose to replace the loose pins or to remove the fixator and use external coaptation for the remainder of fracture healing. In certain cases, one may be able to remove only the loose pins and leave the rest of the fixator undisturbed. This can only be done if at least two pins remain fixed on each side of the fracture.

Generally, an external fixator can be removed without anesthesia or even sedation. The clamps and connecting bars are loosened and removed. Smooth fixation pins can be pulled out by hand or with a pair of pliers. Positive profile threaded fixation pins must be un-screwed from the bone with a hand chuck or power drill. The small amount of hemorrhage that usually occurs from the pin holes can be controlled with a light pressure bandage. The animal's activity should be restricted for several weeks after removal of the fixator while re- modeling of the holes in the bone begins.

Radial Physeal Fracture-Separations

Fracture-separation through either radial physis is uncommon. Such fractures occur through the zone of hypertrophied cartilage. The animal's owner should always be warned that premature physeal closure and angular limb deformity may follow such a fracture. If premature physeal closure does occur, it usually happens within 2 weeks of the fracture.

Closed reduction of a radial physeal fracture and external coaptation should be attempted first. If closed reduction fails, open reduction should be performed. The fracture can be stabilized with small Kirschner wires (See Figure 57-11). The wires are driven from the epiphysis across the physis and into the metaphysis. To minimize premature physeal closure, the wires should be as parallel to one another as possible and as perpendicular to the physis as possible. Some form of external coaptation is advisable for 2 weeks, especially for distal physeal fractures. These fractures usually heal within 3 weeks. The pins should be removed if possible.

Correction of Radial and Ulnar Growth Deformities Resulting from Premature Physeal Closure

Dominique J. Griffon and Ann L. Johnson

Introduction

The most common angular deformities in dogs affect the antebrachium and represent 0.74% of all skeletal diseases in dogs. Among these, angular deformities attributed to crushing injuries (Salter V fractures) of the distal ulnar growth plate have been well described. This type of injury may result in external rotation, radius valgus, cranial bowing of the radius, radio-ulnar incongruence, and limb shortening. Retained cartilage core, hypertrophic osteodystrophy, nutritional disorders, asymmetrical crushing injuries (Salter VI) and other fractures of the growth plates can also result in premature physeal closure of the antebrachium. Scientific documentation of the effects of angular deformity and limb shortening on limb function and secondary degenerative joint disease is limited. However, surgical correction has traditionally been recommended in cases with elbow dysplasia, more than 10 degrees of angulation, and / or more than 20% limb length discrepancy. The management of growth deformities of the antebrachium is based on consideration of the following factors:

1. Presence of a unifocal or bifocal (resulting in translation of the limb) deformity
2. Three-dimensional (rotation, medio-lateral and craniocaudal planes) assessment of the severity of the angular deformity
3. Point of maximum deformation
4. Limb length discrepancy (actual and expected)
5. Growth potential of the affected limb and the contralateral limb
6. Congruence of the elbow joint

Careful patient selection and thorough pre-operative planning are crucial to optimize treatment outcome. Physical examination is essential to evaluate the overall function of the limb and evaluate joints for pain on manipulation, crepitation, effusion and range of motion. Rotational deformity is easier to measure on physical examination than radiographs, by comparing the planes of flexion and extension of adjacent joints. Planning requires a minimum of two orthogonal radiographic views including the elbow and the carpus of the affected limb. Similar radiographs of the contralateral antebrachium are useful as a reference. Additional radiographs and/or computed tomography of the forelimb are indicated to evaluate the elbow for any evidence of dysplasia.

Ulnar Ostectomy in the Immature Dog

The purpose of this technique is to release the constraint created by the ulna on the remaining growth of the radius in immature dogs. Postoperative increase in radial length and correction of the angular deformity correlate with the growth potential in the radial physes. Owners should be warned that any rotational deformity will most likely persist and that additional surgical correction may be warranted at skeletal maturity. Ulnar ostectomy is always coupled with procedures to prevent premature union of the ulnar segments, such as the insertion of a fat graft.

The dog is placed in lateral recumbency, with the affected forelimb and ipsilateral flank prepared for aseptic surgery. A lateral approach to the distal ulna starts with a skin incision extending over the mid to distal ulna. Subcutaneous tissue is incised and the lateral digital extensor muscle is separated from the extensor carpi ulnaris muscle. Fascia and surrounding soft tissues are dissected to expose a segment of ulna carefully insuring that all periosteum, with its osteogenic potential, remains with the segment of bone to be resected. Depending on the size of the dog, a one to three centimeter segment of the ulna is resected using bone cutters or an oscillating bone saw cooled with a saline flush. The segment of bone and associated periosteum are removed (Figure 57-12). If the interosseous artery is disrupted during the ostectomy, effective hemostasis must be achieved.

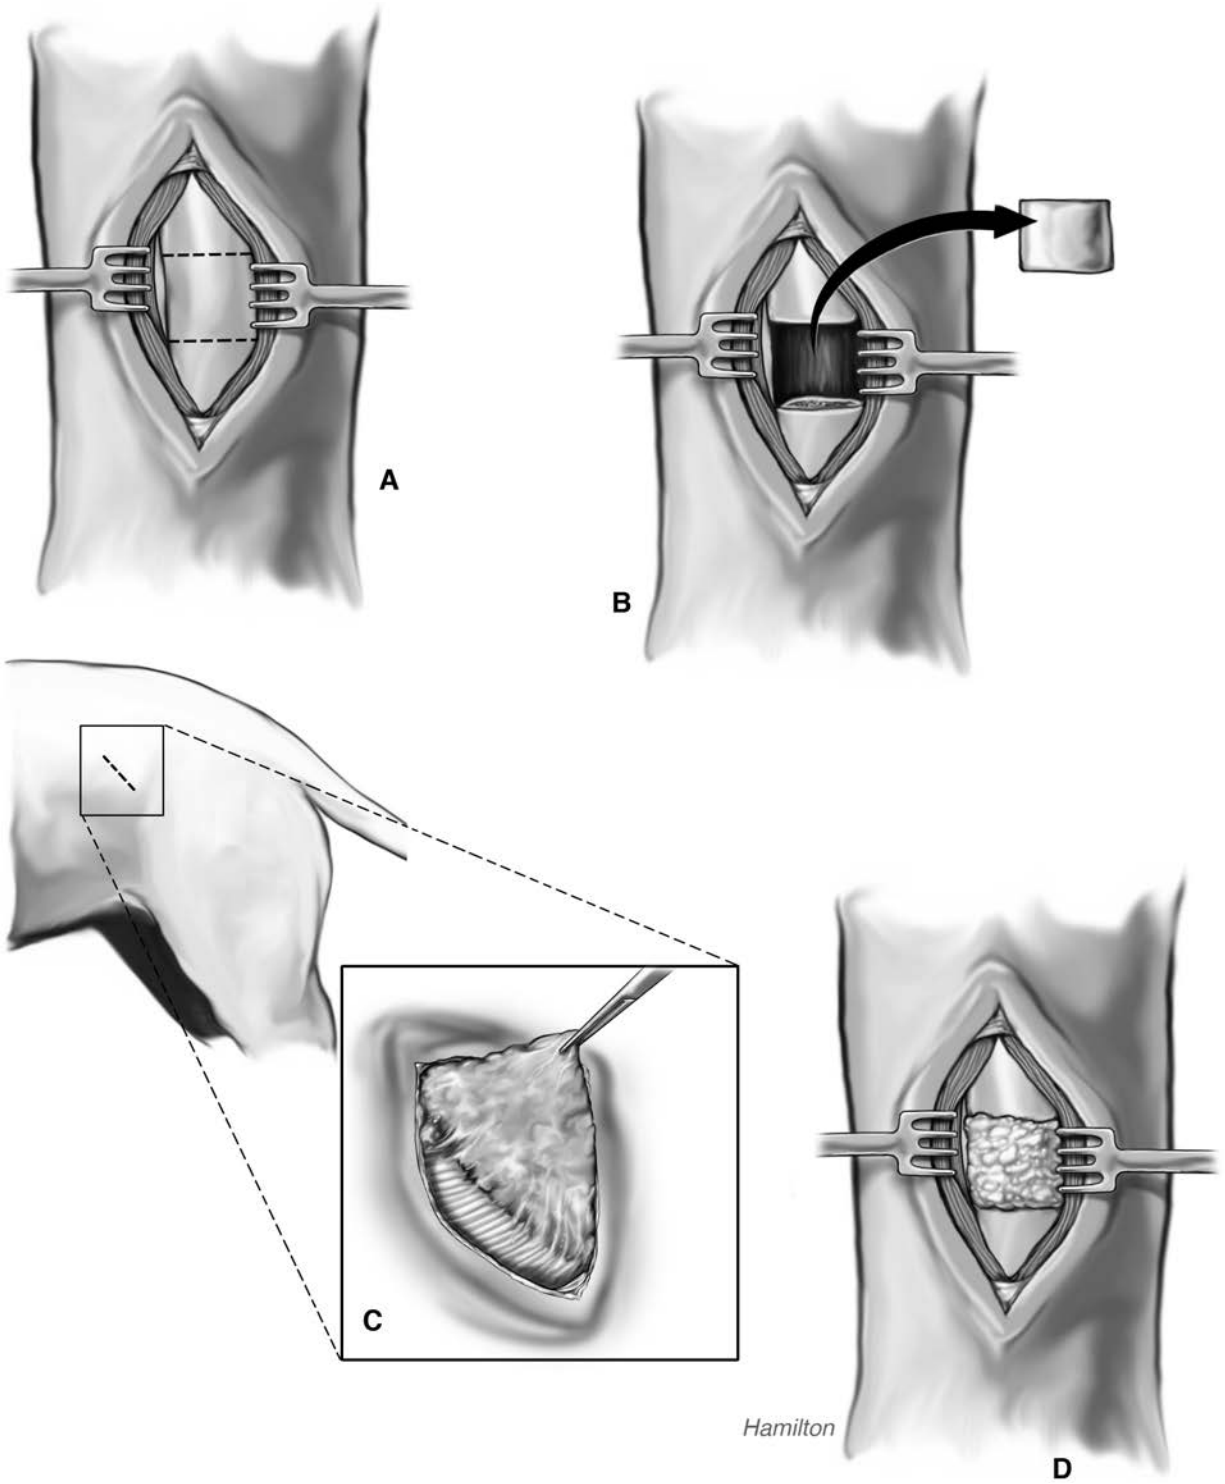

Figure 57-12. Distal ulnectomy in the immature dog. **A.** The distal ulna is exposed. An ostectomy is performed just proximal to the distal physis. **B.** A 1- to 3- cm section of bone and surrounding periosteum is removed. **C.** A large piece of fat is atraumatically harvested from the flank. **D.** The fat is inserted in the ostectomy gap and the fascia closed.

Bone wax may be applied directly over the proximal and distal ends of the osteotomized bone to prevent premature healing of the ulna. While this procedure effectively inhibits bone formation and development of a synostosis, it is associated with a risk of foreign body reaction. Other surgeons have recommended suturing the periosteum covering the resected segment of ulna over each end of the osteotomized bone. However, the procedure most commonly used to prevent premature healing of the ulna consists of interposing a fat graft in the ulnar defect. A 2 to 3 centimeter skin incision is made in the ipsilateral flank area, exposing the subcutaneous fat. A large single piece of fat is sharply dissected free and placed in the ostectomy gap (See Figure 57-12). Hemostasis is achieved at the donor site and the subcutaneous tissue and skin are sutured. The transplanted fat is secured in the ostectomy gap by suturing adjacent soft tissues. The subcutaneous tissues and skin are closed in a routine fashion.

Post operative radiographs are obtained to document the location and length of the ostectomy gap. A soft padded bandage is placed for 2-4 days after surgery to prevent seroma formation. A splint is recommended to protect the limb for 2 weeks if bilateral procedures are done. The dog is released to the owners with instructions to limit activity. Monthly radiographs are indicated until skeletal maturity, to allow serial evaluation of radial growth, correction of the angular deformity and persistance of the ostectomy gap. Restoration of the normal configuration of the elbow due to the release of the proximal ulna may be noted. Union of the ulna prior to skeletal maturity may require reoperation. A corrective osteotomy of the radius may be indicated if angular deformity remains clinical at maturity.

The ostectomy should be performed in the distal ulna just proximal to the physis to effectively relieve the restraints on the radial growth plate without affecting the stability of the elbow or carpus. Failure to remove all of the periosteum at the ostectomy site will result in premature bone bridging of the ostectomy gap. Meticulous apposition of soft tissues and obliteration of dead space minimizes the risks of herniation of the fat graft (potentially leading to dehiscence and premature union of the ulna) and seroma formation at the donor site. Postoperative splint support for two weeks is important with bilateral ostectomies to prevent motion at the ostectomy gap and displacement of the fat graft. However, splinting an immature dog often leads to laxity of the flexor tendons and hyperextension of the carpus. Therefore careful attention must be paid to removing the splint at the appropriate time.

Radial Ostectomy in the Immature Dog

The goals of treatment are to allow unrestricted growth of the normal physes of the radius and ulna, and to restore and maintain elbow congruity. This procedure is indicated in immature dogs with premature closure of the proximal or distal radial growth plate and active ulnar physes.

The animal is treated with a middiaphyseal ostectomy of the radius coupled with the placement of a free autogenous fat graft in the defect to prevent bone union (Figure 57-13A and B). Release of the tension on the proximal and distal radius will

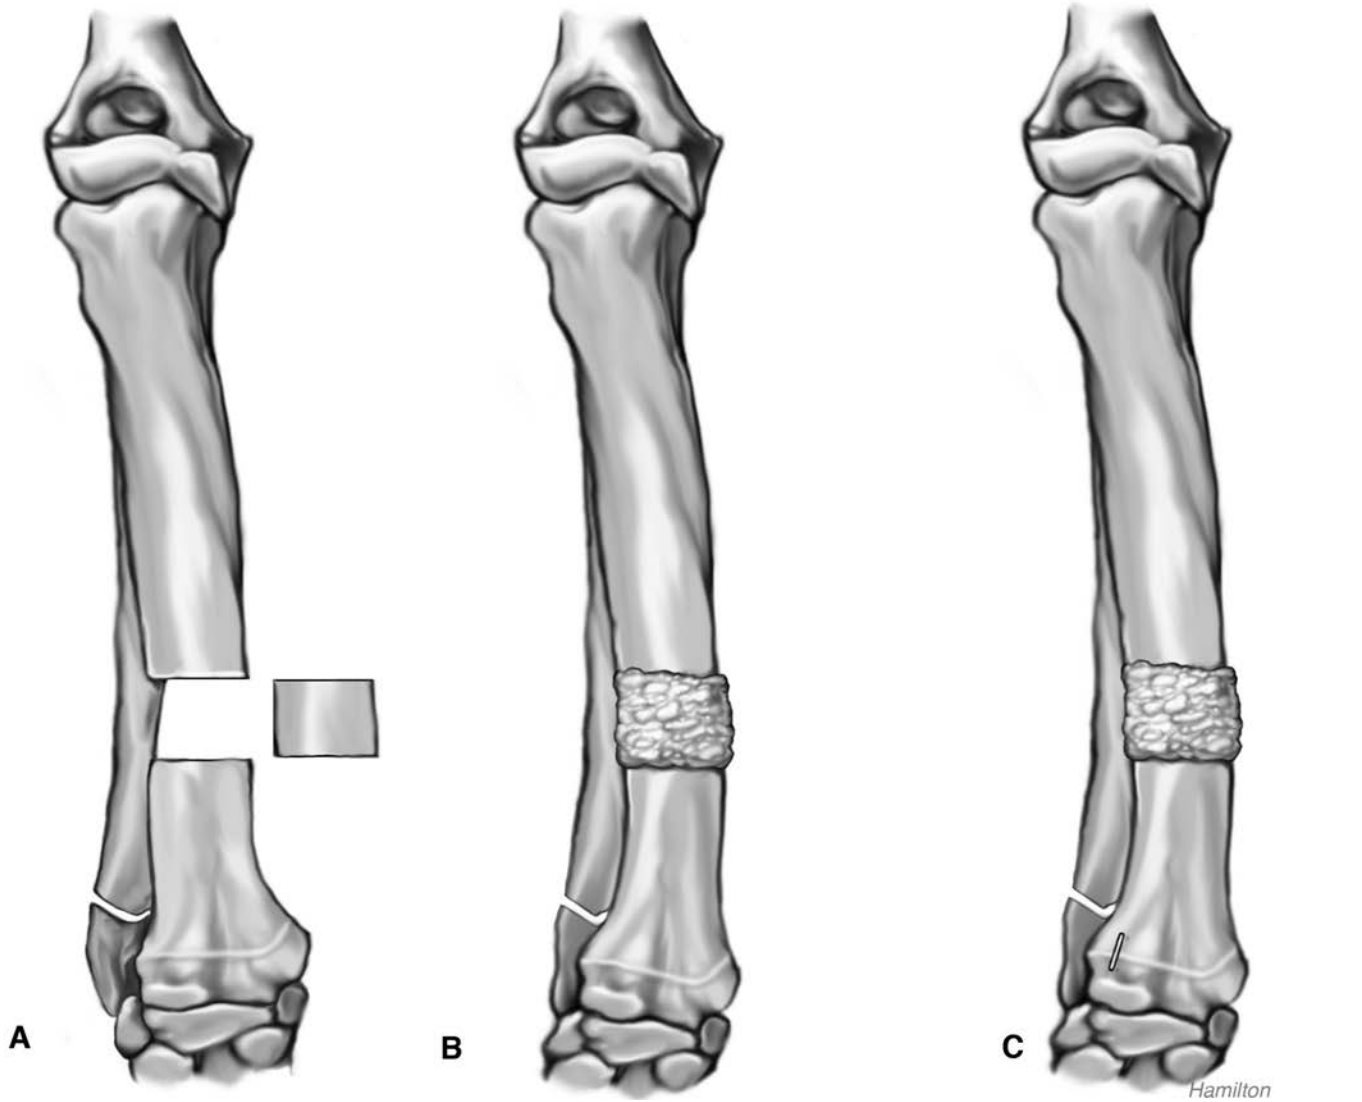

Figure 57-13. Radial ostectomy in the immature dog. **A.** A 1- to 2- cm segment of radius is resected. **B.** A large piece of fat is placed in the ostectomy gap. **C.** If this technique is used to treat an incomplete, premature closure of the distal radial growth plate, staples are placed across the functional portion of the growth plate to prevent future interference.

usually allow the adjacent joints to reestablish normal position. A postoperative splint is applied for three to four weeks once surgical swelling has decreased (24 to 48 hours after surgery), as the radius is the primary weight bearing bone in the distal forelimb. The limb should be splinted in a slight flexion and varus, to minimize post-immobilization laxity of the carpus. The dog is released to the owners with instructions to limit activity. Monthly radiographs are indicated until skeletal maturity, to allow serial evaluation of radial growth, correction of the angular deformity and persistance of the ostectomy gap. Thickening and cranial bowing of the ulna commonly occurs in response to the increased mechanical loading of the bone. A second surgical procedure to reunite the radial segments by bridging the ostectomy gap with autogenous cancellous bone graft once the dog has reached skeletal maturity is therefore rarely indicated.

Radial ostectomy can also be considered in dogs with asymmetrical closure of the radial growth plate secondary to retained cartilage core or Salter VI fracture. In these cases, the active portion of the affected growth plate may be stapled to prevent any further deviation of the radial segment and interference with the ostectomy site (Figure 57-13C). Partial closure of the distal radial growth plate has also been treated by resection of the bone bridging the physis and placement of a fat graft. Whereas this option may decrease the risk of postoperative fracture and compensatory changes in the ulna, identifying the margins of diseased growth plate may require advanced imaging and is technically challenging. Complications include incomplete resection of the bone bridge and collateral damage to remaining growth plate resulting in failure to correct the deformity.

Closing Wedge Osteotomy and Plate Fixation in the Mature Dog

A closing wedge osteotomy can be used to treat an angular deformity of a long bone that is not significantly shortened, as this procedure will result in loss of bone length. This procedure results in cortical apposition if no rotational correction is required.

Preoperative planning is based on radiographs of the affected and contralateral control radius and ulna, including the adjacent joints. The radiographs of the affected radius are studied to determine the location of the point of greatest curvature of the radius and to evaluate the anatomy of the adjacent elbow and carpus. The affected limb is compared to the control limb to determine the discrepancy in length. The plane of angulation may be calculated based on the deviations measured on lateral and cranio-caudal projections. It may also be directly determined on a radiograph which best shows the angle of the deformity. Lines are drawn parallel to the proximal and distal joint surfaces to determine the angle of deformity of a radius (Figure 57-14). A line is then drawn perpendicular to the proximal line and centered within the proximal diaphysis. A similar line extends from the distal line, centered within the distal diaphysis. The intersection of these lines identifies the location of the osteotomy. At the osteotomy site, lines are drawn parallel to the proximal and distal joint lines. These lines intersect to form the wedge to be removed. The base of the wedge is at the convex surface of the deformity. The distance between the osteotomy line and the

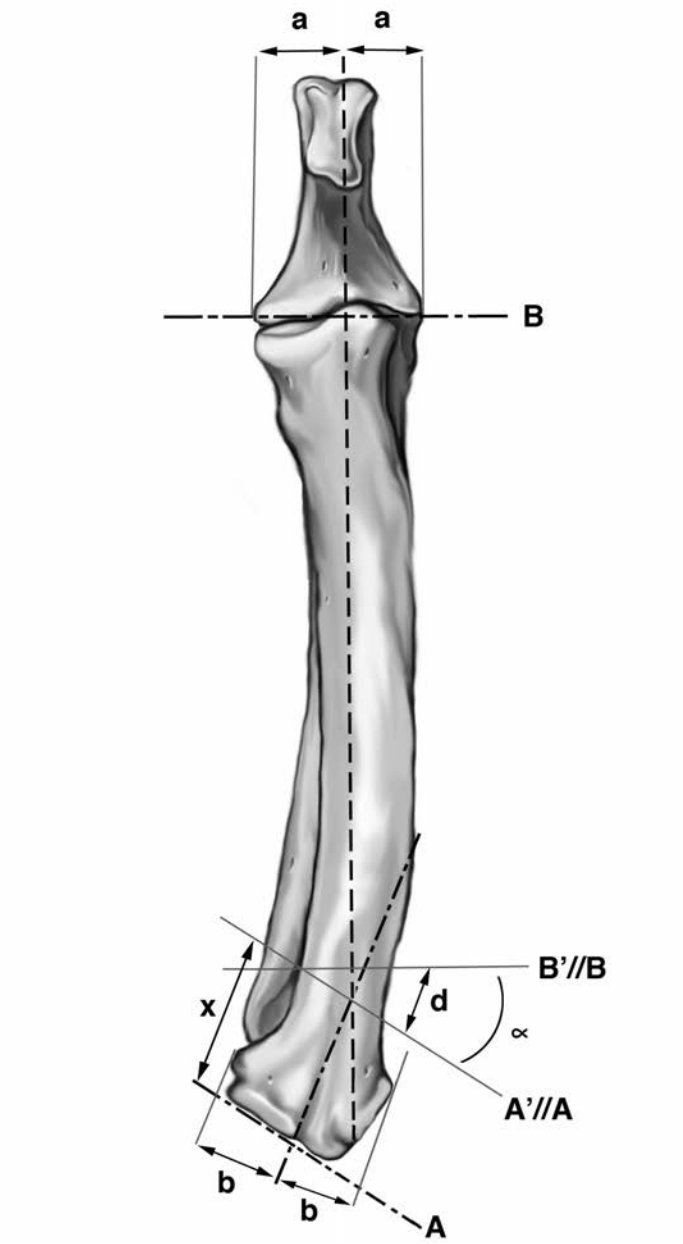

Figure 57-14. Preoperative planning of a closing wedge osteotomy to correct a radius valgus. Lines *A* and *B* are parallel to the distal and proximal radial articular surfaces, respectively. The axis of the proximal and distal radius is drawn perpendicular to the closest joint surface and originating in the center of the bone. The point of intersection of these axes locates the site of maximum deformation of the bone. A line *A'* is drawn from that point, in a direction parallel to the distal joint surface (Line *A*), representing the distal osteotomy. The point of intersection of this line with the concave surface of the bone corresponds to the origin of the distal osteotomy. The distance between this point and the carpal joint *(x)* can be used as an intra-operative landmark. A second line *(B')* extends from the origin of the distal osteotomy on the concave aspect of the radius in a direction parallel to the elbow joint (line *B*). This line represents the proximal osteotomy. The angle between lines *A'* and *B'* *(α)* corresponds to the amplitude of angulation. The distance between these two lines *(d)* may be measured along the convex surface of the radius to provide an intraoperative landmark for the proximal osteotomy. The section of bone comprised between lines *A'* and *B'* represents the wedge of bone that should be removed in order to correct the deformity.

carpal joint, and the width of the wedge to be removed on the convex side of the radius are measured and corrected for radiographic magnification (115%). A template of the selected plate can be used to verify that the bone stock between the osteotomy and the joint will allow screws to purchase six cortices. If necessary, the location of the wedge may be moved slightly proximally to secure a plate. However, moving the osteotomy site away from the area of greatest curvature results in a translational deformity. The dog is placed in dorsal recumbency, with the affected limb prepared for aseptic surgery and hanging from the ceiling. A sterile hook connects the distal extremity of the limb to a hook fixed to the limb, to allow aseptic, intra-operative manipulation of the limb. Draping the contralateral limb (if normal) in the surgical field allows intra-operative comparison, which is especially helpful in chondrodystrophic breeds. Kirschner wires are placed parallel to the proximal joint and parallel to the distal joint. A small needle may be inserted in the carpal joint as a landmark. The proximal and distal osteotomies should be parallel to the proximal and distal Kirschner wires, respectively. The distal osteotomy is located as close as possible to the point of maximum deformation, at the predetermined distance from the carpal joint. The proximal osteotomy should intersect the distal osteotomy at the convex surface of the bone, creating a bone wedge of a similar size to the preoperative plan. (Figure 57-15). The bone wedge is removed and may be morsellised to use as an autogenous graft. An ulnar ostectomy is performed via a separate lateral approach to the bone. Removing a small segment of ulna prevents interference of the ulna during manipulation of the radius and provides additional bone graft. The major segments of the radius are reduced and rotational alignment verified and corrected, if needed. Bone segments are stabilized with a compression plate. Correction of any rotational deformity will affect cortical apposition and complicate plate contouring, since the distal radius is not cylindrical.

Postoperative radiographs are indicated to evaluate correction of the deformity and implant placement. Postoperative care is similar to the management of a plated fracture. Bone healing should occur within 6 to 12 weeks.

Figure 57-15. Closed corrective osteotomy in the mature dog. The distal osteotomy is performed from a distance *(x)* from the carpal joint determined on pre-operative radiographs. This osteotomy should be parallel to the distal articular surface. The proximal osteotomy is started at a predetermined distance (distanced on Figure 57-14) on the convex surface and aimed toward the distal aspect of the opposite cortex. The wedge of radius removed is morsellised and used as a graft. An ulnar ostectomy is performed prior to reduction of the radius and plate fixation.

Open Corrective Osteotomy and External Fixation (Linear or Hybrid) in the Mature Dog

This procedure combines an oblique osteotomy of the radius and a transverse osteotomy of the distal ulna to correct angular and rotational deformities while preserving pre-existing limb length. This technique is therefore preferred in mature dogs with minor limb length discrepancy, especially if morbidity would result from shortening of the limb secondary to a closed wedge osteotomy. External fixation is a versatile method of stabilization of the osteotomy, which allows additional postoperative correction if necessary. Hybrid fixators add further versatility to this technique, especially when osteotomies are located close to a joint. These advantages facilitate the correction of angular deformities in multiple planes, and avoid the technical difficulties associated with plate contouring. However, the owners must be willing to comply with the post-operative care of external fixators. In addition, type II linear fixators are not very effective at correcting the cranio-caudal component of antebrachial deformities, most likely because this plane is perpendicular to that of the fixator.

The dog is placed in dorsal recumbency with the affected limb prepared for aseptic surgery and securely suspended from the ceiling. A sterile hook connects the distal extremity of the limb to a hook fixed to the limb, to allow aseptic, intra-operative manipulation of the limb. The contralateral limb may be included in the surgical field for comparison. In addition, a donor site for cancellous bone (usually the proximal humerus of the affected forelimb) should be prepared for aseptic surgery and draped off if the surgeon plans to fill the open osteotomy site with an autogenous bone graft.

Small needles may be placed in the carpal and elbow joints as landmarks. The lateral head of the radius is palpated, the skin incised and the bone exposed by blunt dissection of the subcutaneous tissues and grid dissection of the muscle. Small Hohmann retractors may be placed on the cranial and caudal cortices of the radius to facilitate placement of the pin in the center of the bone. Using predrilling technique, a centrally-threaded positive profile fixation pin is placed through the proximal radius from the lateral aspect. The pin should be parallel to the proximal radial articular surface and should be within the lateral transverse plane of the proximal radius. The lateral aspect of the distal radius is palpated and the ulnar styloid process is identified. Using predrilling technique, a centrally-threaded positive profile fixation is placed through the distal radius, starting cranially to the ulnar styloid process, from the lateral aspect. The pin should be parallel to the distal radial articular surface and should be within the lateral transverse plane of the distal radius.(Figure 57-16) A lateral approach is made to the distal ulna (see ulnar ostectomy) and a transverse osteotomy is performed with an osteotome or oscillating saw. Intraoperative radiography or fluoroscopy may be used to verify acceptable placement of the pins in relation to the joints. A skin incision is made over the cranio-medial aspect of the distal radius at its point of greatest curvature. Dissection through the subcutaneous tissues exposes the radial diaphysis. An oblique osteotomy of the radius is made at the point of greatest curvature using an osteotome or an oscillating bone saw. The osteotomy line should be directed parallel to the distal radial articular surface (See Figure 57-16). The operating table is lowered so the weight of the animal is suspended from the ceiling. The weight of the animal distracts the distal radius and helps to align the proximal and distal joint surfaces parallel to each other. The proximal and distal transfixation pins are aligned parallel to each other and in the same transverse plane which should eliminate any angular or rotational deformity. Connecting rods with two to six single fixation clamps on the medial rod are connected to the transfixation pins on the lateral and medial aspect of the limb. Additional fixation half-pins are driven through the unused single clamps and into the medial aspect of the radius, penetrating both cortices. One to two additional pins should be placed in each radial segment (See Figure 57-16). Placing these pins on the medial aspect of the radius allows post-operative destabilization and conversion of the type II external fixator to a type Ia. Autogenous cancellous or allogeneic bone (demineralized bone matrix) is placed at the radial osteotomy site. The wounds are closed by suturing the subcutaneous tissue and skin separately.

A circular ring and fixation wires may be used to secure the distal radial segment instead of threaded pins (Figure 57-17).

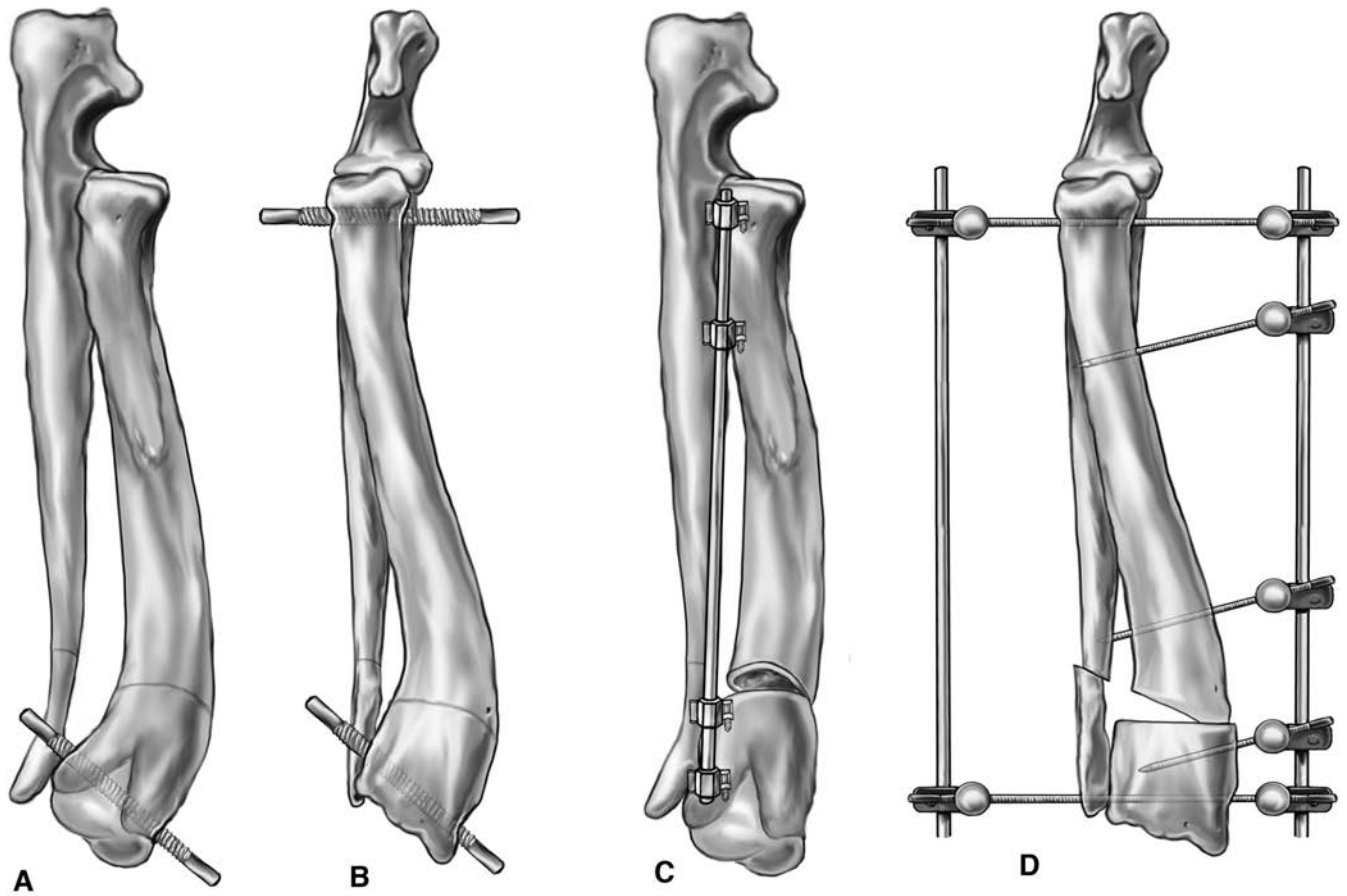

Figure 57-16. Open corrective osteotomy and linear external fixation in the mature dog. **A** and **B**. The proximal pin should parallel the proximal radial articular surface and should be within the lateral transverse plane of the proximal radius. The distal pin should parallel the distal radial articular surface and should be within the lateral transverse plane of the distal radius. An oblique osteotomy of the radius is made at the point of greatest curvature with an osteotome or an oscillating saw, directing the osteotomy line parallel to the distal radial articular surface. A transverse osteotomy of the ulna is performed. **C** and **D**. After the osteotomy, the radius is aligned so the proximal and distal transfixation pins parallel each other and are in the same transverse plane, and the remainder of the type II external fixator frame is constructed.

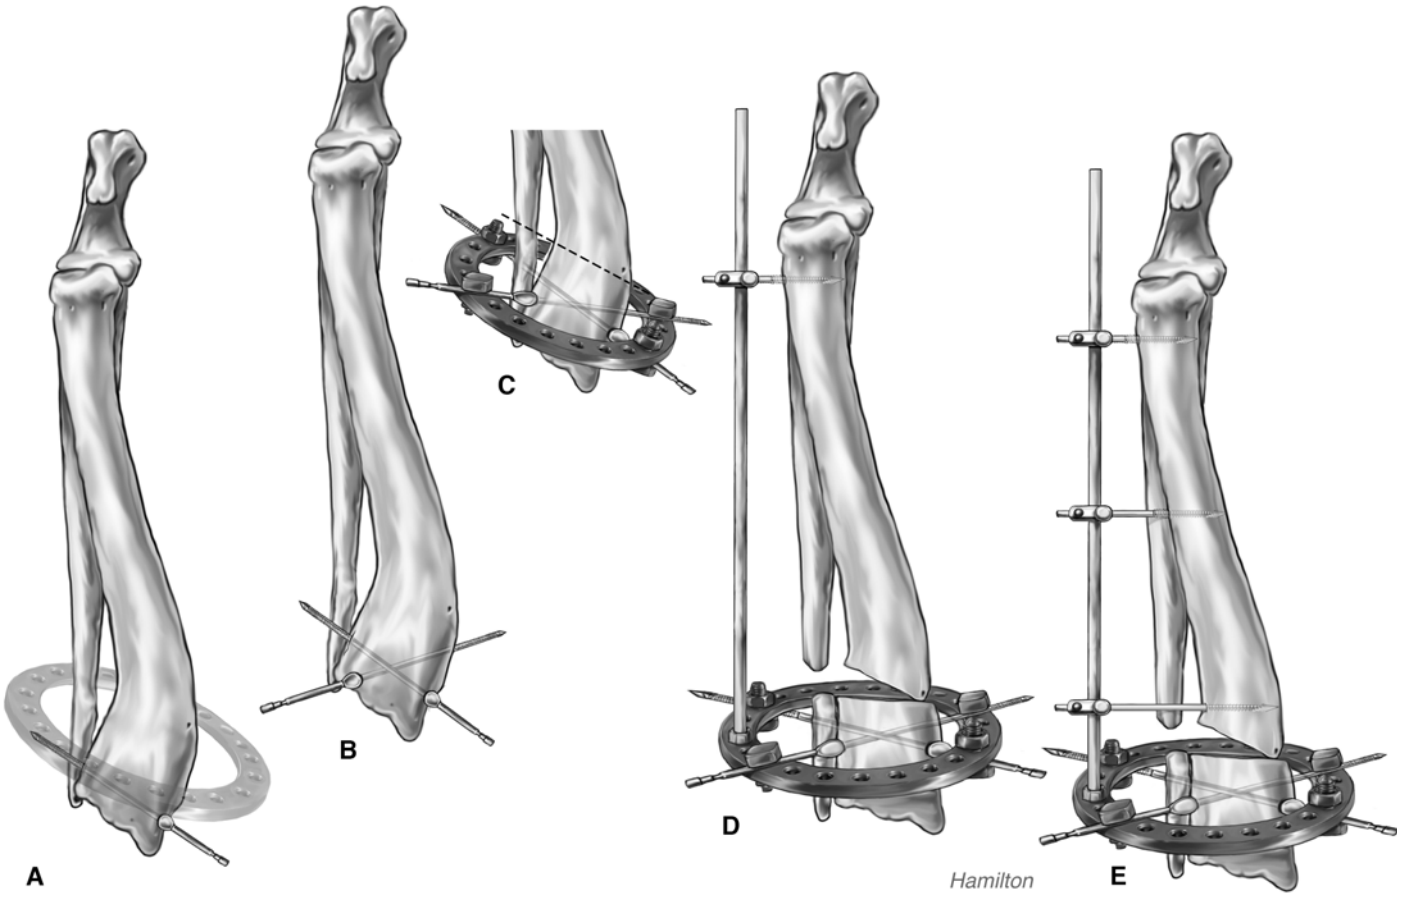

Figure 57-17. Open corrective osteotomy and hybrid external fixation in the mature dog. **A.** A ring is passed around the limb, with a diameter allowing a space of one to two cm between the inner edge of the ring and the skin of the distal antebrachium. An olive wire should be placed parallel to the distal radial articular surface and should be within the lateral transverse plane of the distal radius. This wire can then be used as a reference to correct the alignment of the limb, and as the most distal point of fixation. **B.** The most distal wire is secured to the bottom of the ring and a second olive wire is inserted from the proximal aspect of the ring. This wire should cross the first wire through the center of the radius and be inserted in a safe corridor, at a 60 to 90 degree angle from the first wire. The proximal reference wire should parallel the proximal radial articular surface and should be within the lateral transverse plane of the proximal radius. **C.** An oblique osteotomy of the radius is made at the point of greatest curvature with an osteotome or an oscillating saw, directing the osteotomy line parallel to the distal radial articular surface. A transverse osteotomy of the ulna or an ulnectomy is performed. If the distal radial segment is too short to accommodate a second ring, a drop wire (not shown) is added to the distal ring. **D.** The radius is aligned so the proximal and distal reference wires parallel each other and are in the same transverse plane. A connecting rod is placed on the ring and connected to an end-threaded pin positioned in the proximal radius through a stab incision. The proximal reference wire is removed.

Hybrid fixation is especially relevant for adequate fixation of a short segment of bone in dogs with a point of maximum angulation located very distally along the radius. In these cases, the osteotomy site may need to be displaced proximally to allow placement of at least two threaded pins in the distal segment, thereby creating a translation of the radial segments during correction of the deformity. Use of a circular ring and fixation wires to capture the distal segment requires less bone stock and allows optimal placement of the osteotomy. The dog is placed in dorsal recumbency with the affected limb prepared for aseptic surgery and securely suspended from the ceiling. A sterile hook connects the distal extremity of the limb to a hook fixed to the limb, to allow aseptic, intra-operative manipulation of the limb. The procedure starts with the placement of the distal ring around the limb (See Figure 57-17). The most distal wire is inserted parallel to the plane of the distal radial articular surface to serve as a reference. This wire may be used as the most distal element of fixation and fixed to the bottom of the ring. The second wire is inserted from the proximal aspect of the ring, at a 60 to 90° angle from the first wire. Both wires are secured to the ring and tensioned appropriately. Another wire is placed distal and parallel to the elbow joint to serve as reference. An osteotomy of the radius and ulna are performed as described above. The operating table is lowered so that the weight of the animal distracts the distal radius and helps to align the proximal and distal joint surfaces parallel to each other. The proximal and distal references are aligned parallel to each other and in the same transverse plane to eliminate any angular or rotational deformity. A hybrid rod is attached to the ring with a pair of nuts and an SK single fixation clamp applied to the rod is used to secure a threaded half pin placed in the most proximal, medial or cranio-medial aspect of the radius. Limb alignment and range of motion are checked prior to application of additional fixation pins to the proximal segment to complete the hybrid fixator. The positioning of wires and rod (thereby determining the plane of the most proximal pin) on the distal ring should be planned

to allow insertion of a drop wire, providing a third element of fixation in the distal segment (See Figure 57-17). Clamps and fixation pins are added to stabilize the proximal segment and form a Type I-a hybrid construct. A type I-b construct may be preferred, especially in cases with cranio-caudal angulation. In these cases, the hybrid rod placed cranially should be short enough to allow flexion of the elbow. Olive wires may be used for better control of the distal radius, especially if cranio-caudal correction is attempted and/or if only two wires are placed in the short segment of bone.

Postoperative radiographs are obtained to document radial alignment and implant position. The limb is bandaged with gauze sponges wedged between the apparatus and the skin to minimize soft tissue swelling. As postoperative swelling decreases, the limb may be left unbandaged. A light wrap around the rods and rings minimizes the risk of catching the fixation on surrounding objects after discharge from the hospital. Owners are instructed to confine their dog, limit activity to leash walking and clean the pin tracts daily. Weekly rechecks should be scheduled initially, to monitor pin tracts, remove sutures (at 2 weeks) and change the bandage around the frame. Radiogaphic evaluation of healing of the osteotomy is indicated every 4 to 6 weeks. The fixator is removed when the osteotomy site is bridged with bone.

Suspending the limb from the ceiling during the osteotomy aids the surgeon in aligning the limb, and apparently decreases the amount of postoperative swelling because of the minimal manipulation needed to support the limb during correction and fixation. It is important to make the radial osteotomy cut parallel to the distal radial joint surface not only in the lateral to medial plane but also in the cranial to caudal plane to enable correction of a severe cranial bowing deformity. External fixation of the osteotomy is useful for several reasons. The proximal and distal transfixation wires serve as external landmarks to help align the bone after osteotomy. Additional manipulations can be easily made after the surgical procedure if the surgeon is not satisfied with the corrections. The rigidity of the fixator can be altered to fit the animal and the stage of healing of the osteotomy. Finally, removal of the fixation after bone healing is simple and generally requires only sedation. The disadvantages of external fixation lie in the aftercare which the owner must perform, and the damage the external fixator can do to the dog's surrounding environment.

Correction of Angular Deformity and Continuous Distraction with a Circular External Fixator

Circular fixators are indicated as treatment for adult dogs that have a limb length discrepancy of at least 20%, or immature dogs with anticipated extensive growth. Circular fixators can be effectively used to simultaneously correct angular deformities and length discrepancies. It is also indicated to treat dogs with complex deformities such as 1) bifocal angulations, resulting in a translation of the limb, or 2) significant cranio-caudal and rotational deformities. Although the circular fixator can be used to treat dogs with varus/valgus deformities, there are simpler techniques that are equally as effective using plate or standard external fixation. However, the advantage of the circular fixator in treating angular deformities consists in its flexibility in allowing correction of the deformity and length discrepancies simultaneously. The disadvantages of the circular fixator in correcting deformities are the intensive and sometimes lengthy learning curve for the surgeon, the detailed preoperative planning, and the need for regular postoperative monitoring of the distraction process. Length deficit, rotational, craniocaudal and mediolateral angulations are determined as previously described (see pre-operative planning in closing wedge osteotomy and Figure 57-14).

The simplest method described to treat angular deformities with circular external fixators (CEFs) consists of an acute correction of the angulation and rotation, followed by a linear distraction. The procedure starts by placing the most proximal and distal rings parallel to the plane of the proximal and distal joint surfaces of the radius, respectively. The radial osteotomy is then performed at the point of maximum curvature, parallel to the carpal joint. The periosteum should be incised along with the cortex to allow manipulation of the bone, but care is taken to avoid stripping this layer. The ostectomy of the ulna can be achieved through the same incision, or via a lateral approach to the ulna. The antebrachial deformity is corrected by aligning the proximal and distal rings (Figure 57-18). Additional fixation is added to the short segment using a second ring and fixation wires (preferably) or a drop wire, depending on the bone stock available. Another ring is placed in the proximal segment and connecting rods are added between these rings. Linear motors connect the ring immediately proximal to the osteotomy to the ring immediately distal to the osteotomy to enable postoperative lengthening of the bone.

Limb alignment and implant position are confirmed on postoperative radiographs. The limb is bandaged with gauze sponges wedged between the apparatus and the skin to minimize soft tissue swelling. As postoperative swelling decreases, the limb may be left unbandaged. A light wrap around the rods and rings minimizes the risk of catching the fixation on surrounding objects after discharge from the hospital. A delay, or latency period, is recommended after surgery, before distraction is initiated. This allows local cellular and vascular responses to occur in order to facilitate optimal distraction osteogenesis. The recommended latency period varies from 1 to 3 days for immature animals to 5 to 7 days for adult animals. Early distraction may cause diminished callus production while unduly delayed distraction may allow premature consolidation. For the same reasons, distraction is started at a rate of 1 to 2 mm daily, divided into two to four increments. Physiotherapy and pain medications are indicated until the dog is bearing full weight on the limb. Low-impact exercise is essential to encourage use of the limb and stimulate formation of regenerate bone. Owners are shown how to turn the linear motors in order to provide a rate of distraction adjusted to the age and size of the dog. For example, the distraction rate may be increased to 2 mm daily in large dogs, less than 6 months of age, who have undergone an osteotomy of the radial metaphysis. Daily cleaning of the skin with 0.05 percent chlorhexidine solution and application of a triple antibiotic ointment around the wire-skin interface minimize the risk of wire tract infection.

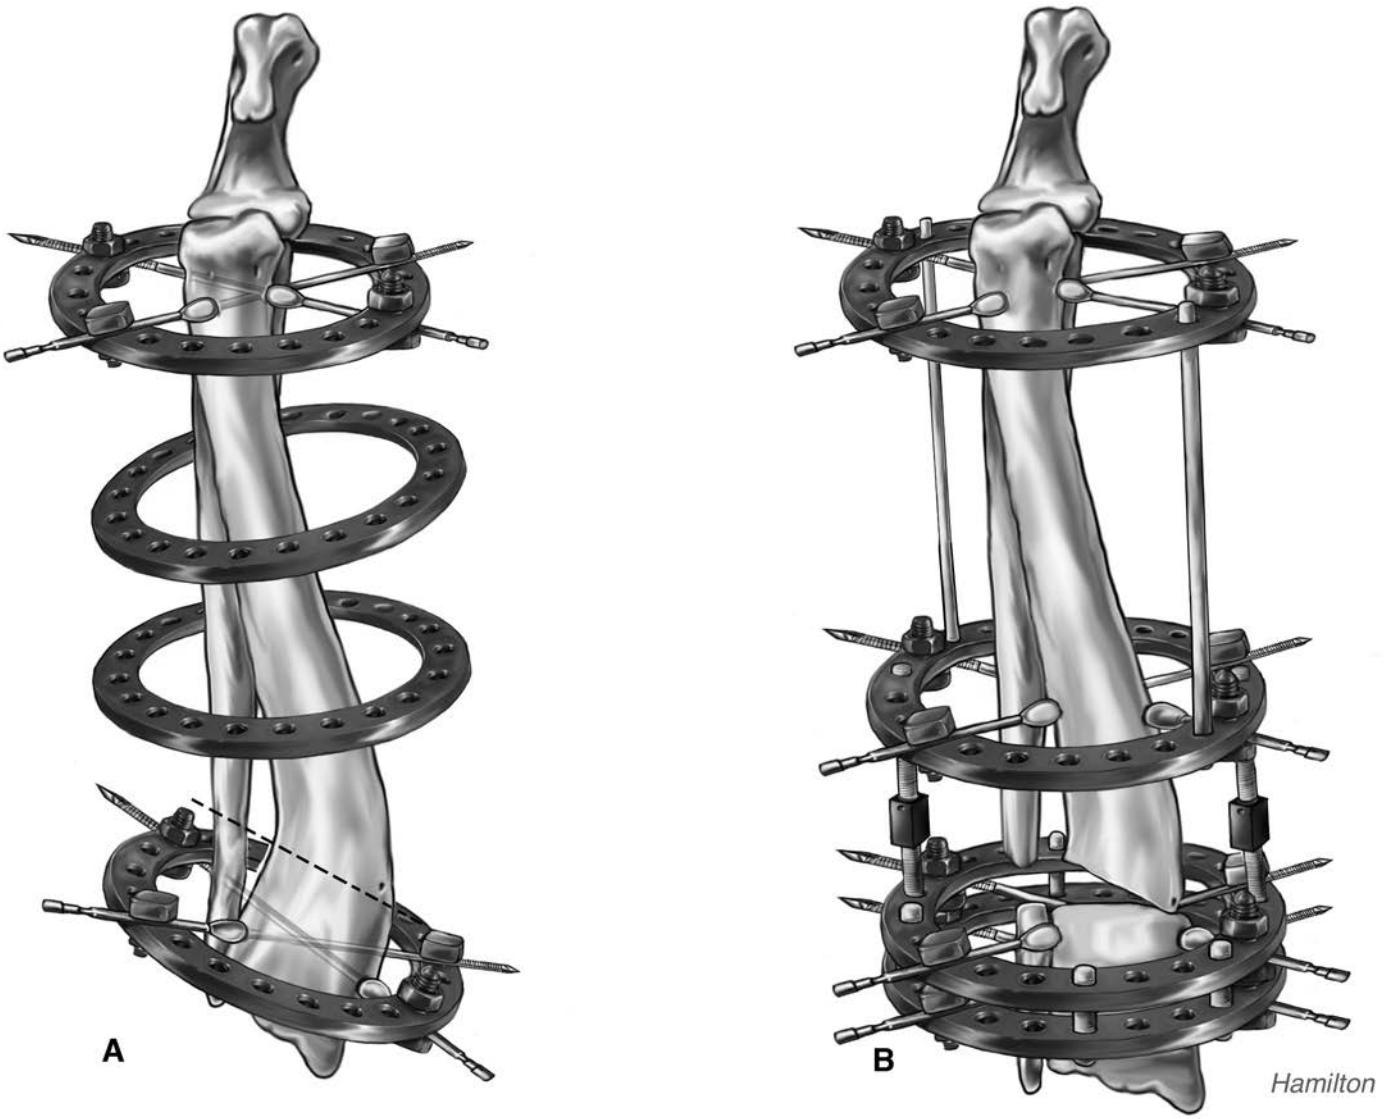

Figure 57-18. Correction of an angular deformity and limb shortening with standard circular ring fixators. **A.** The proximal and distal rings should be parallel to the proximal and distal radial articular surfaces, respectively. Two wires are tensioned on each side of the corresponding ring, crossing each other in the center of the bone and at an angle of at least 45° from each other, avoiding neurovascular structures. A second ring is added on each side of the anticipated osteotomy, so that each segment of radius will be immobilized with two rings. Alternatively olive wires and a drop wire may be used to control a short segment of radius. An oblique osteotomy of the radius is made at the point of greatest curvature with an osteotome or an oscillating saw, directing the osteotomy line parallel to the distal radial articular surface. A partial ulnectomy is performed. **B.** Rotation and angulation are acutely corrected by aligning the rings placed in the proximal and distal radial segments. Linear motors connect the rings placed on either side of the radial osteotomy to allow post-operative distraction of the bone.

Use of the limb, range of motion of the carpus and radiographs are re-evaluated every seven to ten days. Because planned and actual adjustments routinely differ by 25%, the distraction regimen is adjusted based on serial radiographs. Contracture of the flexor muscles is a common complication, leading to decreased range of motion of the carpus and reluctance to use the limb. This complication is more likely in dogs requiring more than 10 percent lengthening and is best managed by decreasing the distraction rate (to 0.5 mm daily), pain medications and aggressive physical therapy. When the distraction is complete, the frame is left in place until the gap has completely filled with new bone, typically three to five weeks after distraction has stopped. CEFs are removed under sedation and exercise is limited to low-impact activity for three weeks thereafter.

This standard circular fixator is a relatively simple technique to allow lengthening of the bone if there is no angular deformity, or if the deformity is mild and can be corrected as a one-stage procedure. However, it requires complete transection of the periosteum and limits contact between the proximal and distal radial segments. The resulting gap increases the stress placed on the frame, may slow bone healing, and increases postoperative morbidity. Complications requiring a second surgery have been described in 29 to 67% of cases, with good to excellent results reported in 68% of dogs treated with this method. To address these limitations, another strategy consists of placing hinged external fixators to gradually correct the angular deformity and length deficit. The positioning of the hinges is critical to the outcome and requires careful pre-operative planning to determine the direction and amplitude of the oblique deformity.

The frame is assembled before surgery so that the rings are placed at an angle to each other corresponding to the amount of deformity. Hinges are levelled with the origin of the deformity. Their axis (line joining these hinges) should be perpendicular to the direction of the deformity and tangential to the bone at the origin of the angulation. The angular motor is placed on a third connecting bar in the plane of deformity and on the concave side of the deformity. Positioning olive wires against the concave surface of the bone prevents translation of the radius during angular correction. Acute, intra-operative correction of any torsional deformity simplifies the design of the frame. As the angulation is corrected, an opening wedge of regenerate bone is formed, resulting in an overall gain of length equal to half of the length gained on the concave surface of the bone. Hinge fixation is also indicated in the treatment of bifocal deformities, where bone lengthening and correction occur at two osteotomy sites, effectively doubling the rate of distraction.

Chapter 58

Carpus, Metacarpus, and Phalanges

Classification and Treatment of Injuries to the Accessory Carpal Bone

Kenneth A Johnson

Introduction

The accessory carpal bone seems more prone to injury than the other carpal bones, perhaps because it is such an integral component of the palmar support structure that prevents hyper-extension during full weight bearing. Fractures of this bone are commonly in the region of ligamentous insertions (sprain avulsion fractures), and frequently they involve the articular cartilage surface on the dorsal end of the bone that forms part of the accessory-ulnar carpal joint. Most fractures of this bone occur in racing greyhounds.[1,2] Similar types of fractures are seen occasionally in dogs of other breeds, and these fractures may be due to trauma, landing awkwardly on the limb, stepping in a hole while running, and falling from heights. Swelling, instability, and pain are common features of carpal injuries, but the diagnosis and classification of fractures are made from radiographs. Fractures can usually be visualized in mediolateral radiographic views with the carpus in full extension or slightly flexed. Additional information about the type and extent of the fracture can be obtained from the dorsopalmar radiographic view. Luxation of the accessory carpal bone, without any fracturing of the bone, can also result from severe trauma in sporting dogs.[3]

Fracture Classification

These fractures have been classified into five types, on the basis of their radiologic and pathologic features (Figure 58-1).[1,4,5]

Type 1

Injuries are avulsion of bone in the region of the insertion of the accessory-ulnar ligament. Fracture fragments may be large slabs or multiple comminuted chips that are best appreciated on the mediolateral radiographic views. These fractures involve the distal margin of the articular surface, and this feature, combined with disruption of the ligamentous support, leads to instability, subluxation, cartilage damage, and secondary osteoarthritis. Chronic fractures often do not proceed to bony union, and the bone fragments become surrounded by proliferative bone and fibrous tissue.

Type I fractures are further defined as being palmarolateral (type 1A) or palmaromedial (type 1B).[4,6] The type IA fracture of the palmaorolateral prominence may be visualized on a dorsolateral palmaromedial oblique radiographic view.

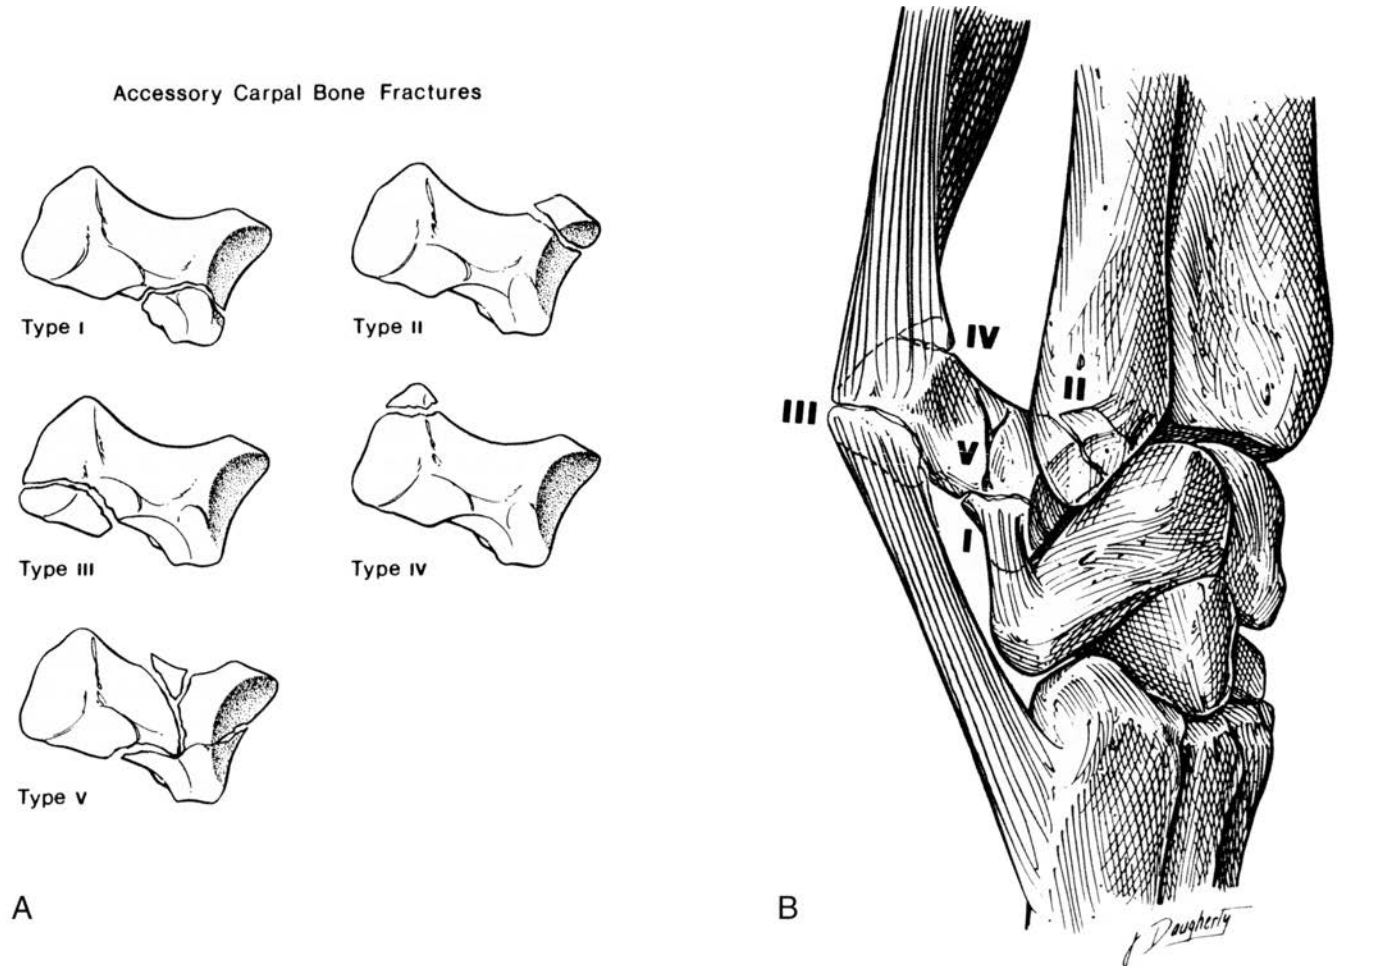

Figure 58-1. Classification scheme of accessory carpal bone fractures, depicted on the right bone. (From Johnson KA and Piras A: Fractures on the carpus. In Johnson AL, Houlton JEF, Vannini R, eds.: AO Principles of Fracture Management in the Dog and Cat. Davos Platz: AO Publishing: 341, 2005.)

Type II

Injuries are avulsion fractures of the proximal margin of the articular surface and involve bone at the insertion of the palmar ulnocarpal and radial carpal ligaments that connect to the caudomedial surface of the distal ulna and the caudal surface of the distal radius. They are often associated with a type I injury. Like type I injuries, they allow subluxation, and articular cartilage damage and secondary osteoarthritis are sequelae.

Type III

Injuries are avulsion fractures of the distal surface of the palmar end of the bone, at the origin of the two large accessory-metacarpal ligaments that connect to metacarpal bones IV and V. Such injuries disrupt the stay apparatus provided by the accessory-metacarpal ligaments that normally counteract carpal hyperextension during full weight- bearing.

Type IV

Injuries are strain-avulsion fractures of bone from the proximal surface of the palmar end of the bone, at the tendon of insertion of the flexor carpi ulnaris muscle. Bone fragments are distracted proximally by the flexor tendon. The fracture may be an apophyseal avulsion in dogs up to 5 months of age.

Type V

Injuries include all other fractures of the carpal body, and these fractures may be comminuted or intra-articular. Fractures may be in a longitudinal, sagittal, or transverse plane, dividing the bone into two or more fragments.

Treatment and Prognosis of Fractures

Screw Fixation

Open reduction and internal fixation with screws are indicated in certain type I, II, and III injuries with large, noncomminuted bone fragments (Figure 58-2).[7,8] The aims of treatment are restoration of ligamentous integrity and the prevention of subluxation and secondary osteoarthritis. Dogs are positioned in lateral recumbency with the affected limb uppermost for surgery. A skin incision, 5cm long, is made palmarolateral to the carpus.[9] The palmar carpal retinacular fascia is incised to expose the accessory carpal bone and supporting ligaments. The abductor digiti quinti muscle is elevated and is retracted medially from the accessory-metacarpal IV and V ligaments. A lateral arthrotomy of the accessory-ulnar joint is performed to allow inspection of the articular cartilage surface and accurate reduction in type I and II injuries. Small pointed AO/ASIF forceps are used to maintain reduction (Figure 58-3). Lag screw fixation is with 1.5 or 2.0 mm cortical screws (Figure 58-4). If

the fragment is thin, countersinking is not performed. The drill hole should be measured and tapped completely to minimize the risk of screw breakage, an occasional problem with 1.5 mm screws.

The internal fixation is protected with a palmar fiberglass slab splint for 4 to 6 weeks after surgery. Initially, the carpus is immobilized in slight flexion, but then it is moved progressively to a more extended position. Radiographs are taken at 6 and 12 weeks postoperatively to monitor fracture healing.

One study of 12 greyhounds with fractures treated by internal fixation found that 10 returned to racing, and five of those won one or more races.[7] Animals with type I and II fractures are expected to have a worse prognosis because these fractures are intra-articular, but further studies are needed. Although internal fixation of these fractures seems more logical, this operation is technically demanding, and some fracture fragments are simply too small to permit screw fixation, so excision becomes unavoidable.

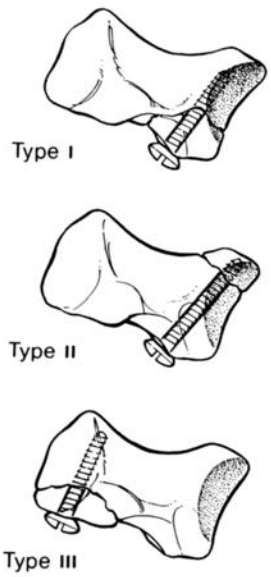

Figure 58-2. Screw fixation of fracture types I, II, and III. (From Johnson KA, Dee JF, Piermattei DL Screw fixation of accessory carpal bone fractures in racing greyhounds: 12 cases (1981 -1986). J Am Vet Med Assoc 1989;194:1618-1625.)

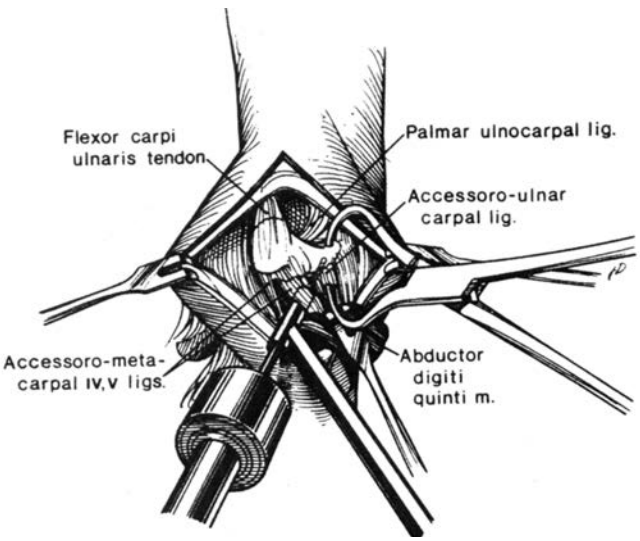

Figure 58-3. Reduction of a type I fracture with pointed reduction forceps and drilling a I. I hole for screw fixation. (From Johnson KA, DeeJF, Piermattei DL Screw fixation of accessory carpal bone fractures in racing greyhounds: 12 cases (1981-1986). J Am Vet Med Assoc 1989; 194:1618-1625.)

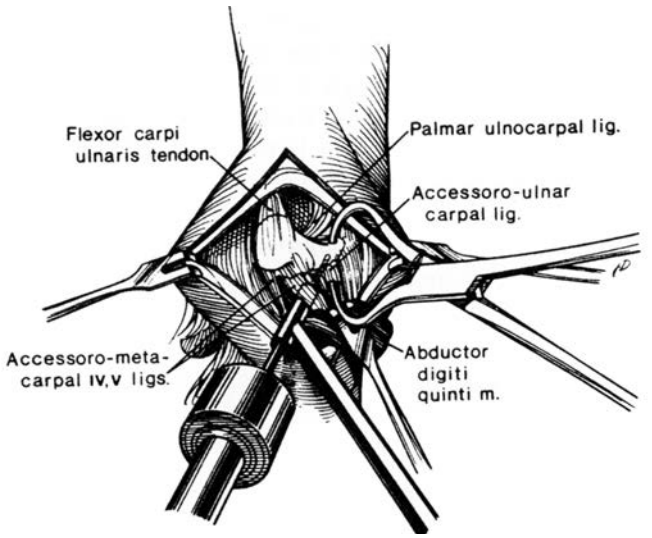

Figure 58-4. Fixation of a type I fracture with a 1.5-mm cortical screw. (From Johnson KA, Dee JF, Piermattei DL. Screw fixation of accessory carpal bone fractures in racing greyhounds: 12 cases (1981 -1986). J Am Vet Med Assoc 1989; 194:1618-1625.)

Fragment Excision

Removal of avulsed fracture fragments is an alternative treatment for type I and II fractures. Access for fragment excision is a limited lateral approach, similar to that used for lag screw fixation. Fragments are usually found attached to the accessory-ulnar ligament of the joint capsule, and they are excised with a No. 11 or 15 scalpel blade.

No attempt is made to suture the damaged ligament or capsule after fragment excision, and healing proceeds by fibroplasia. Without surgical treatment, type I and II fractures do not naturally heal by bony union, and often they damage the articular cartilage on the ulnar carpal bone. When internal fixation is not possible, fragment excision perhaps may be preferable to nonsurgical management, but further studies are needed. One study in Scotland found that, of 19 racing greyhounds that had type I fragments removed, 13 returned to race and nine won races. Of the other six, three became sound but were unable to race, whereas the other three remained lame.[10]

External Coaptation

For comminuted fractures that are not amenable to internal fixation and for minimally displaced fractures in young dogs, immobilization of the carpus in flexion is indicated. Malunion of the fracture may be well tolerated unless the fracture is intra-articular.

Partial Arthrodesis

Animals with hyperextension injuries confined to the accessory-ulnar joint frequently have concurrent type I and II fractures of

the accessory carpal bone. A partial carpal arthrodesis of this joint may stabilize the carpus while preserving motion in the antebrachiocarpal joint.[11] The surgical approach is similar to that used for fracture repair by internal fixation. After the joint is opened, articular cartilage is removed, the space is bone grafted, and a lag screw is placed in a palmarodorsal direction from the accessory carpal bone into the ulnar carpal bone. Additional support is provided by a cerclage wire from the palmar pole of the bone, down to the fifth metacarpal bone.

Surgical Treatment of Injuries to the Antebrachial Carpal Joint and Carpus

Alessandro Piras and Jon F. Dee

Introduction

The carpus is a complex joint composed of seven bones arranged in a proximal row of three bones and a distal row of four bones. The radial carpal bone is the medial bone of the proximal row. It is the largest of the carpal bones and articulates with the radius. The lateral bone of the proximal row is the ulnar carpal bone and articulates with the ulna and with the radius. The accessory carpal bone is located on the palmaro lateral aspect of the proximal row and articulates with the ulnar carpal bone and with the ulna styloid process. The four carpal bones of the distal row are named from medial to lateral as I, II, III, and IV.

Three joint levels are present: the antebrachiocarpal joint between the distal end of the radius and ulna and the proximal row of carpal bones, contributing 70% of the carpal motion; the middle carpal joint is between the proximal and distal row of carpal bones and contributes 25% of total carpal motion; and the carpo-metacarpal joint between the distal row of carpal bones and the bases of the metacarpal bones that contributes only 5%.

The carpal joint is a complex ginglymus joint that allows movements of extension, flexion, internal and external rotation, a few degrees of valgus, varus and a few millimeters of translation in the palmaro dorsal direction. Several ligaments join the various bones at different levels. The dorsal ligaments are quite thin and join the adjacent bones individually, the palmar ligaments are thicker and are in part embedded in the robust palmar fibrocartilage that attaches to the palmar aspect of the carpal bones and to the bases of the metacarpal bones (with the exception of the accessory carpal bone). This structure provides a strong support to the palmar aspect of the carpal joint and is constantly under tension. The collateral ligaments are strong, especially the medial ligament that is constantly under tension due to a normal five degrees of carpal valgus that is present. Unlike the tarsus, the collateral ligaments span only one joint level. The joint capsule separates the antebrachiocarpal joint from the middle carpal and carpo-metacarpal joints, creating two separated compartments. The types of carpal injuries include sprain, hyperextension, luxation and fracture.

Clinical Examination

Carpal fractures are usually avulsion fractures of ligaments (origin or insertion) and tendon insertions or the result of the combination of shearing and compressive forces acting on the bones during hyperextension. Most of these fractures are intra articular with few exceptions.

The clinical examination consists of palpation to localize pain, soft tissue swelling, crepitus and joint instability. The range of motion of the joint should be tested in flexion and extension. Additional maneuvers include internal or external rotation of the carpal joint while in extension or 90 degrees of flexion. Cranial translation is evaluated with the carpus in 90 degrees of flexion. Both are useful tests for an accurate evaluation of joint stability. In cases in which carpal damage is suspected, but the injury cannot be localized, it is useful to apply a well padded compressive bandage, supported by a palmar meta-splint, prescribe an anti-inflammatory and rest. After two or three days, re-examine the patient, the decrease in soft tissue swelling will facilitate the examination.

Radiographic Examination

Radiographic examination of the carpus starts with routine views. However, due to its anatomical complexity, injuries may be obscured by the superimposition of the different bony structures. In order to make or confirm the diagnosis of a suspected injury, supplemental or additional radiographic views are often required.

Additional radiographic views often consist of special projections such as flexed or extended oblique views and stress views.

Stress projections, are views taken during "the application of controlled force to a joint to demonstrate abnormal spatial relationship between two or more of its components"(Farrow 1982). Stress views can be obtained by application of shear, traction, wedge and rotatory maneuvers. When ligamentous injuries are suspected, stress views are invaluable in demonstrating the presence of subluxation, joint instability, or in evaluating the location and size of avulsed fragments.

A variation of stress views are; the weight bearing views, taken with the dog in standing position and the x-ray beam in horizontal position in respect to the weight bearing limb. Adequately exposed radiographs are essential and high detail screens, such as rare earths and mammography mono-emulsion films are recommended to achieve fine detail. Whenever doubts about the radiographic anatomy exist it is helpful to x-ray the contra-lateral normal limb for comparison. In cases of hairline or incomplete fractures is useful to repeat the x-ray in a week so that osteolysis can highlight the fracture line.

Routine Projections

Medio-Lateral (ML) views and Dorso-Palmar (DP) views

Additional Projections

Dorso-Lateral Palmaro-Medial Oblique 45 degrees (DLPMO);
Dorso-Medial Palmaro-Lateral Oblique 45 degrees (DMPLO);
Medio-Lateral Flex (ML-Flex): this view is helpful to evaluate the dorsal articular margin of the radius, the dorsal surface of the radial carpal bone and the articular surface of the accessory carpal bone.

Stress Views

Hyperextended ML views are very useful to evaluate palmar instability, subluxation of the radial carpal bone, subluxation of the proximal carpal joint, subluxation and luxation of the carpo-metacarpal joints and fractures affecting the accessory carpal bone.

DP views with application of lateral or medial stress: very helpful views in case of suspected collateral instability, damage to the collateral ligaments with avulsed fragments from the styloid process, subluxation of the second carpal bone, carpo metacarpal collateral instability.

Dedicated Views

Specific radiographic views are sometimes necessary to critically evaluate some of the carpal bones or the dorsal articular margin of the radius and the ulnar styloid.
Palmaro-Lateral Dorso-Medial hyper flexed oblique view (PLDM-Flex)
Palmaro-Medial Dorso-Lateral hyper flexed oblique view (PMD-Flex). (Figure 58-5A, B, and Figure 58-6).

Skyline or tangential views are invaluable for a complete evaluation of the dorsal aspect of the radius. This view, with other views, can confirm the presence of a fracture or chip affecting this region. Incomplete fractures and small chips can sometimes be detected only with the aid of this view (Figure 58-7, and Figure 58-8A and B).

Treatment Principles

Complex fractures of the carpal bones are associated with ligament damage, severe comminution, and variable degrees of subluxation. Therefore, careful preoperative planning should consider the type of fracture in relation to the age, breed and the expected level of physical activity of the dog, the level of expertise of the surgeon and the availability of mini implants; after reviewing these considerations, arthrodesis may be the best choice. Open reduction and internal fixation is the treatment of choice to achieve results compatible with normal joint function. Carpal fractures are usually treated with K wires and tension-band wiring, or lag screw fixation. In case of non surgical treatment, as for any other intra-articular fracture, the development of osteoarthritis due to fracture instability is expected.

Fractures of the Radial Carpal Bone (RCB)

Fractures of the body of the RCB are uncommon injuries and are

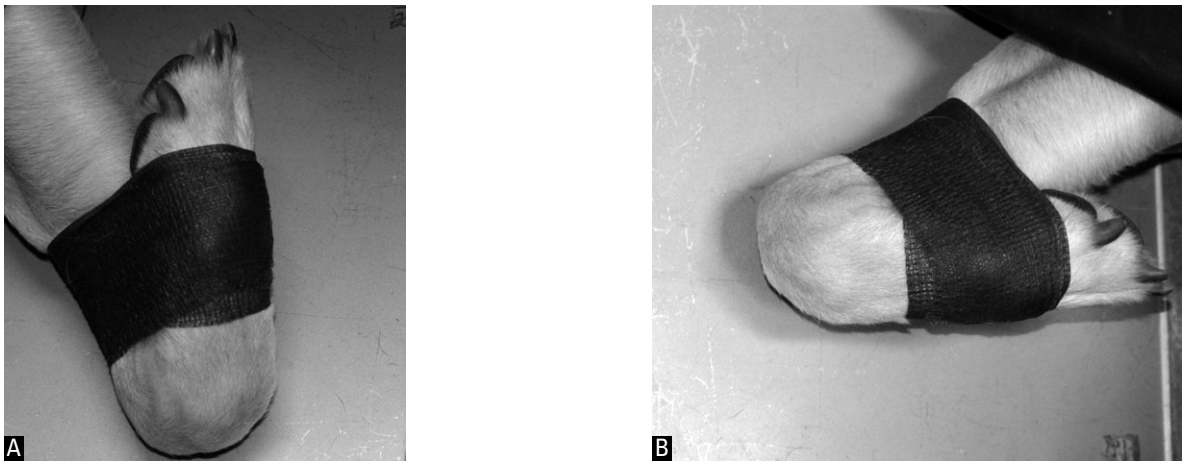

Figure 58-5. A. and **B.** PLDM- Flex **A.** PMDL-Flex **B.** The carpus is in direct contact with the x-ray cassette. Position the limb at an angle that may vary from 30 to 45 degrees.

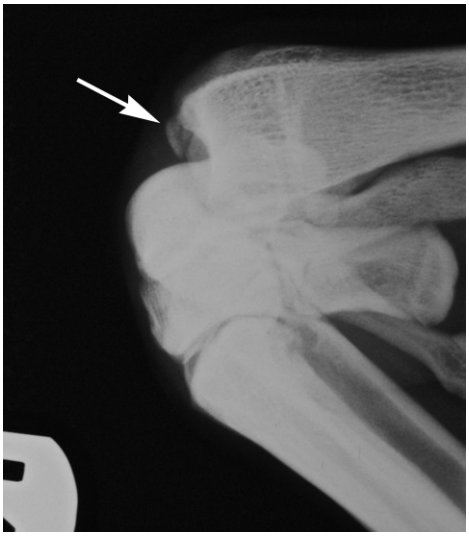

Figure 58-6. PLDM-Flex view showing a chip fracture of the dorsal articular margin of the radius (white arrow).

Figure 58-7. Lock the wrist at the maximum degree of flexion that is possible and secure it with a strip of tape. With the dorsal aspect of the distal row of carpal bones in direct contact with the x-ray cassette, position the beam tangent to the dorsal articular margin of the distal radius with an angle that can vary between 40 to 60 degrees. Two or three views are obtained at different angles to allow a complete study of the region.

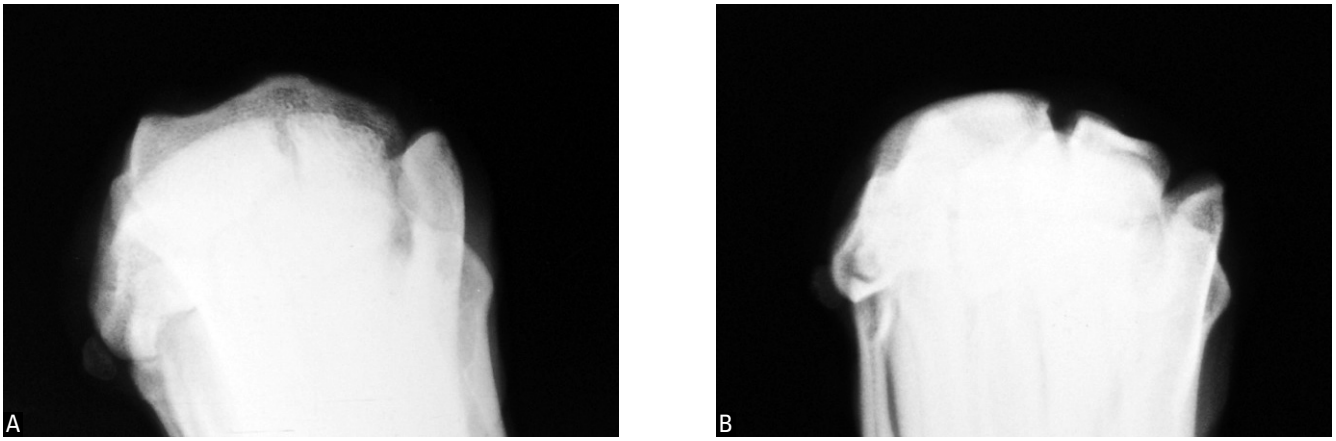
usually caused by compressive forces during hyperextension of the carpal joint. Different types of fractures have been identified: midbody saggital, saggital oblique (this fracture can be either complete with displacement or a hair-line fracture), comminuted or "Y" shaped composed generally of three fragments; and fracture of the dorsal margin (usually a small chip) (Figure 58-9).

Midbody fractures are often incomplete and have been described in racing Greyhounds. Some authors suggest that these fractures are more common in the right leg (Dee, personal communication: 6 cases) but insufficient numbers exist to completely define this type of predisposition. Overall, the clinical signs are variable. With complete fractures, the dog is lame and often non-weight bearing on the limb. Joint swelling, pain upon palpation, crepitation, and decreased range of motion in flexion is usually present. With hairline fractures, the diagnosis can be very difficult as this type of injury is subtle, showing minimal clinical signs, minimal joint effusion, and pain only on forced flexion. Radiographic examination consists of Dorso-Palmar (DP) and Medio-Lateral (ML) views. In addition to the routine views, PMDL-Flex, PLDM-Flex, Dorso-Palmar oblique, and Skyline views are recommended.

With incomplete fractures, the fracture line may not be detectable for several weeks, until bone resorption creates some widening at the fracture line. These fractures are intra-articular and are treated with open reduction and internal fixation. According to the type, the fracture can be approached surgically either with a standard dorsal or a palmaro-medial approach or a combination of the two.

Midbody fractures are accurately reduced and stabilized with lag screws, generally 1.5, 2.0 or 2.7 mm cortical, inserted from the palmaro-medial aspect of the bone in an oblique dorso-lateral direction. Accurate countersinking of the screw head and precise measurement of the screw length are vital to avoid interference of the implant with adjacent bones or soft tissues (Figure 58-10).

Some authors suggest that "Y" shaped fractures of the RCB that occur without a history of trauma share a common etiopathogenesis. Considering that the two main fracture lines recognized on radiographs and CT scan correspond approximately to



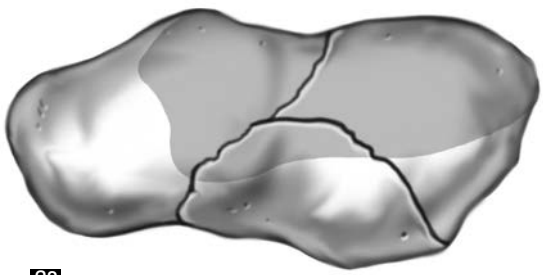


Figure 58-8. A. Skyline view at 60 degrees shows the contour of the dorsal articular margin of the radius and the articular portion of the ulnar styloid. **B.** 40 degree skyline view shows the dorsal surface of the radial carpal bone and the ulna carpal bone.

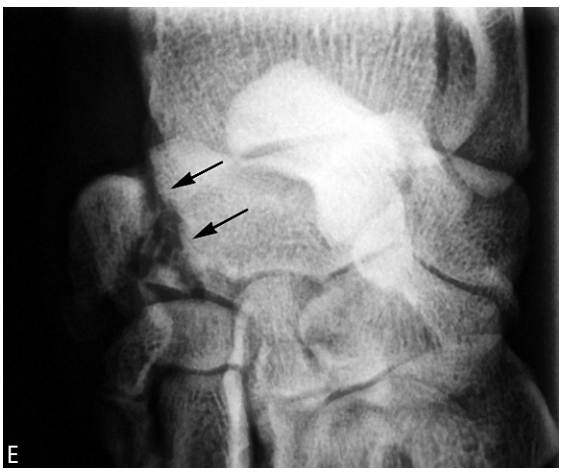

Figure 58-9. Different types of fractures of the radial carpal bone: **A.** saggital oblique; **B.** hair-line fracture); **C1, C2.** comminuted or "Y" shaped generally composed of three fragments, **C3**. This schematic of the left radial carpal bone illustrates the typical pattern of a three piece fracture; **D.** chip fracture of the dorsal aspect of the bone; **E.** fracture of the palmar process.

the fusion planes of the three ossification centers of the bone, it has been hypothesized that an incomplete fusion of these areas predisposes to this injury. According to these authors, the breeds most commonly represented are the Boxer, Labrador Retriever, English Setter, English Springer Spaniel and Pointer. These breeds often present with bilateral involvement. In acute cases, an attempt at fixation can be made using two 1.5 or 2.0 mm lag screws inserted from the dorsal fragment to engage the medial and the lateral fragments (Figure 58-11). Due to the nature of these fractures they tend to respond poorly to internal fixation. The fragments are prone to non-union with resulting implant failure and subsequent osteoarthritis. In most of the cases, these fractures are best managed with pan-carpal arthrodesis.

Fracture of the palmar process has been described as a sprain avulsion of the palmar radial carpo-metacarpal ligament. This injury is treated with open reduction and internal fixation using lag screws or K-wire and tension band wire techniques (Figure 58-12).

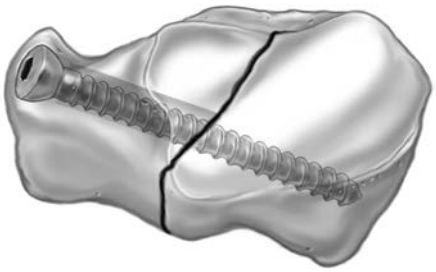

Figure 58-10. A midbody fracture of a left radial carpal bone is repaired with a 2.7 mm cortical screw, inserted from the palmaro-medial aspect of the bone in an oblique palmar-lateral direction. The head of the screw is countersunk and the screw is just a few millimetres shorter than the measured length to avoid protruding from the bone.

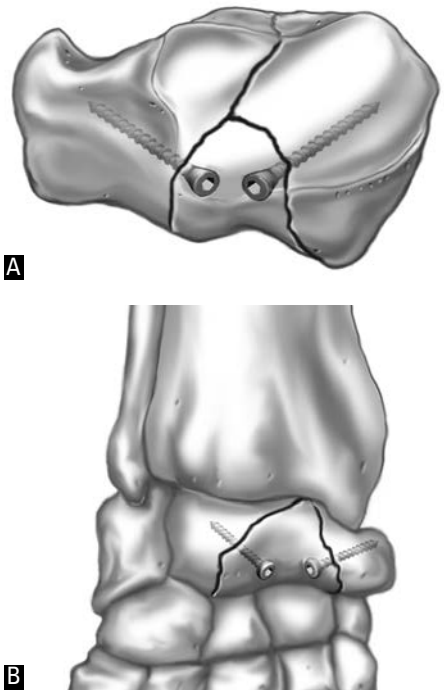

Figure 58-11. A. and **B.** A three fragment fracture is repaired using two 2.0 mm lag screws inserted from the dorsal fragment to engage the medial and the lateral fragments. The screws heads are well countersunk.

Dorsal RCB chip fractures are extremely common in racing Greyhounds consisting in most cases of a small chip. They are likely the result of impingement of the distal dorsal margin of the radius over the RCB during hyperextension of the joint. The history is variable with the trainer reporting poor performance and the dog "checking" and running wide in the turns. Lameness, when present, usually appears following intense exercise and tends to disappear within 12 hours. Clinical examination usually reveals pain with flexion. Joint effusion can be minimal to absent. Direct finger pressure on the dorsal aspect of the carpus does not necessarily elicit a pain response. Diagnostic radiographic views are usually the medio-lateral and medio-lateral oblique. In many cases, skyline views are of invaluable help to define three dimensionally the fragment location, thus decreasing the size of the surgical approach and the surgical time. With small chip fractures surgical removal is the treatment of choice. Larger slabs can be reduced and stabilized with 1.0 or 1.5 mm screws applied in a lag fashion, while insuring that the screw head is well countersunk.

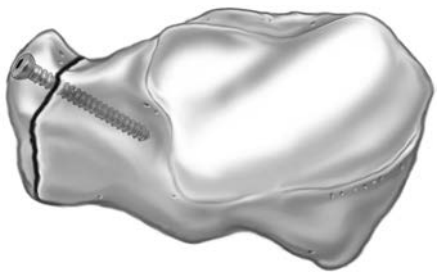

Figure 58-12. A fracture of the palmar process is repaired with a 1.5 mm lag screw inserted in a palmar lateral direction. The head of the screw is deeply countersunk in the palmar process of the bone.

Fractures Of The Other Carpal Bones

Ulnar Carpal Bone

Complete fractures are very rare, however they have been observed in conjunction with other carpal fractures and luxations, as well as an isolated fracture. Fractures affecting the palmar component are quite difficult to diagnose with routine radiographic views. In addition to routine views the PMDL- Flex view offers an excellent visualization of the palmar aspect of the bone (Figure 58-13). Treatment consists of stabilization of the fragment with a lag screw inserted in palmaro dorsal direction.

Dorsal chip fractures are more common and are often detected as an incidental finding. They share the same etiopathogenesis, diagnostic approach and treatment as the RCB dorsal chip.

Second and Third Carpal Bones

These uncommon and isolated fractures usually consist of a very small chip or a dorsal slab. In addition to routine radiographic views, ML-Flex, Semi Flex views and either standard and/or oblique are recommended.

Treatment consists of surgical excision of the small chips and lag screw fixation for larger dorsal slabs.

Figure 58-13. The Palmaro-Medial Dorso-Lateral-Flex view offers an excellent visualization of a fracture of the palmar aspect of the ulnar carpal bone.

Post Operative Considerations

Following surgical repair of the fracture, the carpus is supported with a padded bandage and a palmar splint from 2 to 4 weeks according to the severity of the injury. Restricted and controlled activities are maintained until radiographic signs of healing are evident. Avoid prolonged immobilization of the carpus and promote early physiotherapy. In case of chip removal apply a light padded bandage to decrease postoperative swelling. The bandage is usually removed after a week and physiotherapy is started after 2 weeks.

Fractures of the Distal Radius and Ulna

Fractures of the Radial Styloid

These are uncommon intra-articular fractures. They are avulsion sprain fractures of the origin of the short radial collateral ligament. Normally the short radial collateral ligament provides medial stability for the antebrachiocarpal joint in both flexion and extension. This ligament has two components originating on a tubercle on the styloid process and inserting respectively on the medial (straight portion) and palmaro-medial (oblique portion) aspects of the radial carpal bone.

Clinical signs include variable degrees of lameness according to the severity of the injury, soft tissue swelling (usually diffuse around the carpal region), and pain upon palpation and manipulation of the area.

Treatment Principles

These fractures are treated by open reduction, accurate anatomical realignment and internal fixation. The surgical exposure is made with a longitudinal incision directly over the styloid process. In case of a larger fragment, a dorsal approach to the carpal joint can be combined to evaluate the quality of fracture reduction.

Several fixation techniques have been described, including K wires with a figure-of- eight tension band wire for the small fragments, or multiple divergent K wires or lag screws and anti rotational K wires for larger fragments. Very small fragments can be excised (Figure 58-14A, B, Figure 58-15 and Figure 58-16).

When inserting K wires, it is always advisable, in order to achieve better stability, to drive them from the fragment across the metaphyseal bone into the far cortex.

Fractures of the Ulnar Styloid

The ulnar styloid process, in association with the radial styloid, buttresses the proximal carpal bones. The short ulnar collateral ligament, the radio-ulnar ligament, and the palmar ulno-carpal ligament, originate on the ulnar styloid, providing lateral and palmar stability for the joint. Fractures of the ulnar styloid can be divided into two types: fractures affecting the proximal portion of the styloid, (usually 1 to 3 cm from its distal end) and fractures of the distal portion characterized by a small avulsed fragment.

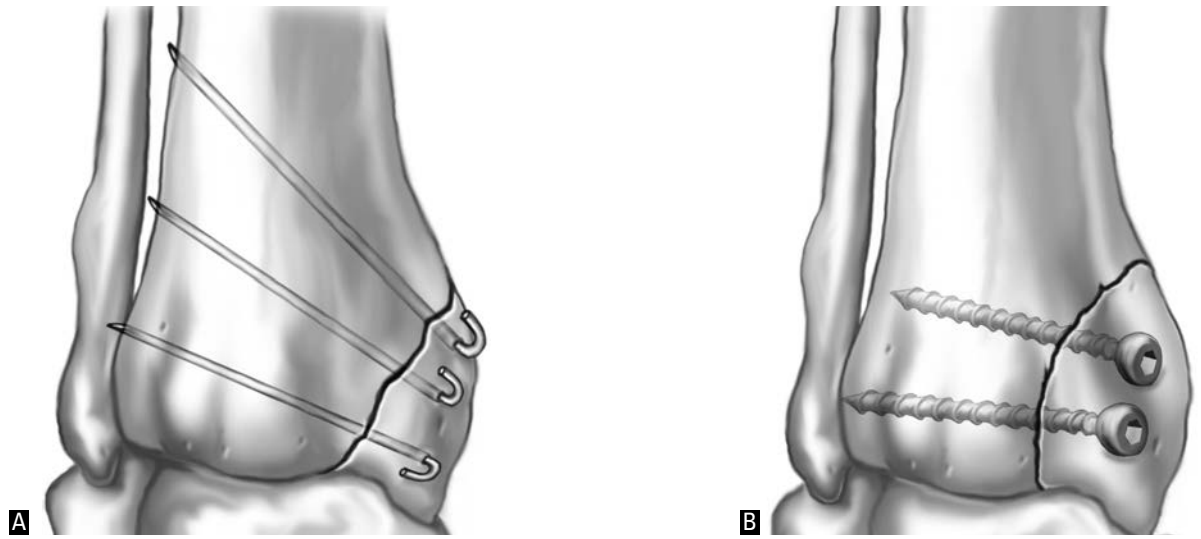

Figure 58-14. A. A fracture of the radial styloid process is repaired with three divergent K wires. This form of repair can be acceptable in small patients but does not guarantee a stable fixation. **B.** The same type of fracture repaired with two lag screws provides superior stability and a better prognosis.

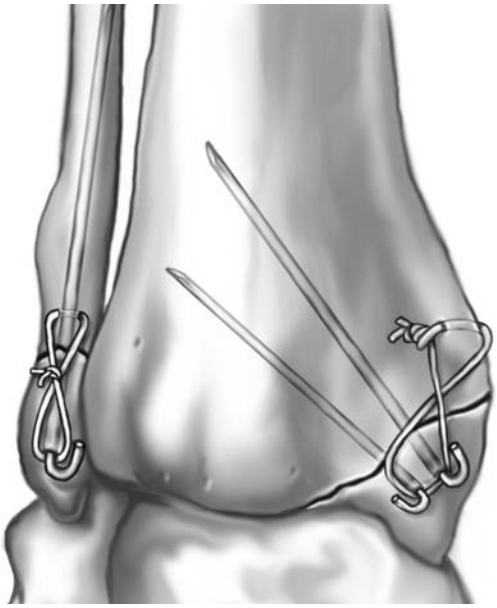

Figure 58-15. A fracture of the radial styloid process is repaired with two K wires and a figure- of- eight tension band wire. A fracture of the ulnar styloid is repaired with a similar technique.

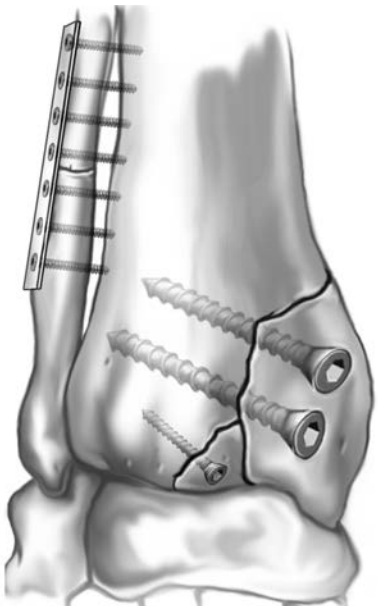

Figure 58-16. A comminuted fracture of the radial styloid is repaired with two lag screws, the small dorsal fragment is repaired with a 1.5 mm lag screw. An extra articular fracture of the distal ulna is repaired with a Veterinary Cuttable Plate applied on the lateral aspect of the bone. Care should be taken to avoid excessive protrusion of the screw tips.

Ulnar styloid fractures are not necessarily intra-articular and if incomplete, can be treated conservatively with external coaptation. Complete fractures can be associated with antebrachiocarpal subluxation, luxation of the radial carpal bone, or accompanied by fracture of the radial styloid; in any case they require open reduction and internal fixation.

Technique of choice is generally K wires with a figure-of-eight tension band wire for distal fractures and IM pinning or a small lateral plate (2.0/2.7 mm VCP or DCP) for more proximal fractures (See Figures 58-15 and 58-16).

Post Operative Considerations

A post operative bandage is recommended to support the repair of styloid fractures, with restricted and controlled activity maintained until radiographic signs of healing are evident. Implants are left in situ unless they become loose or are irritating the soft tissues.

Fractures of the Dorsal Articular Margin of the Distal Radius

Fractures of the distal articular radius can involve the central or lateral portions of the articular surface. As with any other intra articular fracture, open reduction and rigid, "gap free" internal fixation is preferred. This fracture of the dorsal articular margin of the radius was first described in racing Greyhounds by Ferguson (1986). Although not common in the pet population, it has been described in sporting breeds. The following information on this injury is focused on the racing Greyhound. This fracture is most commonly located at the origin of the dorsal radiocarpal ligament that joins the dorsal articular margin of the radius with the ulna carpal, is probably caused by a combination of compressive and torsional forces during hyperextension of the carpal joint. The history can be subtle; usually the trainer reports the dog "checking" in the turns and running wide. The lameness affects the dog for the first 24/36 hours after a trial or race but the dog is weight bearing. Generally, after a few days the dog seems to be normal but is lame again after a gallop or a trial. The clinical examination reveals pain in flexion, as well as on internal or external rotation of the carpus. Cranial translation with the joint at 90 degrees of flexion elicits a pain response. Swelling is not a constant finding and identifying the lesion by the application of direct pressure does not necessarily evoke a pain response. Radiographic examination consists of multiple views including standard and oblique views. Some authors describe the straight medio-lateral as the best diagnostic view. The radiographic findings of 150 cases have been compared to determine the location and type of injury and the sensitivity of standard lateral, dorso palmar and oblique views compared with skyline (tangential) views. The results of this unpublished study suggest that there are four types of lesions that can be described and that the skyline view is, in some cases, the only diagnostic view allowing identification and location of the injury. When available, CT scan is the tool of choice due to its superior diagnostic sensitivity. On the basis of the radiographic and surgical findings, four main lesion patterns are recognized. The first type consists of chondromalacia and erosion in the area of the origin of the dorsal radio-carpal ligament. The second type is an incomplete mono-cortical fracture, usually perpendicular to the dorsal articular margin, entering the joint for a few millimeters. The third type is a fracture avulsion of the origin of the radio-carpal ligament consisting of one fragment, or multiple small fragments, ranging from 2 to 6 mm in size. The fourth type is a dorsal slab fracture, which is usually complete and non-displaced, varying in size from 1 cm to a large slab (Figure 58-17A, B, C, and D). The fracture is exposed with a small incision made, between the extensor carpi radialis and the common digital extensor tendon. Surgical removal of small fragments by curettage and/or lag screw fixation of larger or incomplete fractures, offers the best prognosis (Figure 58-18 and Figure 58-19). Removing the small

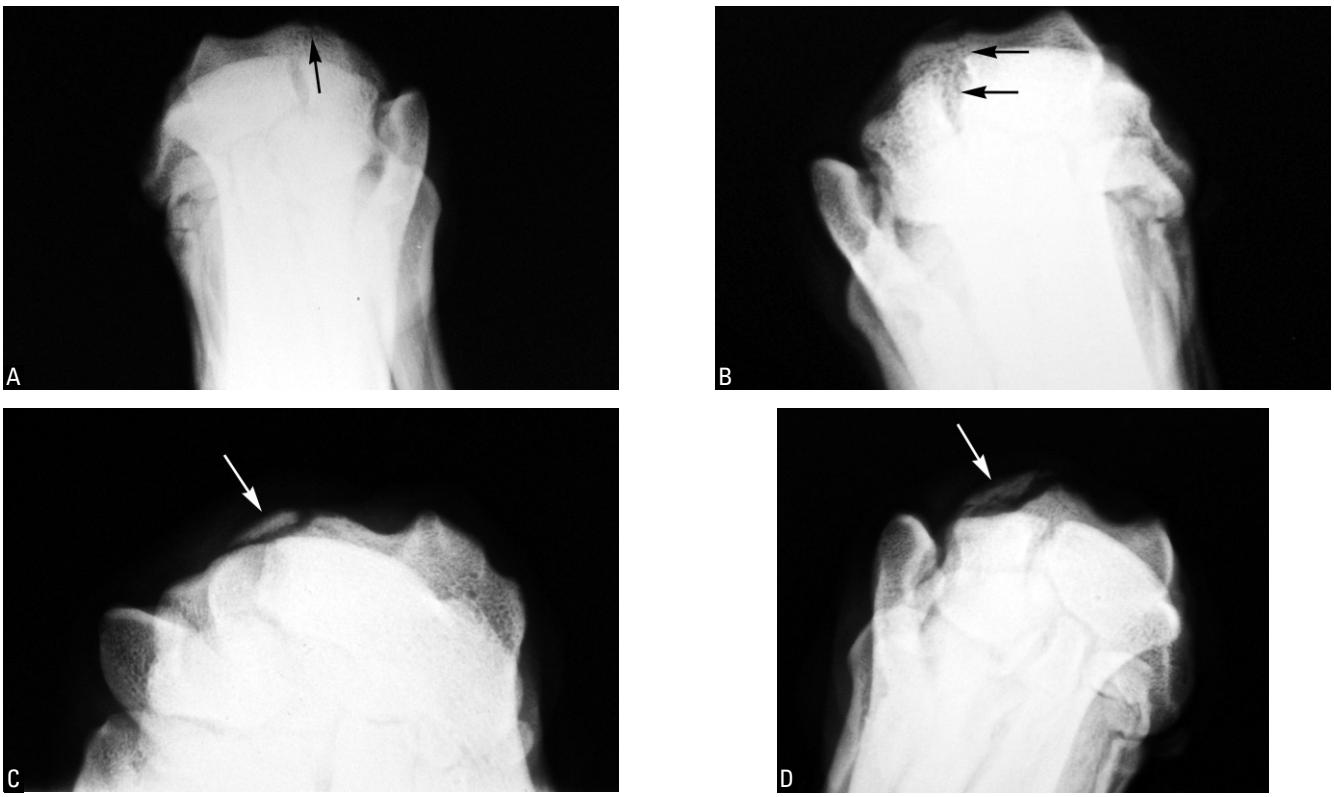

Figure 58-17. A. Type I: chondromalacia and erosion at the origin of the dorsal radio-carpal ligament that appears usually thickened and partially damaged. A skyline view illustrates the erosion of the dorsal articular margin. **B.** Type II: An incomplete mono-cortical fracture line, usually perpendicular to the dorsal articular margin. It enters the joint for a few millimeters. A skyline view of this lesion is shown with an arrow pointing to the fracture line. **C.** Type III is a fracture avulsion of the origin of the dorsal radio-carpal ligament consisting of one fragment as shown by this skyline view. **D.** Type IV is a dorsal slab fracture, usually complete and non-displaced. Skyline view of the same lesion.

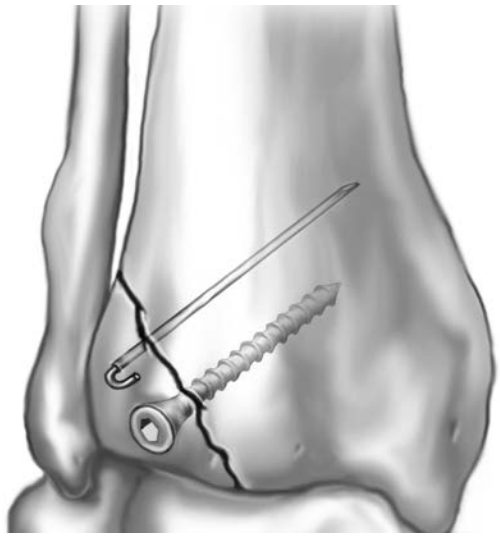

Figure 58-18. A fracture of the dorsal articular margin of the radius is repaired with a 2.0 mm lag screw and a K wire. The head of the screw is well countersunk. In case the K wire is interfering with soft tissue it can be cut flush to the bone surface.

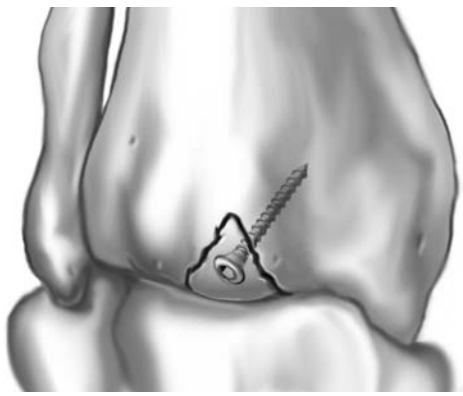

Figure 58-19. A chip fracture of the dorsal articular margin is repaired with a 1.5 mm lag screw. Aggressive countersinking should be avoided to prevent splitting of the small fragment.

fragments creates damage to the dorsal radio-carpal ligament that heals by formation of fibrous tissue. The involvement of this small ligament in the etiopathogenesis of this type of fracture and its role in the joint's stability is yet to be clarified.

Post Operative Considerations

After the surgery a light bandage is applied on the carpus for 10 days. After suture removal, a light bandage is reapplied for another 15 days and light exercise and physiotherapy are encouraged. The dog is expected to restart training between 6 and 10 weeks after surgery.

Partial Carpal Arthrodesis

Thomas Van Gundy

The purpose of partial carpal arthrodesis is to provide a bony union across the carpometacarpal, middle carpal, and intercarpal joints. Indications for this procedure include luxation, subluxation (e.g., hyperextension injury), chronic instability resulting in degenerative joint disease, intra-articular nonunion, and arthritis (septic or immune-mediated) not responsive to medical treatment. The antebrachiocarpal joint must be stable and pain free. Stability is assessed by palpation and stress radiography. Instability and subluxation of the accessory-ulnar carpal joint complicate partial carpal arthrodesis, making pancarpal arthrodesis the procedure of choice.

The animal is placed in dorsal recumbency. The limb is prepared for surgery. Proper use of a temporary tourniquet fashioned of wide Penrose drain or elastic bandage material facilitates the surgical procedure. Access to the joints involved is gained through a cranial approach. The skin incision is offset, to avoid overlying bone plates directly. The middle carpal, intercarpal, and carpometacarpal joints are opened with full carpal flexion, and the cartilage surfaces removed using an air-powered bur and rongeurs. The joints are then lavaged thoroughly and are placed in extension (neutral alignment of carpal and metacarpal bones) and stabilized. Preferred stabilization uses a cranially applied T or L plate with screws in the radial carpal, intercarpal (if possible), and metacarpal bones. A single plate overlies the proximal third or fourth metacarpal bone (Figure 58-20). Larger dogs may have two opposite-angle L plates applied, allowing screw purchase in the radial and ulnar carpal bones and both central metacarpal bones (Figure 58-21). Proper plate and screw placement is crucial to avoid impingement of screws or plates on the antebrachiocarpal joint. Cancellous bone graft harvested from the ipsilateral humerus is liberally packed into all joints to be fused, and overlying tissues are closed in a routine manner. An alternative method of fixation uses intramedullary Kirschner wires placed in retrograde fashion from the distal dorsal surfaces of the second, third, fourth, and fifth metacarpal bones, seating into the radial and ulnar carpal bones (Figure 58-22).

Postoperative radiographs (including stress views) determine implant placement and the need for further implant removal if antebrachiocarpal joint impingement is noted. Postoperative management includes 6 weeks in a cast or splint and implant removal at the time of bony fusion if clinically indicated.

Figure 58-20. A T plate is applied to the dorsal aspect of the left carpus with two bone screws seated in the radial carpal bone, one in carpal bone III and two in the proximal aspect of metacarpal III.

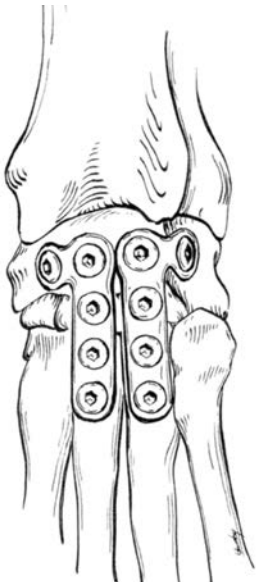

Figure 58-21. Paired 2.7-mm L plates are applied to the dorsal aspect of the left carpus. With this technique, two carpal bones are secured with screws, and the lateral plate spans the radial and ulna carpal bones. A total of four screws may purchase in metacarpal bone.

Proper patient selection and procedure are paramount for success. Insufficient evaluation of a pathologic antebrachiocarpal joint may allow progressive hyperextension and may require subsequent pancar-pal arthrodesis. Careful radiographic comparison of the accessory-ulnar carpal bone articulation with normal stress radiographs is helpful. Proper placement of implants can be facilitated by careful antebrachiocarpal joint arthrotomy to visualize radial and ulnar carpal bone geometry. Persistent lameness may require re-evaluation of implant placement or of antebrachiocarpal joint disease.

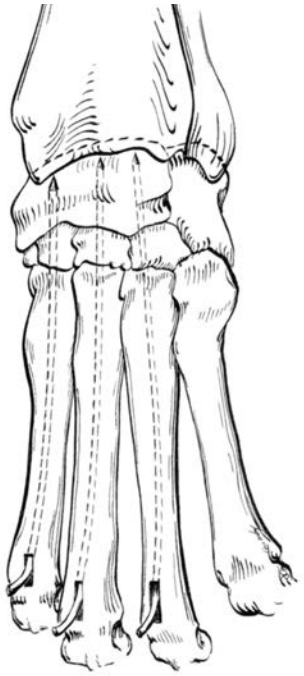

Figure 58-22. Kirschner wires are used with this technique by retrograde placement. The wires are started from an extra-articular position just proximal to the metacarpophalangeal joint. The points of the Kirschner wires extend to just below radial carpal bone articular cartilege.

Pancarpal Arthrodesis

Arnold S. Lesser

Indications

The primary indication for pancarpal arthrodesis is irreparable damage to the articular surfaces of the antebrachiocarpal joint or the soft tissues around the joint that causes intractable pain and loss of limb function. This damage may be from trauma, infection or arthritis. Examples of trauma would be highly comminuted fractures of the articular surface or fracture luxations with significant soft tissue and or bone loss where a primary repair would still be unstable. Severe cartilage damage can also result from chronic osteoarthritis, infection from septic arthritis or open, infected fracture luxations. Rheumatoid arthritis, seen mostly in small breeds, causes severe ligamentous instability that does not respond well to soft tissue repairs. Pancarpal arthrodesis is effective in these cases but the disease may affect multiple joints. Partial carpal arthrodesis is sufficient in those cases with hyperextension injuries where the antebrachiocarpal joint is not damaged.

There are other less common indications for pancarpal arthrodesis. It is used to increase purchase for a plate in the fore leg with atrophic nonunions of the radius and ulna in miniature breeds, and limb salvage procedures for Osteosarcoma treatment. In both of these cases there is not enough distal radius to anchor a plate. Arthrodesis allows the plate or External Skeletal Fixator to extend down to the metacarpal bones. Radial paralysis and mild brachial plexus injuries can be treated with a pancarpal arthrodesis. Pure radial paralysis is rare. There are other treatments such as muscle transfers, but pancarpal arthrodesis to keep the paw in the proper orientation is one alternative. These animals may still bear weight on the side of the paw and a protective boot may be necessary. In Brachial plexus injuries the patient must be able to extend the elbow in order to make the procedure worthwhile. Fusing the carpus in severe brachial plexus injuries with a nonfunctional elbow will not have any benefit.

Procedure

In a pancarpal arthrodesis, the antebrachiocarpal, middle carpal, and carpometacarpal joints are included. It has been reported that fusing only the antebrachiocarpal joint and not the distal joints will lead to degenerative joint disease of the latter due to excessive stress. All the cartilage in these joints must be removed with a power burr or curette. The fascia, joint capsule and intercarpal ligaments must be incised to expose the cartilage. With a dorsal approach the cephalic and accessory cephalic veins and the common digital extensor tendons must be retracted but the extensor carpi radialis and abductor pollicus longus tendons can be sacrificed to expose the intercarpal and carpometacarpal joints. Some form of graft material should be placed between the denuded joint surfaces. Autogenous cancellous chips are the best but there are now numerous choices from freeze dried, decalcified, cancellous allograft to artificial Ca Phosphate substitutes. The carpus is fixed in 5 to15 degrees of dorsiflexion to place the foot in a more natural weight bearing position.

Plate fixation is the most commonly used method although external fixators and even cross pins have been advocated. Both plates and external skeletal fixation are acceptable methods of providing

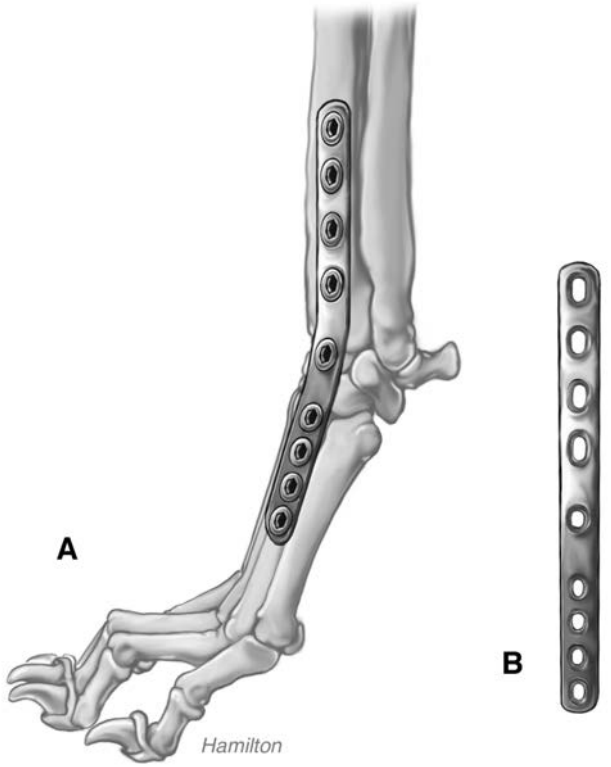

Figure 58-23. A. The preferred method of pancarpal arthrodesis is a plate with at least 3 to 4 screws in the radius, 1 in the radial carpal bone, and 3 more in the third or fourth metacarpal bone. The carpus is placed in 5 to 15 degrees of extension. **B.** Newer plats allow downsizing of screws to be placed in the metacarpals.

stable long term fixation. External fixators have an advantage in type III open fractures or at the site of an infection. No metal is buried and it is possible to treat the open wounds around the fixation. A type II, or rarely, a type III ESF can be used. Ring fixators and hybrids are also an effective choice in these situations. In clean, uncomplicated cases plates are usually the preferred implant and are better tolerated during the long periods required for arthrodesis. DCP plates also have the advantage of applying compression across multiple joint surfaces. The plate is placed dorsally (Figure 58-24) in most cases. The plate can also be placed ventrally, which is the tension band side, although this approach is much more difficult and involved (Figure 58-25). There is also a recent report in which the plate is placed on the medial aspect of the radius and carpus. This placement removes the plate from the compression side of the fixation. The newer locking plates can be contoured in four directions allowing the 10 to 15 degtrees of dorsiflexion with a medial plate. By far the most commonly used position is dorsal. Three or four screws are placed in the radius, one in the radiocarpal bone to pull it up to the plate, and at least 3 in the 3rd or 4th metacarpal bone. Depending upon how the plate lays on the radius and intrercarpals it may line up on either the 3rd or 4th metacarpal. Some newer plates taper down distally permitting the use of smaller screws for the metacarpal bones For example a 3.5 mm screw and plate over the radius and radiocarpal bone and 2.7 mm screws for the metacarpal bone. Others allow placement of screws in both the 3rd and 4th metacarpals.

A cast is usually added to plate fixation since there is no worry about joint stiffness and it adds a measure of safety. The cast can be left on until radiographic signs of fusion are seen, or removed at the discretion of the surgeon in a smaller quieter patient. The plates are rarely removed but fractures at the end of the plate are a concern in large active patients.

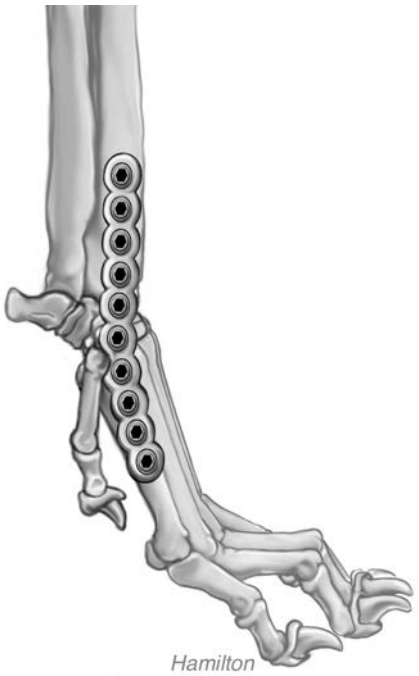

Figure 58-24. Placing the plate on the medial side but allowing 5 to 15 degrees of extension requires a plate to be contoured in two planes. The newer locking plates allow this.

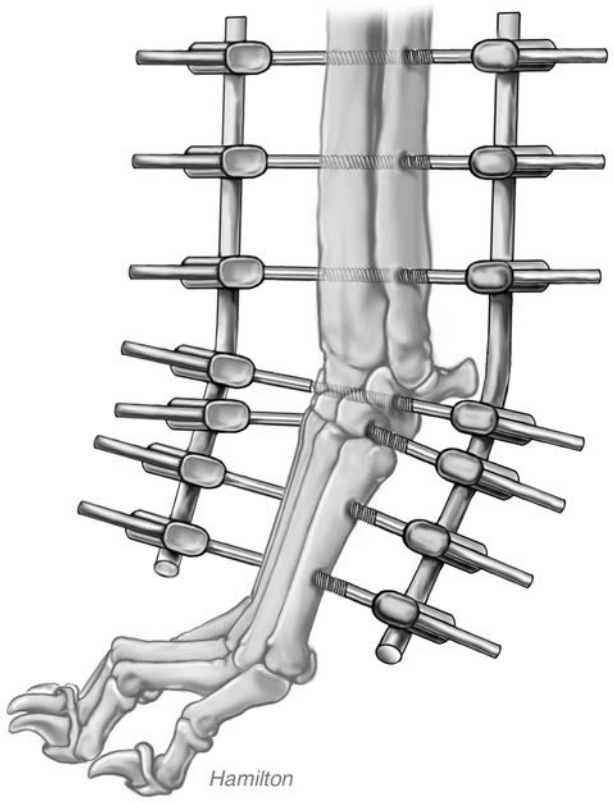

Figure 58-25. External skeletal fixators, ring fixators or hybrids work well as an alternative to plates especially in the presence of infection or major soft tissue damage.

Repair of Fractures Involving Metabones and Phalanges

Alessandro Piras and Jon F. Dee

Introduction

Metacarpal and metatarsal fractures are a common injury in small animals. Although they can occur from direct trauma or from a collision against a stationary object, other causes are recognized. Entrapment of the paw while leverage is applied to the area or a fall can cause the fractures. Fractures caused by falls usually have associated hyperextension injuries.

In a retrospective study of 37 cases of meta-bone fractures, metatarsal fractures were over represented (Muir 1997). Fractures of one metacarpal or metatarsal bone occurred in 24% of the dogs, two meta-bones were involved in 16% of the cases, three meta-bones in 19% and four meta-bones in 41% of the cases. Fractures of the metacarpal/tarsal bones are classified according to their anatomical location: fractures of the proximal end (base), fractures of the shaft, and fractures of the distal end (head).

Clinical Examination

The degree of lameness that is observed increases as the severity of the injury increases. Isolated non-displaced fractures affecting the II or the V meta-bones, can cause a mild lameness that tends to resolve in 48 to 72 hours. Fractures affecting the III and IV bones or multiple bones are generally accompanied by severe non-weight bearing lameness. Clinical signs in acute cases include: swelling, and pain on digital palpation. With complete fractures, crepitus and deformity are usually also detectable.

Radiographic Examination

A complete radiographic assessment should include dorso-palmar/plantar and lateral views. Isolated metacarpal\tarsal views are not possible. Dorso-palmar/plantar 15° oblique views and lateral 45° oblique views (Figures 58-26, 58-27 and 58-28). are often necessary to isolate individual bones or to evaluate complex multiple fractures.

Figure 58-26. Dorso-palmar/plantar 15° oblique positioning.

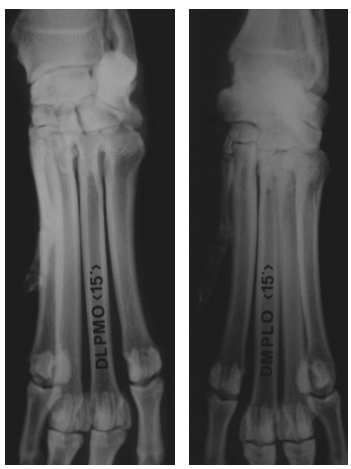

Figure 58-27. Dorso lateral – Palmaro medial (15°) oblique and Dorso medial – Palmaro lateral (15°) oblique view.

Figure 58-28. Plantaro-Dorsal view shows how difficult it can be to highlight a fracture of MTV in contrast to the oblique view.

Preoperative Considerations

The application of a modified Robert Jones bandage supported by a meta-splint for 24 to 48 hours prior to surgery will dramatically decrease swelling and facilitate fracture reduction. Application of a stockinette will enhance skin retraction and sterility. Judicious use of a tourniquet will decrease bleeding.

Surgical Approachs

(Figure 58-29A, B and C)

Fractures of the Base

Basilar fractures usually involve the second and the fifth meta-bones. These uncommon fractures are usually avulsions of ligament or tendon insertions and may be associated with some degree of varus/valgus deviation of the foot. Conservative treatment is considered for non-displaced, stable fractures. In the case of unstable fractures the fragment tends to displace due to the pulling action of the ligament or tendon; the risk of

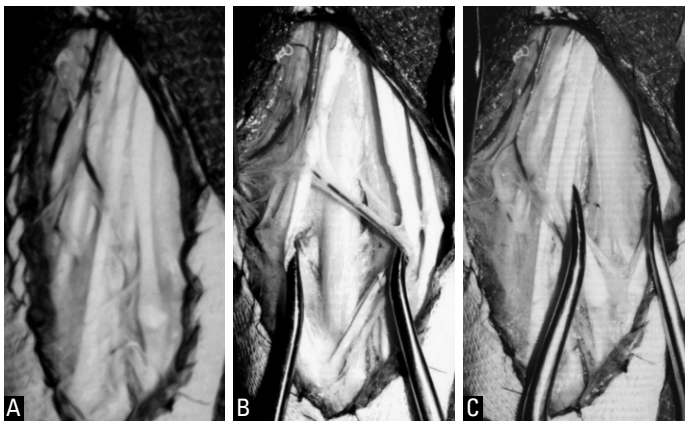

Figure 58-29. A. The skin is retracted and sutured to the stockinette. The deeper structures are visible, especially the dorsal common digital veins and the tendons of the common digital extensor muscle. **B.** The tendons are elevated and retracted together with the vascular structures to expose the fracture. **C.** Medial or lateral retraction of tendons allows exposure of the metabones.

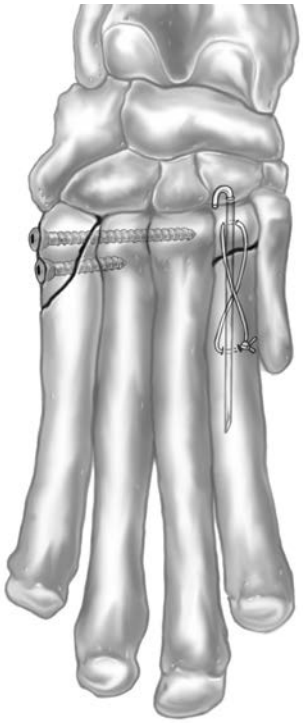

Figure 58-30. Fracture of the base of the II metacarpal bone treated with a small K wire and a figure-of-eight tension band wire. Fracture of the base of the V metacarpal bone treated with two lag screws. The heads of the screws are countersunk. The screws can be inserted to engage one or two adjacent metacarpal bones.

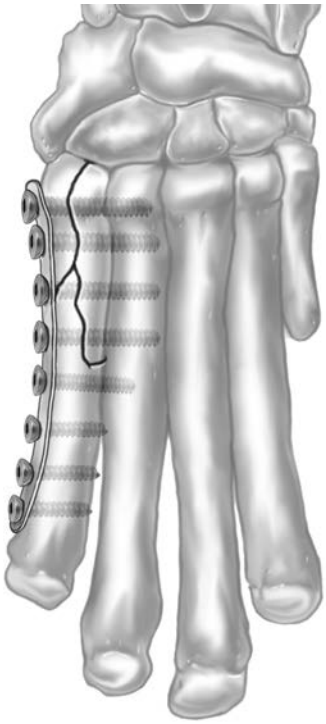

Figure 58-31. Comminuted fracture of the base and shaft of the V metacarpal bone treated with a Veterinary Cuttable Plate (Synthes Ltd. USA, Paoli, PA), applied on the lateral aspect of the bone. The first four screws are applied in lag fashion.

mal-union and consequent angular deviation justifies open reduction and internal fixation as the treatment of choice in these cases.

Fixation can be achieved with a small K wire and a figure-of-eight tension band wire or with multiple 1.5 mm or 2.0 mm lag screws (Figure 58-30). The most proximal screws are usually inserted to engage the proximal cortex of the adjacent meta-bone. Comminuted fractures of the base can be repaired with a small plate (Figure 58-31). A careful clinical and radiographic examination with stressed views is necessary to assess complex and multiple basilar fractures, as they can be associated with a hyperextension injury, resulting in palmar/plantar and lateral or medial instability. These complex injuries are best treated with carpal arthrodesis.

Fractures of the Shaft

Metacarpal/tarsal fractures can be treated either conservatively or surgically: Displacement of shaft fractures is limited by the surrounding soft tissue structures and by the support of the adjacent meta-bones. Transverse fractures of one or two metacarpal/tarsal bones, if located in the proximal and middle third tend to be stable, and can be treated with closed reduction and external coaptation. The meta-bones tend to spread in their distal third and less adjacent support is present, so fractures located in the distal portion of the shaft tend to displace, and are more difficult to maintain in a reduced position with conservative treatment.

Internal fixation of shaft fractures is usually indicated when there are more than two metacarpal/tarsal fractures in the same leg, when the two weight-bearing bones (third and fourth) are fractured, or when there is significant displacement or shortening. In large breed dogs and athletic or working dogs, fractures of even a single bone are ideally treated with internal fixation in order to achieve the best functional results.

Transverse Fractures

Transverse fractures often result from a direct blow. These fractures usually present with dorsal angulation and palmar/plantar displacement of the distal fragment, due to the direction of the deforming forces and the pull of the interosseous muscles and flexor tendons.

Plate application of transverse fractures assures a very stable fixation. External post-operative support needs to be maintained for a shorter period compared with other methods of internal fixation, thus speeding the functional recovery and allowing an earlier rehabilitation. The plate is applied to the dorsal aspect of metacarpal/tarsal III and IV, to the medial aspect of metacarpal/tarsal II and to lateral aspect of metacarpal/tarsal V (Figure 58-32). The Veterinary Cuttable Plate (VCP-Synthes™) is an excellent implant for repair of large patient metacarpal/tarsal fractures. These plates, available with 1.5 mm/2.0mm and 2.0 mm/2.7 mm screw holes, offer unique advantages; a thin profile plate with close screw holes and excellent mechanical properties.

Intramedullary pinning has been described as a successful method of treatment. A small size Kirschner wire (1.5 or 2.0 mm) can be

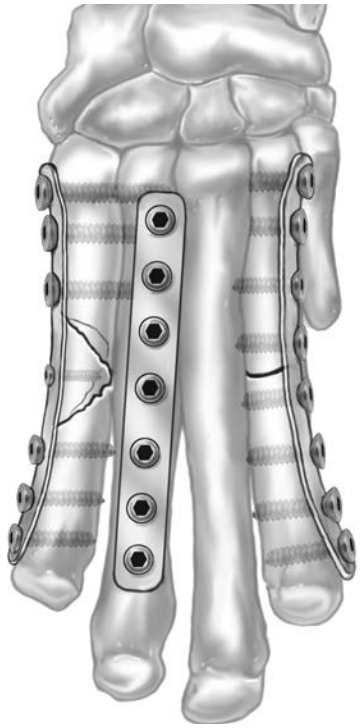

Figure 58-32. Transverse fractures of the II and IV metacarpal bones treated with medial/ lateral and dorsal plating. A comminuted fracture of the V metacarpal bone treated with a bridging plate. In this case it is possible to stabilize the large butterfly fragment with a 1.5 mm screw applied through the plate.

Figure 58-33. Transverse fractures of the III and IV metacarpal bones repaired with IM pins using the "slot" technique. A transverse fracture of the metaphysis of the V metacarpal bone repaired with two Rush pins.

inserted orthograde (normograde), starting distally, close to the dorsal attachment of the joint capsule. Reduction is achieved with a combination of traction and leverage applied with a small periosteal elevator. The pin is driven into the proximal fragment to the base of the bone. The protruding portion of the pin is cut after bending it into a hook shape. Ideally, the pin should be retracted slightly, bent into a hook and then reseated into the base in order to diminish the irritation of the pin to adjacent joint structures. A slot can be created with a high-speed burr to facilitate the insertion of the pin and the lodgement of its tip (Figure 58-33). Pre-sizing the length of the pins to the pre-operative x-ray will reduce the risk of penetration of the base and violation of the carpo-metacarpal/ tarso-metatarsal joints. Intramedullary pinning is advocated for fractures that are stable after reduction, for fractures in young non-athletic breeds and for fractures involving only one or two meta-bones.

Oblique Fractures

Oblique and spiral fractures tend to telescope--producing shortening and rotational deformity. Because these factors are difficult to control by external coaptation, the best option is open reduction and internal fixation. Most long-oblique and spiral fractures can be successfully repaired with multiple lag screws. Screws can be used as the only form of fixation if the length of the fracture is at least twice the diameter of the metacarpal/ tarsal bone and a minimum of two screws can be placed (Figure 58-34). Countersinking of the screws will improve the loading characteristics and will decrease soft tissue irritation. Whenever required, the repair can be supported with a neutralization plate. This is especially valid for fractures involving the III or IV meta-bones. Multiple cerclage wiring has been described

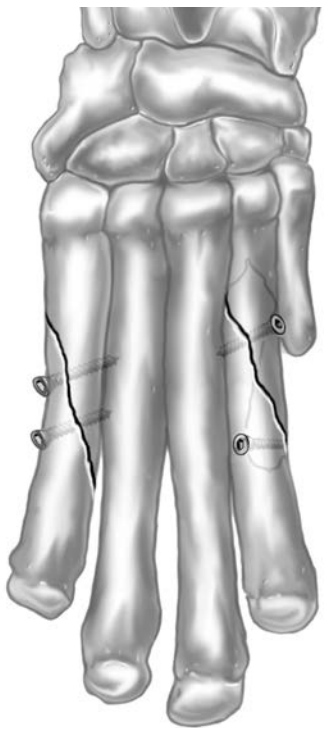

Figure 58-34. Two oblique shaft fractures repaired with lag screws. In involvement of the III or IV meta-bones it is possible to reinforce the repair by adding a neutralizing plate.

as a successful alternative to screw application; however the author does not recommend this technique. Cerclage wiring in conjunction with lag screws may be useful in selected cases.

Comminuted Fractures

Reconstructable comminuted fractures are best repaired with a combination of lag screws and mini plates or VCP. Large fragments can be lagged through the plate.

For highly comminuted fractures, a biological approach is recommended. Due to the anatomical characteristics of the area, the intact meta-bones offer a natural splintage to the fractured bone, minimizing the necessity for a perfect anatomical reconstruction. The plate can simply bridge the fracture, guaranteeing axial alignment and length.

Comminuted open metabone fractures have been successfully treated using external fixation, either with linear fixators, using epoxy resin putty, or with ring fixators.

Fractures of the metaphysis, immediately proximal to the condyles, are uncommon. These fractures are usually transverse, and tend to be stable, with the proximal fragment impacted a few millimeters into the distal fragment. A mild rotational deformity may be present. Conservative treatment with external coaptation is sufficient for isolated injuries. Surgical treatment is indicated when the fracture is in combination with other metacarpal\tarsal fractures or when it is displaced and difficult to reduce. Two pins inserted in a Rush fashion medial and lateral to the condyles and driven proximally are generally sufficient for repair (See Figure 58-33). In sporting dogs, the use of a more stable fixation with mini T or L finger-plates is recommended (Figure 58-35).

Fractures of the Head

Fractures of the head are usually intra articular fractures involving the condyles and consequently the metacarpo/tarso–phalangeal joint. Closed reduction is only used for incomplete or non-displaced fractures. Surgical treatment is indicated for mono-condylar and for T or Y fractures. Internal fixation is achieved with a lag screw or with a small cerclage wire for simple fractures and with mini T or L plate for more complex fractures (See Figure 58-35).

Post Operative Treatment

After surgery, a padded bandage is applied for approximately 3 to 4 weeks or until radiographic signs of bone healing are seen. Kennel confinement is strongly recommended until bandage removal. This period is followed by 4 to 8 weeks of restricted exercise. Fractures involving multiple bones will require either a cast or a molded splint.

Conservative Treatment

A padded bandage is reinforced with a molded splint or with a fiberglass cast. Kennel confinement and rest are required until there are radiographic signs of bone healing, which occurs usually within 4 to 8 weeks.

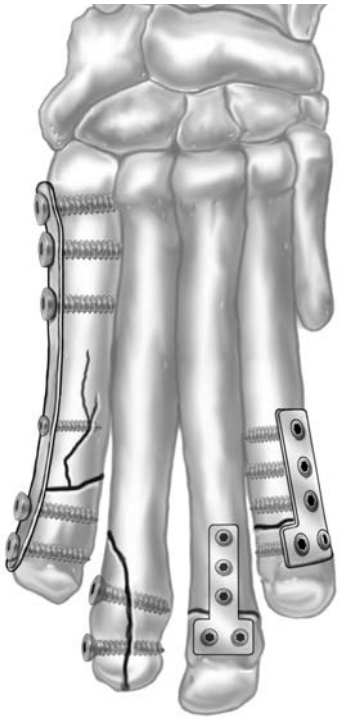

Figure 58-35. Fractures of the metaphysis of the II and III metacarpal bones. These fractures are treated with a small L plate and a small T plate. Care should be taken to avoid the joint space and to avoid allowing the screws to protrude into the sesamoids. A fracture of the head of the IV metacarpal bone is repaired with two lag screws. Excessive countersinking of the head of the most distal screw can damage the insertion of the collateral ligament and can irritate the joint capsule. A fracture of the metaphyseal area of the V metacarpal bone presents several fissures extending proximally. This fracture is repaired with a Veterinary Cuttable Plate in a bridging fashion. Two proximal and two distal screws are usually sufficient.

A retrospective study comparing the outcome of metacarpal/tarsal fractures treated conservatively versus surgically suggests that the outcome was not statistically affected by surgery or conservative treatment however this was a small non-randomized population of pet dogs, not performance nor working dogs (A. Kapatkin 2000).

Metacarpal/Tarsal Fractures in Racing Greyhounds

Metacarpal/tarsal injuries are extremely common in the racing greyhound with a high incidence in dogs between 14 and 28 months of age. Metacarpal and metatarsal fractures are, for the vast majority, fatigue or stress fractures resulting from repetitive cyclical loading as documented by (Bellenger C.R.et al 1981, Boemo 1989 & Johnson A. K. 2001). Exceptions are the traumatic fractures sustained in a fall, or following a collision against stationary objects.

Traumatic injury can involve any metacarpal bone but are usually multiple, involving two to four bones. Stress fractures almost always involve the left V and the right II metacarpal bones. Fracture of the IV left metacarpal bone can be associated with a fracture of the V left metacarpal bone, and has not been described or reported as an isolated injury. The metatarsal

bones affected by stress fractures are the left V and the right III. Greyhounds are high performance dogs and internal fixation is recommended in the majority of the cases.

Phalangeal Fractures

Introduction

Phalangeal fractures are common injuries and are often considered insignificant. As a direct consequence of this underestimation, the treatment of these injuries is not always optimal. The most common complications associated with inappropriate treatment of phalangeal fractures are: malunion with imbalance of the flexor and extensor mechanism, limited range of motion, degenerative joint disease and deformity with interference between toes.

There are a variety of factors to consider when deciding the optimal treatment. Breed, age, type of activity, owner expectations and compliance, as well as injury characteristics, pattern of the fracture, and soft tissue damage are all important when establishing a treatment plan.

The goal of the treatment of fractured phalanges is to achieve the best possible reduction and the most effective means of maintaining the reduction in order to promote bony union, early mobilization and function. This concept is particularly valid for sporting dogs in which performance is directly related to anatomical integrity and function.

Anatomy

The base of P1 articulates with the head of its corresponding metacarpal/tarsal bone at a dorsal angle slightly more than 90 degrees. In this position the first phalanx is almost parallel to the ground. P2 articulates with P1 forming a palmar/plantar angle of 135°. The superficial digital flexor tendon inserts on its proximal palmar/plantar aspect. Distally, P2 forms an obtuse dorsal angle with the shallow, sagitally concave articular surface of P3. The deep digital flexor tendon inserts on the broad palmar/plantar tubercle of P3. Each side of the tubercle is perforated transversely by a vascular bone tunnel. On the dorsal aspect of P3 there is another bony prominence, the ungual crest, which is the area of attachment of the extensor tendon and the dorsal elastic ligaments.

Clinical Examination

Variable degrees of lameness are usually present. Clinical examination reveals swelling that is often associated with crepitus and deformity of the affected phalanx. A thorough soft tissue evaluation is necessary to detect the presence of small wounds, some of which may arise from an open fracture.

Radiographic Examination

Radiologic evaluation of phalangeal injuries commences with plain radiographs. A minimum of two views taken at orthogonal angles provides information on two planes. Standard dorso palmar/plantar (DP) and lateral (L) views are the core of the radiologic assessment. DP views should include the metacarpo/tarso–phalangeal joints and the distal inter-phalangeal joints. The L view is taken with the toes spread in opposite directions with the aid of a stirrup of tape, applied on the nail of the second and fifth digit ("fan lateral") (Figure 58-36A, B). Oblique views are used to increase the sensitivity of imaging of phalangeal fractures, especially in cases of severely comminuted fractures. A lateral view with traction applied to the nail is useful to assess the shape and size of the fragments in case of a comminuted fracture of P2.

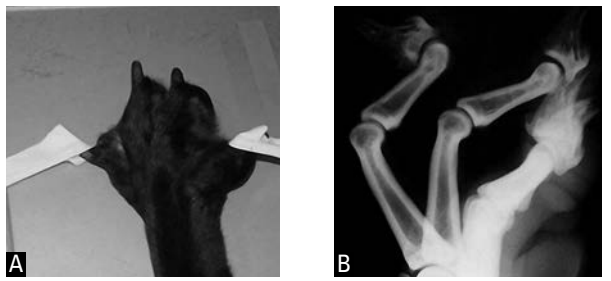

Figure 58-36. A. and **B**. The L view is taken while spreading the toes in opposite directions with the aid of a stirrup of tape, applied on the nail of the second and fifth digit ("fan lateral").

Treatment Principles

To rationalize the treatment of phalangeal fractures it is necessary to take into account the anatomical characteristics of the area as well as the functional angles of the digits. Fractures of P1 and P2 are the most common, while fractures of P3 are less frequent.

In a survey on 40 phalangeal fractures affecting racing Greyhounds (un-published data) P1 was involved in 20 cases, P2 in 14 cases and P3 in 6 cases. P1 fractures were intra-articular in 6 cases P2 in 10 cases and P3 in all of the cases. The head of P1 was involved in 3 cases, in P2 the head was involved in 9 cases and the base of P1 in 3 cases.

Fractures of the Shaft

Fractures of the shaft of P1 and P2 can vary in configuration from: transverse, oblique, spiral with or without a butterfly fragment, to comminuted. Simple, stable non-displaced fractures, especially in young dogs, can be treated by closed reduction with splinting in a functional position.

Fractures with unstable configuration are best treated with open reduction and internal fixation with lag screws (1.5 mm to 2.0 mm) and/or mini plates applied on the dorsal or lateral aspect of the phalanges. In spite of the apparent simplicity of the surgical approach, internal fixation of complex fractures can be very challenging. Careful handling of the fracture fragments with appropriate instruments and gentle traction is mandatory in order not to compromise the delicate vascular structures in this area. Failure to respect the blood supply can lead to severe complications ranging from non-union to necrosis of the toe.

Fractures of P2 tend to displace due to the pull of the flexor tendons therefore the reduction of comminuted P2 fractures can be extremely challenging. A single screw is not sufficient to withstand rotational and shear stress. Ideally a minimum of two screws should be used for oblique fractures. Unfortunately this

is not always possible due to the small size of the bones. An anti-rotational small K wire can be added to improve the stability. The screw head should be countersunk to avoid interference with the gliding tendons. When using mini plates, always try to secure two screws proximal and two screws distal to the fracture site. As this is possible only in very large breeds, one screw may be sufficient in selected cases, especially if the plate is applied in neutralization (Figures 58-37 and 58-38).

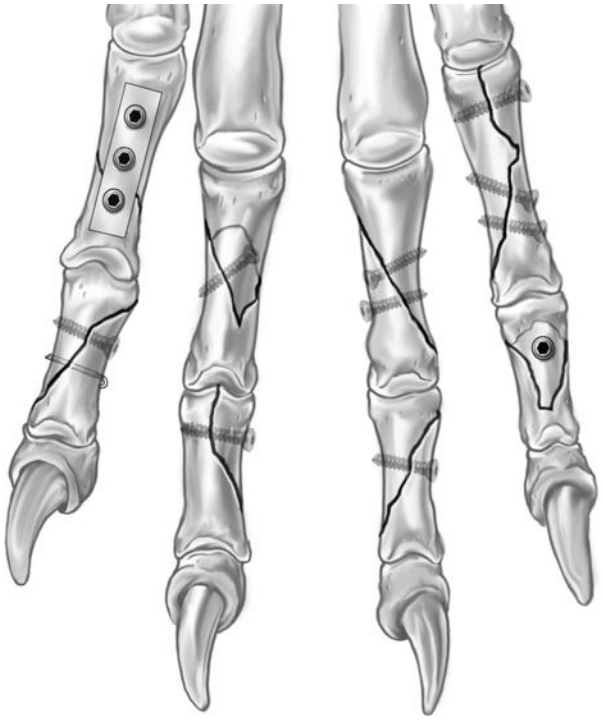

Figure 58-37. Different types of phalangeal fractures repaired with 1.5 mm lag screws. According to their shape, one or multiple screws are used. In the case of the second phalange on the left, a small K wire and a lag screw are used in combination. The protruding portion of the K wire should be bent over to prevent pin migration. A three holed mini cuttable plate is applied on the dorsal aspect of the first phalanx on the left.

Fractures of the Base and Head

Fractures of the base or of the head are articular, and almost invariably involve the insertion of a collateral ligament. Fractures of the condyles can be handled with application of lag screws or with a loop of cerclage wire unless the fragments are too small to be safely secured in place. Very small fragments can be excised, but in cases with large unstable fragments involving the joint, amputation or arthrodesis is usually necessary.

Operative Considerations

Traditionally, the lag screw technique has been the gold standard for fixation of oblique, spiral and condylar fractures. This technique, which is relatively straightforward for most long bone fractures, can be technically challenging when attempting fixation of small bones. Despite the availability of very small implants (1.0 mm to 1.5 mm to 2.0 mm) the size remains large, relative to the phalanges and the fragments to be fixed… leaving little room for error.

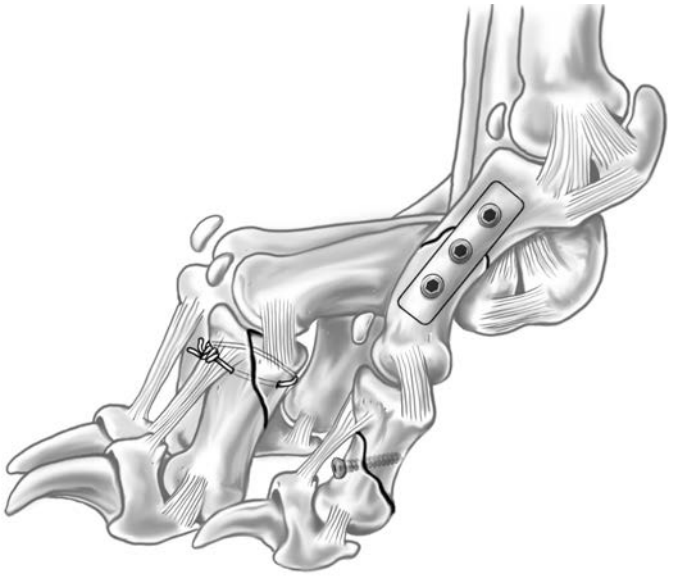

Figure 58-38. A fracture avulsion of the insertion of the superficial digital flexor tendon is repaired with a small cerclage wire. The wire is passed through two parallel, A-P bone tunnels and is tightened on the dorsal aspect of the bone. Care must be taken to bend the wire twist appropriately to avoid irritation to the extensor tendon. A three hole mini cuttable plate is applied on the lateral aspect of the first phalanx. A lag screw is applied to the second phalanx to repair an oblique fracture.

The application of bicortical (positional) self-tapping screws eliminates one surgical step and eliminates the risk of losing reduction and of splitting the fragments during the tapping process. With bicortical screws the proximal cortex is not over-drilled and the screw threads achieve purchase in both cortices while reduction and compression are maintained with bone clamps.

Open Fractures

Open fractures are often comminuted and highly contaminated with severe soft tissue damage and with devitalized bone fragments protruding through the skin. In these cases, amputation is the best choice offering a good prognosis and for sporting dogs a rapid return to performance.

Fractures of P3

Fractures of P3 can involve the joint, split the phalanx obliquely or can occasionally involve the tuberosity of insertion of the deep flexor tendon or the ungual crest. Due to the small size of P3, attempts at internal fixation are unlikely to be successful and amputation is necessary.

Post Operative Considerations

Postoperative care following surgical repair consists of a padded bandage for 3 to 4 weeks and confinement for a total of 6 to 8 weeks. The bandage can be reinforced with a palmar/plantar splint for the first 2 weeks. After bandage removal and when radiographs confirm that the bone is healed, 3 weeks of limited exercise on a lead should commence, with a gradual increase in activity until a return to full activity is attained.

In the case of amputation, a light bandage is applied for 2 weeks. As soon as the swelling decreases and the reflected digital pad is properly sealed, it is possible to gradually reintroduce the dog to exercise. For sporting dogs, the return to full training following amputation is expected by 5 to 6 weeks postoperatively. The prognosis for uncomplicated cases is usually good to excellent.

Chapter 59

Amputation of the Forelimb

William R. Daly

This topic is written based on the available literature through 2010 and does not cover the most current literature on this topic.

Introduction

Amputation of the forelimb is occasionally indicated as a primary treatment for severe traumatic injuries resulting in irreparable fracture or soft tissue injury. Other indications are severe neurological lesions such as brachial plexus avulsion, irreparable vascular occlusion, and severe congenital or acquired deformities. Amputation may also be considered as an adjunct to the treatment of neoplasia or severe infections involving the limb. With the possible exception of neoplasia, amputation should be considered a last resort "salvage" procedure, indicated only when no alternative exists that would allow the retention of a useful limb. Unfortunately, with the development of more sophisticated and expensive procedures which allow saving a limb with severe fractures or soft tissue injuries, amputation may be requested solely based on economic considerations. Because almost all animals will do extremely well with a forelimb amputation, it is better to offer amputation than resort to euthanasia because the animal owners are unable to afford the more sophisticated procedures.

Preoperative Considerations

Amputation performed at the shoulder level or above is generally preferable because a residual limb below this level serves no useful purpose and is prone to abrasions and infections from frequent trauma if the animal attempts to walk on the limb. Small dogs and cats invariably adapt well to forelimb amputation; however, some giant breed dogs may have some difficulty. If the patient is able to ambulate while carrying the affected limb, it will usually do well following forelimb amputation. It is difficult for some owners to accept the option of amputation. However, for most large breed dogs with otherwise normal bone and muscle structure, amputation is not as limiting as it would seem. Most owners and pets acclimate to amputation within a few days to two weeks. Surveys of owners who wanted to avoid amputation, but ultimately accepted that option, have revealed that 90% felt the amputation resulted in fair, good or excellent quality of life.

Forelimb amputation can be performed through or directly below the scapulohumeral joint, or the scapula may be removed with the limb. Forequarter amputation with the removal of the scapula is advantageous because major vessels and nerves are easily visualized, bone cutting instruments (oscillating saw, osteotome, or Gigli wire) are not required, and no prominent scapular spine remains behind. The procedure of choice, however, is the one that works best for each individual surgeon.

Forelimb amputation is a major procedure that should be

performed only with a thorough knowledge of the patient's physical status. Because blood loss is likely to be greater than in most major surgical procedures, the surgeon must evaluate both the hematocrit and plasma proteins pre-operatively. Anemic or hypoproteinemic patients should be treated medically, if time allows, or provisions should be made for transfusions of whole blood or plasma as the situation dictates. Balanced electrolyte solutions should be given intravenously continuously during the surgical procedure and post-operatively until the patient has recovered from anesthesia. The intravenous catheter should be large enough to allow whole blood transfusion should the need arise. In cases of amputation because of neoplasia or infection, a tourniquet may be used between the disease site and the amputation site to limit metastasis of infection or neoplasia to the general circulation.

Amputation of a limb is by necessity a painful procedure and careful consideration should be given to managing pain pre- and post-operatively. Preemptive analgesia is provided with parenterally administered narcotics and a bupivacaine brachial plexus block. If transdermal Fentanyl is used it must be applied the day before the surgery. Post-operative pain management can include narcotics, NSAIDS, and local anesthetics delivered through a "soaker catheter" placed at the time of surgery.

Regardless of the amputation method used, preliminary preparations for the surgical procedure are identical. The affected limb is clipped with a number 40 clipper blade from the carpus to the dorsal and ventral midlines. Clipping should also extend well cranially and caudally to allow adequate draping. The paw is usually covered with a gauze wrap, plastic bag or latex glove before the patient is transported to the operating room where final skin preparation is done.

Forequarter Amputation

The objective of forequarter amputation is to remove the entire pectoral limb, including the scapula, from the thorax. This procedure involves the division of all muscles, nerves and vessels that normally join the two parts. The muscles are the trapezius, rhomboideus, omotransversarius, serratus ventralis, brachiocephalicus, superficial and deep pectorals, and the latissimus dorsi.

After adequate pre-operative evaluation and preparation including the administration of pre-operative analgesics, the patient is anesthetized and is placed in lateral recumbency with the affected limb uppermost. After draping, a skin incision is made over the scapular spine beginning at the dorsal rim of the scapula and proceeding downward to the acromion. At the acromion, the incision curved cranially to cross the cranial aspect of the forelimb at the level of the greater tubercle. This incision is eventually extended to cross the medial surface of the forelimb in the axilla and to curve around the caudal aspect of the limb at the axillary fold, finally to join the lateral incision at the level of the acromion. (Figure 59-1A). The entire skin incision does not need to be completed at the beginning of the operation. The lateral incision alone allows sufficient exposure to remove all muscle insertions, and the remainder of the incision can be delayed as the final act in amputation of the limb.

After the lateral incision to the level of the greater tubercle is completed, subcutaneous dissection exposes the omotransversarius and trapezius muscles. An incision is made in these muscles to sever their attachments to the scapular spine. (See Figure 59-1A) Retraction of the trapezius muscle reveals the rhomboideus muscle which is severed as close to its attachment to the scapula as possible (Figure 59-1B). Several blood vessels that require ligation are generally encountered in the muscle bellies as they are cut. Smaller vessels may be cauterized, but vessels larger than about 1 mm diameter should be ligated with fine monofilament absorbable suture. Further lateral retraction of the scapula reveals the insertion of the serratus ventralis on the medial face of the scapula. The insertion is easily elevated with a sharp periosteal elevator, and thus the detachment of all muscles connecting the scapula to the trunk is completed (See Figure 59-1B).

At this point the vessels and nerves of the brachial plexus are easily visualized and are transected. The axillary artery and vein should be doubly ligated using a three clamp technique. Use of a transfixation suture is recommended in the axillary artery (Figure 59-1C). Nerves may be divided with either a scalpel or scissors without special treatment of the proximal severed ends. Neuroma formation is not a common problem in dogs or cats.

After division of the brachial plexus, attention is turned to the cranial portion of the limb. The brachiocephalicus muscle is transected near the greater tubercle. This is the only muscle in this procedure that is necessary to divide in mid belly, the remainder being severed at their insertions. The omocervical artery and vein are encountered near the greater tubercle and both should be ligated. The superficial and deep pectoral muscles are transected near their insertions on the greater and lesser tubercles respectively (Figure 59-1D). The cephalic vein can also be ligated and divided at this point. The last remaining muscular attachment, the latissimus dorsi, is severed from its insertion on the teres tuberosity and the medial brachial fascia. The axillary lymph node and the accessory axillary lymph node are located just under the latissimus dorsi muscle near its attachment to the humerus and can be conveniently removed, if indicated as in neoplastic disease) once this muscle has been cut (Figure 59-1E).

The amputation is completed by incising the skin of the medial surface of the brachium. A flap must be made that is sufficiently large to cover the defect caused by removal of the limb. The base of the flap must be in the axillary space and as much skin as possible is taken from the medial brachium. It is always desirable to take extra skin to allow trimming as necessary.

Once the limb has been removed, the muscle bellies are pulled together over the ends of the severed vessels and nerves of the brachial plexus. This maneuver is accomplished by inverting the severed ends of the omotransversarius, trapezius, rhomboideus and latissimus dorsi muscles over the surface of the serratus ventralis muscle with a continuous Lembert suture pattern (Figure 59-1F). The superficial and deep pectorals are then similarly inverted by suturing them to the ventral margins of the more dorsal muscles. If a "soaker" catheter is to be used for

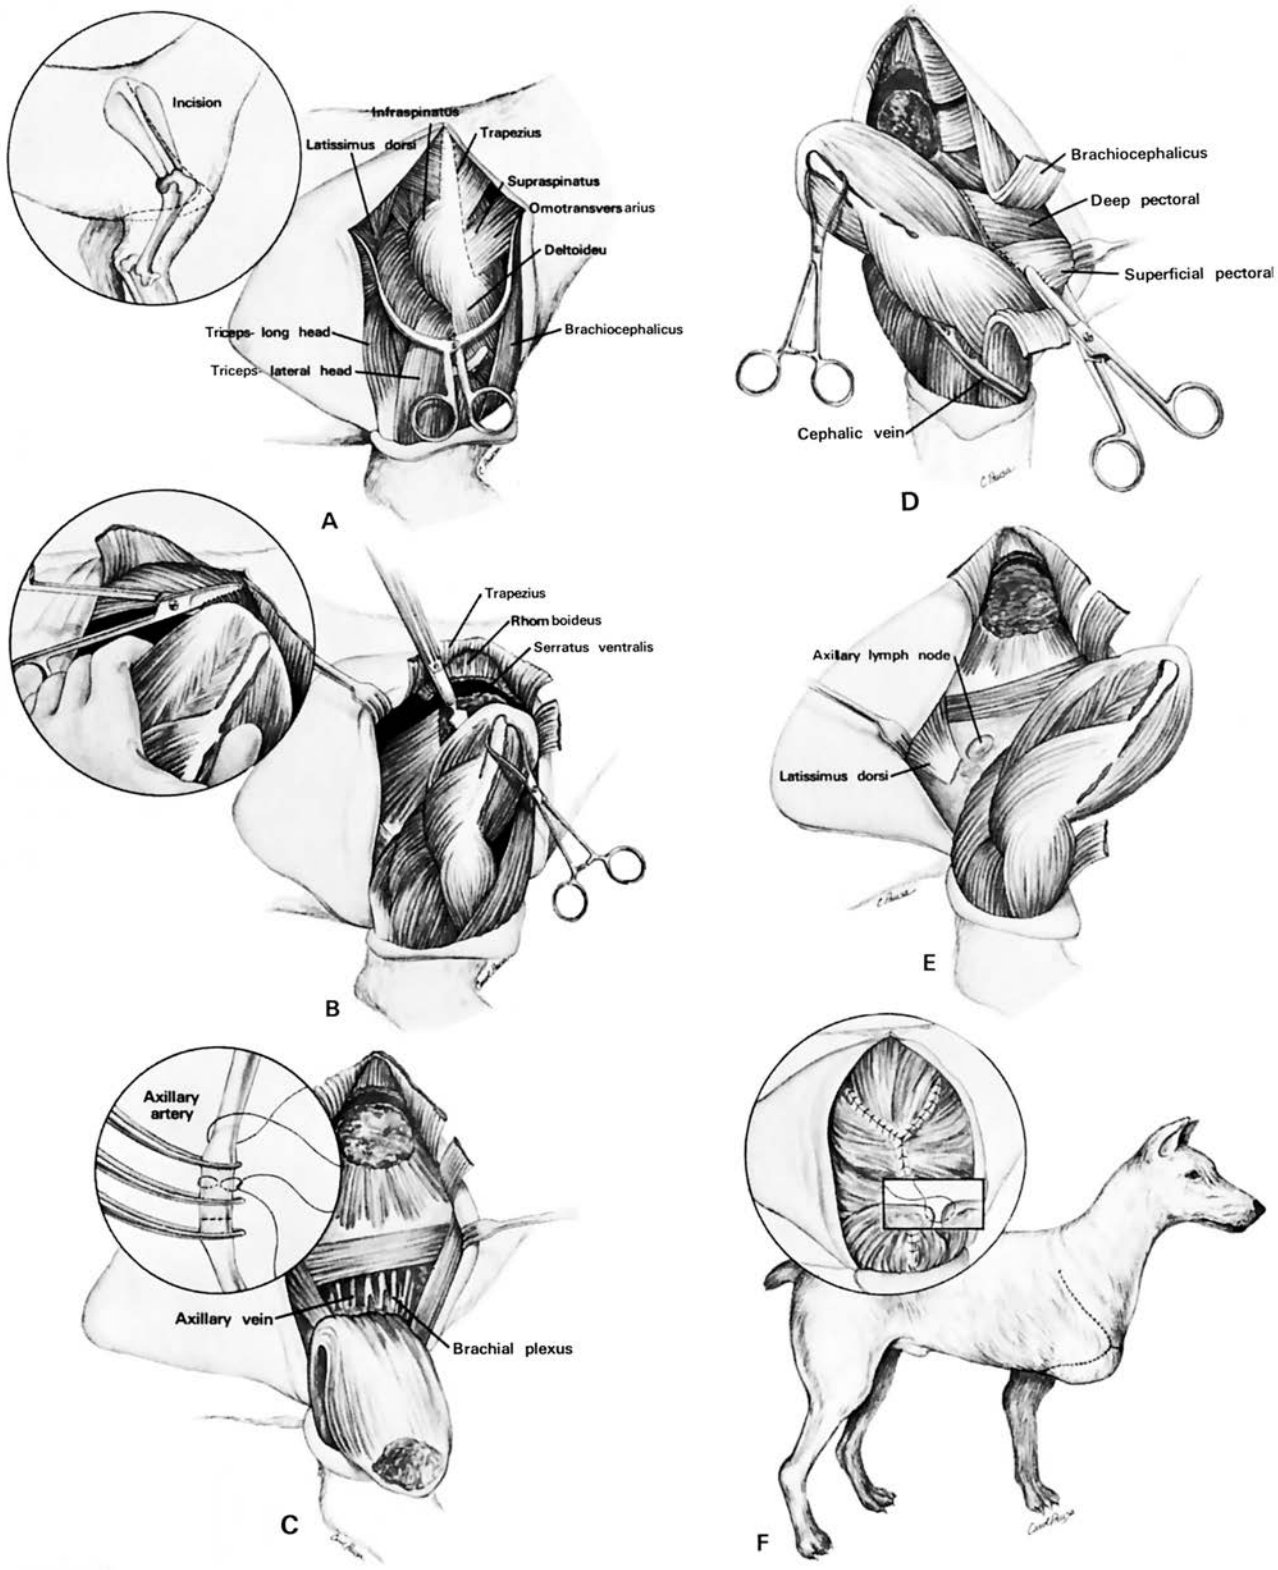

Figure 59-1. **A.** The inset demonstrates the location of the skin incision used for forequarter amputation. After the initial incision over the scapular spine, subcutaneous dissection exposes the trapezius and omotransversarius muscles, which are severed at their insertions (broken line). **B.** The inset demonstrates the rhomboideus muscle as it is severed at its insertion on the scapula. Lateral retraction of the scapula then reveals the serratus ventralis muscle which is sharply elevated from its insertion on the medial face of the scapula. **C.** Complete lateral retraction of the scapula reveals the brachial plexus. The axillary artery and vein are ligated and are severed using the three-clamp technique (inset). **D.** After transaction of the brachial plexus, the brachiocephalicus muscle is divided, and the superficial and deep pectoral muscles are trnasected near their insertions on the humerus. **E.** The final muscular attachment, the latissimus dorsi, is severed at its insertion on the humerus. The axillary lymph node may e removed at this time if indicated. **F.** After removal of the limb, the muscle bellies are inverted over the severed vessels and nerves of the brachial plexus. A Lembert suture pattern works well for this purpose (inset). Subcutaneous tissues and skin are closed routinely.

post-operative administration of local anesthetics to the surgical site, it can be placed just prior to closure of the muscle bellies. Closure of the subcutaneous muscles and skin is routine (See Figure 59-1F). If excessive skin is present, trimming should be done on the medial skin flap in order to preserve the thicker skin and hair coat present on the lateral surface of the limb.

Some veterinary surgeons place several Penrose drains into the wound before beginning closure. If placed, the drains should penetrate the skin as far ventrally as possible. If adequate attention is paid to hemostasis and atraumatic operative technique, drains are not required. In cases that will require surgical drainage, an active suction drain is a better option than the passive Penrose drains. In all cases, a light pressure bandage is used for 2 to 3 days to help prevent swelling, hematoma, and seroma formation. Post-operative pain management will be required. Most patients respond well to morphine at a dosage of 0.25 to 0.5 mg/kg SC or IM q2-6h as needed.

Forelimb Amputation by Scapulohumeral Disarticulation

Scapulohumeral disarticulation is preferred by some surgeons for forelimb amputation. Pre-operative evaluation, preparation, pain management and positioning are identical to that described for forequarter amputation.

In this procedure, the initial incision is made as a semilunar incision that begins at the point of the shoulder, extends across the mid-diaphysis of the humerus, and curves back into the axillary fold. This incision produces a large flap that is later used to cover the wound. A similar flap is then made on the medial side of the limb to ensure adequate surgical exposure for the procedure and a generous supply of skin for closure (Figure 59-2A).

The brachiocephalicus muscle is transected first just below the clavicular tendon. The cephalic vein lies in this region and must be ligated and divided. External rotation of the limb exposes the superficial and deep pectoral muscles which are divided close to their insertions on the humerus (See Figure 59-2A). Retraction of these muscles exposes the nerves and vessels of the brachial plexus, which are separated and ligated as necessary. The nerves may be cut with a scalpel or scissors. The axillary artery and vein should be doubly ligated. The axillary artery is divided distal to the point of origin of the external thoracic and lateral thoracic arteries, which arise close to the first rib.

After division of the brachial plexus, the acromial head of the deltoideus muscle is removed from its origin on the acromion process (Figure 59-2B). Distal retraction of this muscle exposes the insertions of the supraspinatus, infraspinatus and teres minor muscles, which should be transected (Figure 59-2C). The insertions of the latissimus dorsi, teres major, and cutaneous trunci muscles are next divided close to the humerus. The scapulohumeral joint capsule is then opened; total dislocation of the joint is easily accomplished once the tendons of the biceps brachii, coracobrachialis, and subscapularis muscles are severed over the joint space (Figure 59-2D). The spinous head of the deltoideus muscle is elevated from its insertion on the humerus (See Figure 59-2D). The long head of the triceps brachii muscle is then divided as distally as possible to complete the amputation. (Figure 59-2E).

The infraspinatus and supraspinatus muscles soon atrophy from disuse and loss of their nerve supply, exposing the acromion and

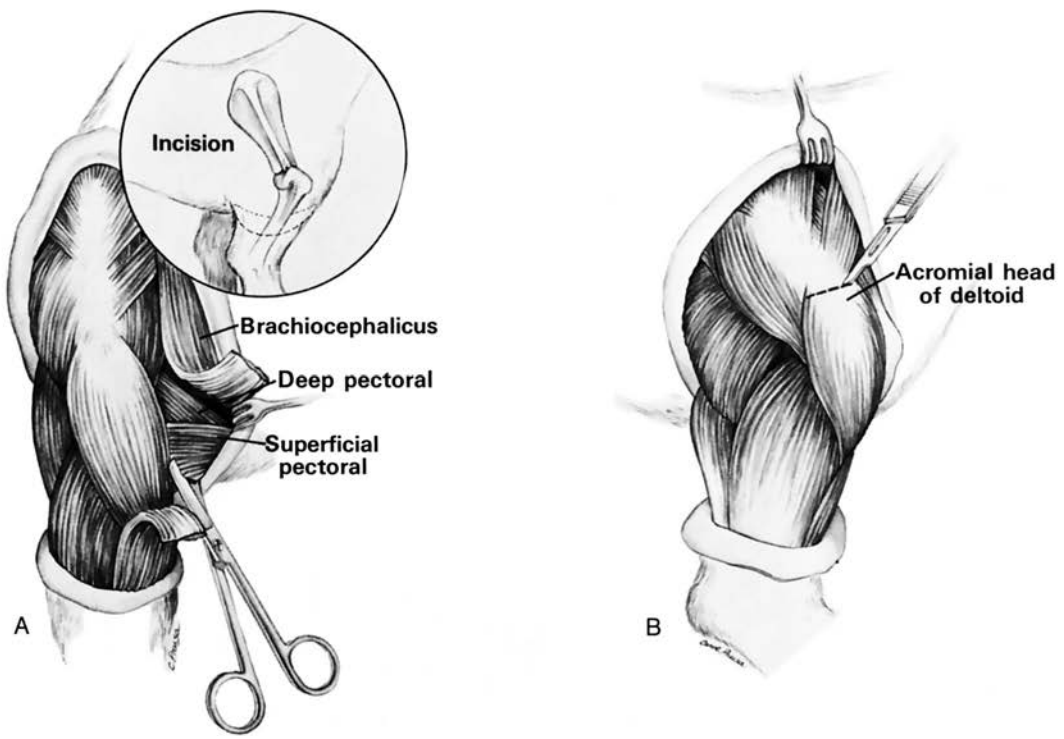

Figure 59-2. A. The inset demonstrates the location of the incision for the scapulohumeral disarticulation technique of forelimb amputation. The brachiocephalicus muscle is transected, and then the insertions of the superficial and deep pectoral muscles are exposed and divided. Retraction of these muscles exposes the brachial plexus. **B.** The acromial head of the deltoideus muscle is severed at its origin on the scapula.

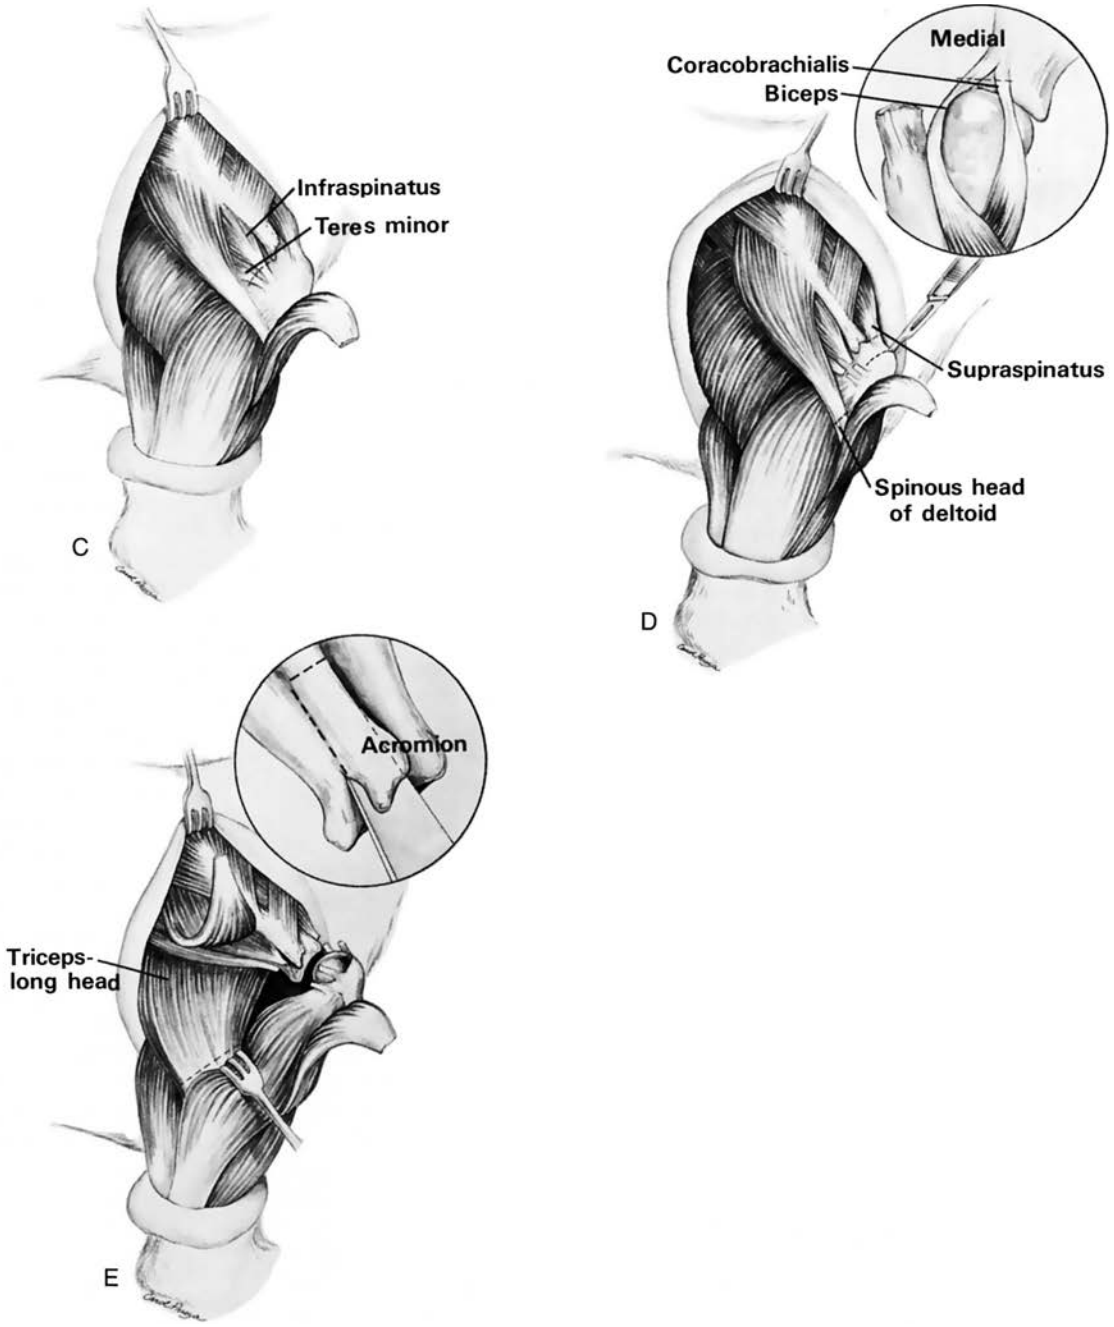

Figure 59-2. (continued). C. Retraction of the acromial head of the deltoideus muscle exposes the tendons of insertion of the infraspinatus and teres minor muscles, which are severed. **D.** The supraspinatus muscle and the spinous head of the deltoideus muscle are severed at their insertions. The joint capsule is then opened and the humerus is totally dislocated after transaction of the tendons of the biceps brachii, subscapularis and coracobrachialis muscles (inset). **E.** After division of the latissimus dorsi muscle, the long head of the triceps brachii muscle is divided as distally as possible to complete the amputation. The prominent scapular sine is removed with an osteotome (inset) for a better cosmetic effect.

spine of the scapula. A better cosmetic effect is obtained if an osteotome is used to remove the scapular spine, or at least the prominent acromion (See Figure 59-2E, inset).

Closure of the wound involves suturing the superficial and deep pectoral muscles to the latissimus dorsi , teres major, infraspinatus, supraspinatus, and brachiocephalicus muscles. During closure of the subcutaneous muscles and skin, an attempt is made to preserve as much of the lateral skin flap as possible because this skin is thicker and has a denser hair coat that produces a more cosmetic final result. Post-operative bandaging for 2 to 3 days is desirable to prevent seroma formation. Post-operative pain management is identical to that described for forequarter amputation.

Chapter 60

Sacroiliac Joint, Pelvis and Hip Joint

Repair of Sacroiliac Dislocation

Charles E. DeCamp

Introduction

Traumatic luxation of the sacroiliac joint results in displacement and laxity of the joint, variable pain, and is almost always seen with other major fractures of the pelvis and hind limbs, disabling both sides. Displacement of the ilial wing is usually cranial and dorsal, and it is not uncommon for the pelvis distal to the sacroiliac joint to be displaced medially to compromise the pelvic canal. Avoidance of severe and chronic pain, and compromise to the pelvic canal are the main indications for surgical repair of the sacroiliac joint. Fixation of the sacroiliac joint allows early weight bearing and reduction of pain, prevents complications from mal-alignment of the pelvis, and prevents potential compromise of other orthopedic repairs. The most commonly applied and effective fixation of the sacroiliac joint is deeply seated lag screws that compress and realign the joint (Figure 60-1A and B). Fixation promotes early weight bearing by reducing instability of the joint and its resultant pain.

General Considerations

There is little natural movement at the canine sacroiliac joint, but this joint does have typical anatomic structures including joint capsule, ligaments and a cartilage covered area described as the auricular surface.[1] The joint undergoes bony fusion in many dogs with age. Traumatic luxation of this joint is described with several other names including fracture-luxation and fracture-separation, all of which have identical meaning. However, sacral fracture indicates that fracture of the sacral bone is present, generally located at the site of the sacral wing. Sacral fractures are more likely to be associated with neurologic injury and have different and more complex surgical considerations. They will not be specifically discussed in this chapter.

Presentation and physical examination of a dog with sacroiliac luxation reveals the dog to be non-weight bearing on the affected side, and commonly unable to stand on either rear limb because of associated traumatic injury. The instability at the sacroiliac joint may be detected with careful digital pressure, however, local pain and swelling prevent effective palpation of this joint. Radiographic evaluation is essential to diagnose sacroiliac luxation and also fully characterizes displacement of the joint and the extent of associated pelvic or long bone injuries. The diagnosis of sacroiliac luxation is best observed on a ventrodorsal radiographic view and is seen in subtle cases as a step between the caudal sacral wing and the ilium. Those dogs with severe displacement have more instability at the joint with more severe pain. Neurologic injury with signs referable to injury of the lumbosacral trunk or to the innervation to the urinary bladder are observed infrequently, especially with severe displacement or bilateral injuries. Fortunately, neurologic injury associated with discrete sacroiliac luxation is most commonly (but not always) reversible within several weeks of the injury.

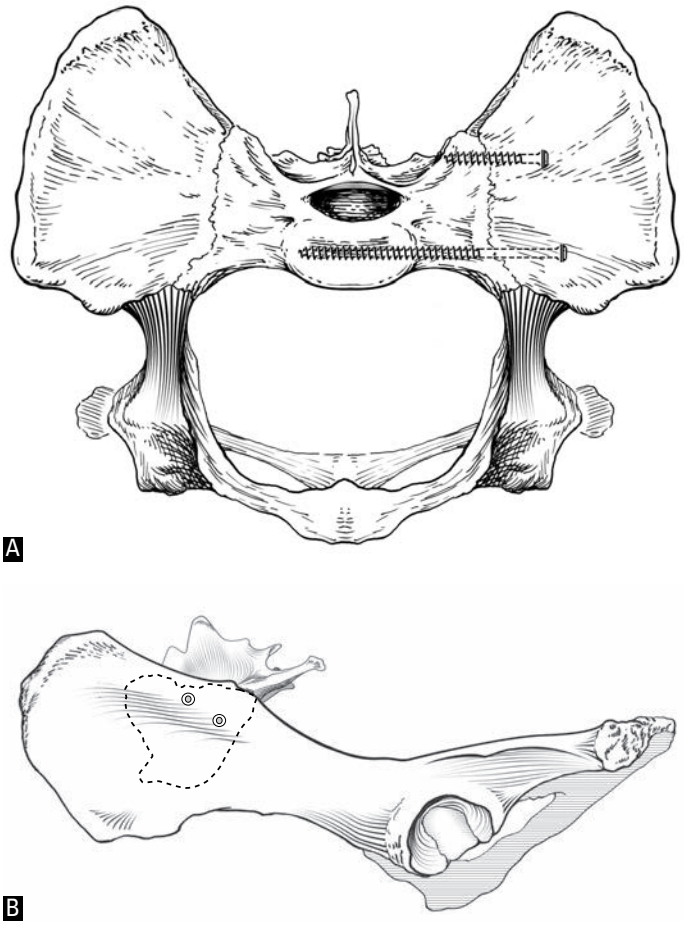

Figure 60-1. A. and **B.** Cranial and lateral views illustrate placement of one long lag screw in the sacral body and a shorter second screw placed dorsal and cranial to the first screw into the sacral wing, stopping short of the spinal canal.

Surgical Indications

Surgical stabilization of the sacroiliac joint is selected for those cases with severe pain or displacement where lack of repair may compromise the pelvic canal, the alignment of the coxofemoral joint, or the stability of other orthopedic fixations of the pelvis or long bones. Displacement of sacroiliac luxation, especially

the medial direction that could compromise the diameter of the pelvic canal, may progress in the first days post-trauma. If case selection for non-surgical care is based upon minimal displacement observed radiographically on the day of injury, additional radiographs should be taken 4 to 6 days later to ensure that the hemi-pelvis has not displaced medially to obstruct the pelvic canal.

Surgical Anatomy and Approaches

An approach to the sacroiliac joint through a dorsal incision allows access and direct visual identification of the anatomy of the sacral wing (Figure 60-2) for precise placement of lag screw fixtion for the routine sacroiliac injury.[2] A different approach is also described to the ventral aspect of the sacrum; however, it does not allow direct visualization of the sacral wing. The ventral surgical approach is useful in the uncommon circumstance when an ipsilateral ilial fracture must be repaired with a sacroiliac injury.[3]

The dorsal approach to the sacroiliac joint is completed with the dog in lateral recumbency, through an incision over the dorsal iliac spine that curves down along the cranial aspect of the ilial wing. After incisions through deep gluteal fascia and fat, the dorsal iliac spine is evident. A sharp incision is made in the dorsal periosteal attachment of the middle gluteal muscle and this muscle is elevated fully from the lateral aspect of the iliac wing. The sacrospinalis muscle is similarly elevated from the medial side of the ilium; however, this muscle and the dorsal sacroiliac ligament have often been disrupted by the trauma. Manipulation of the iliac wing with a bone forceps in a ventral direction and removal of fibrinous debris allows a direct view of the oblique surfaces of the sacral wing (Figure 60-3A). The curved cartilage-covered surface seen on the ventral aspect of the sacral wing is the auricular surface.[4] The surgeon can also identify the dorsal and cranial aspects of the sacral wing by palpation through a layer of fascia. The locations of the spinal canal, the sacral nerve roots, and the sacral body can be deduced in relation to these two structures. The ideal location for the lag screw deeply seated into the sacral body is ventral to the spinal canal, caudal to the lumbosacral intervertebral disc, and cranial to the sacral nerve roots.

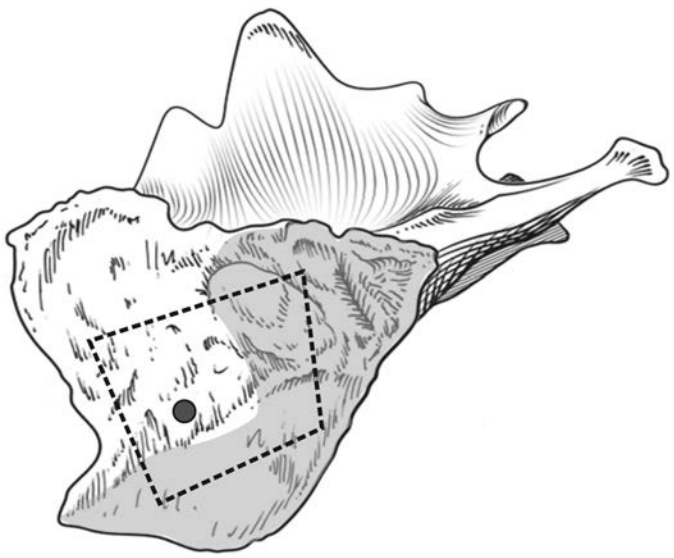

Figure 60-2. Sacral wing anatomy relevant to application of fixation includes area of sacral body (box) and auricular surface (grey area). The black dot indicates site of drill placement for the first, long sacral body screw.

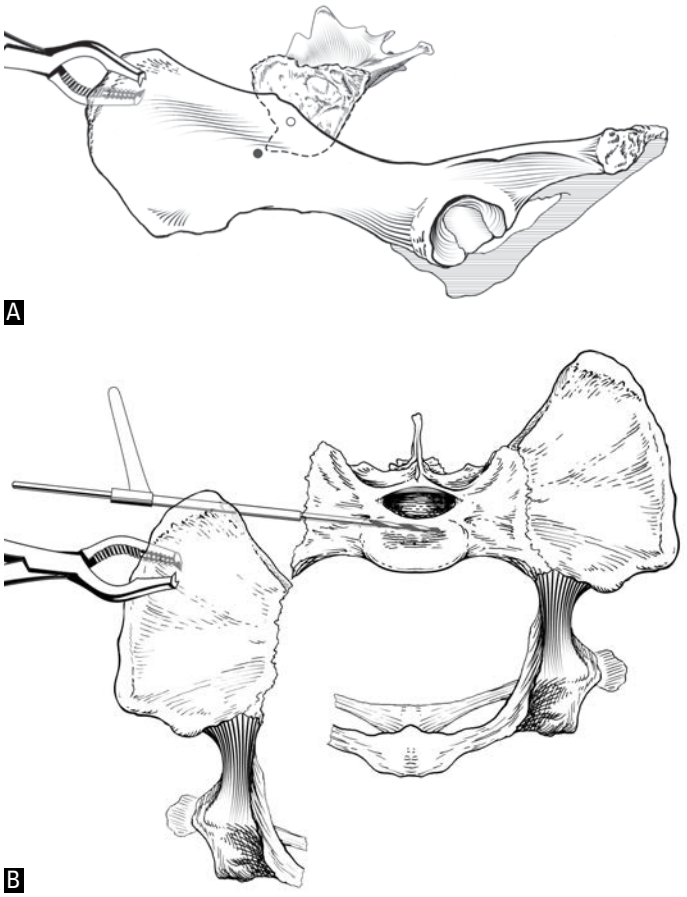

Figure 60-3. **A.** A bone forceps may be used to pull the ilial wing in a ventral direction to identify sacral wing anatomy for precise drill placement. Dots indicate sites of drill holes for the ilium and sacral wing. **B.** A cranial view of the pelvis and sacrum illustrating drill hole placement for the first lag screw, ventral to the spinal canal and beyond midline.

Lag Screw Fixation for Sacroiliac Luxation

One lag screw will be placed through a glide hole in the ilial wing and seated deeply, ventral to the spinal canal into the sacral body. The sacral body generally has space to allow for placement of only one screw, except perhaps in giant breed dogs. A shorter screw is placed through the ilial wing into the dorsocranial aspect of the sacral wing, stopping short of the spinal canal. The screw size selected will depend upon the size of the animal. A screw size of 2.0 to 2.7 mm is selected for cats and small dogs, 3.5 to 4.0 mm cortex or cancellous bone screws are employed in dogs up to approximately 20 kg, while 4.5 mm cortex or 6.5 mm cancellous bone screws can be used in larger dogs. The surgeon must be acutely aware of sacral anatomy to avoid placement of the sacral body screw into the intervertebral space or the spinal canal. Another common mistake is for the screw to exit the sacral body prematurely on its ventral surface resulting in a lag screw with insufficient strength of fixation.

To accomplish accurate screw placement, the surgeon must first identify the sacral wing and the auricular surface. The cranial edge of the sacral wing is established by projecting a line between the craniodorsal aspect of the sacral wing and the ventral aspect of the auricular surface.[4] The screw hole for the sacral body screw is drilled just caudal to this line, approximately 40% from the ventral limit of the sacral wing, taking care to keep the drill hole perpendicular to the lateral surface of the dog. The site for this hole is often centered in the lesser curvature of the auricular surface (See Figure 60-2). If positioned properly, this hole is drilled beneath the spinal canal to a depth of at least 60% of the width of the sacrum (Fig. Figure 60-3B). To achieve this depth, the hole must be drilled in a perfect lateral to medial direction, with the dog perfectly positioned in lateral recumbency. The sacral wing surface is mildly sloped, so that the "safe corridor" drill hole angle, with respect to the sacral wing surface, has been characterized to be 97 + 4°.[5] If the drill exits the sacrum ventrally, the depth must be measured and if insufficient, the angle of the drill must be corrected. When proper depth is achieved, the hole is measured and partially tapped. The glide hole is next drilled through the ilial wing. The site for this glide hole is identified by digital palpation of the roughened surface of the sacroiliac joint on the medial side of the ilial wing, caudal to a bony prominence at this site. The sacral body screw is then placed through the glide hole, and with reduction of the luxation using bone forceps on the ilial wing, the screw is directed by sight into the hole in the sacral body. The screw is tightened to compress the joint and the reduction achieved may be checked by palpation dorsally.

A second screw is placed immediately dorsal and cranial to the first screw, which will locate the screw into the dorsocranial aspect of the sacral wing. This second screw must be shorter to avoid penetration into the spinal canal (Figure 60-4). Closure includes simple interrupted sutures into the layers of the middle gluteal and sacrospinalis fascia, deep lumbar fascia and fat, subcutis, and skin.

Bilateral sacroiliac fracture-luxation is less common than unilateral injury, constituting approximately 23% of sacroiliac injuries.[6] Surgical repair may be completed bilaterally by using the technique described. Although there will be limited space within the sacral body to receive one long screw from either side, screw placement is generally successful. Alternative surgical methods have been described for bilateral sacroiliac repair. One method involves placing the dog in ventral recumbency and approaching both sacroiliac joints simultaneously. A large aiming device is then used to drill a screw hole completely across the sacrum, through the sacral body and both ilial wings.[7] One long screw is placed, compressing the sacroiliac joint on one side and providing a positional screw effect on the other. Another procedure uses a transilial pin, independent of the sacrum to stabilize the sacroiliac joints.[8] This procedure provides less stable fixation, but may be used if lag screw fixation is for any reason unsuccessful.

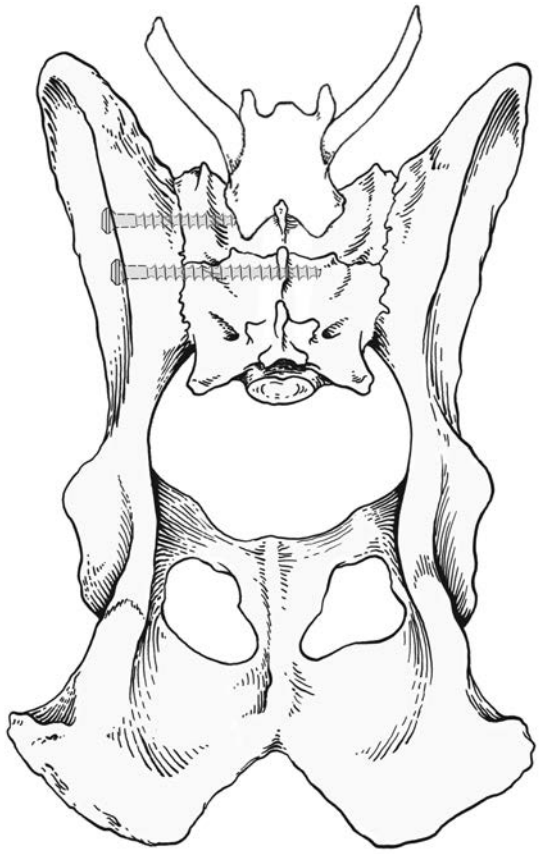

Figure 60-4. Dorsal view of the pelvis and sacrum that illustrates placement of sacral screws.

Minimally Invasive Technique

A technique for closed reduction and percutaneous insertion of lag screw fixation for sacroiliac luxation has been described.[9] Reduction of the hemipelvis is achieved by percutaneous intramedullary pin or bone forceps application to the ischium. Intraoperative fluoroscopic imaging of sacral anatomy is completed using c-arm and radiolucent table top technique. Reduction is achieved and a temporary pin is placed to maintain reduction of the joint. Lag screw fixation, with placement within the sacral body, is then applied using c-arm guidance through several stab incisions.[9]

Prognosis and Results

The clinical results in dogs undergoing sacroiliac repair are generally excellent. Weight bearing begins within several days, often depending upon the severity of associated fractures and other injuries. Slow improvement in lameness and musculoskeletal function can be expected over several months. Exercise restriction is maintained until healing of all fractures is evident clinically and radiographically. A retrospective study reported a rate of loosened sacroiliac fixation of 38%, with frequent shallow screw placement into the sacral body.[6] This same study reported that those fixations with deep screw placement into the sacral body did not loosen. An in vitro biomechanical study of sacroiliac screw fixation reported that two screws placed for sacroiliac fixation were always stronger than one screw and that fixation strength was optimized by use of the largest screws possible.[10]

It is evident that precise and aggressive screw placement in sacroiliac repair improves with clinical experience and provides the best clinical result.

Trans-ilial/Trans-sacral Pinning of Sacral Fractures

Randall B. Fitch

Introduction

Trans-ilial pin fixation is a useful technique for stabilizing fractures and luxations involving the sacrum. Trans-ilial pins can be used as primary fixation or in combination with other implants (sacro-iliac pin or lag screw fixation) to provide reliable stability with minimal additional morbidity. Implantation is technically simple and implant placement can be verified visually and palpably in surgery. The trans-ilial pin engages the thick dorsal iliac spine providing multiple points of fixation intended to maintain rigid pelvic alignment. Standard 5/64 to 1/8 inch Steinmann pins are sufficiently strong for most patients and suitably malleable for ease of application. The implants are solidly attached to the ilia through their own ilial penetration with additional stability provided by polymethylmethacrylate composite fixation to screws placed within the ilia. This fixation is intended to disperse force through multiple attachment sites in the thick dorsal iliac spine of the ilium. The composite repair provides a forgiving and adaptable construct which is less technique sensitive so that ideal apposition or implant position are not necessarily required for construct rigidity and clinical success. The technique is highly adaptable for odd injuries including severe sacral fractures, bilateral injuries and very small patients.

The sacrum has very unique anatomy due to its dual functional roles as a weight-bearing support and as a neurologic conduit. The sacroiliac joint is both a synovial joint and a fibrocartilaginous synchondrosis. Its distinctive anatomy results in a wide variety of injuries many of which do not necessitate surgical intervention. The majority of sacroiliac trauma requiring surgical stabilization occurs in patients with bilateral injuries. Frequently the contralateral injury is not sacral damage, but other orthopedic trauma such as a contralateral pelvic fracture. Therefore common indications for sacroiliac stabilization include providing weight-bearing function, reducing pain and protecting other orthopedic fixations. However, fixation must be provided while respecting the sacrum's neurologic role. The unique structural architecture of the sacrum combines cancellous bone intertwined with nerve roots providing an extraordinary repair challenge. Due to the variety of sacral injuries that occur, the following chapter is subdivided into sections by injury type to provide coherent specific suggestions for different injuries.

Surgical Preparation

Surgical preparation for the majority of sacral injuries consists of placing the patient in ventral recumbency with the legs placed under the patient in a near normal sitting position with the stifles flexed under the body, but the tarsus extended for better stability. Towels, sand bags or positioning bags are placed to ensure symmetry and security of the patient. The patient is prepped from 10 cm cranial to the ilial wings caudally to the tail (which is commonly placed in a temporary wrap). The surgical preparation extends laterally and ventrally to below the greater trochanters of the femur. For patients requiring multiple orthopedic repairs, the sacral trauma is typically addressed first since the sacral repair is more position sensitive. The patient can then be repositioned as required for the additional repairs. Pelvic symmetry and implant position can be more easily assessed with the patient symmetrically positioned in ventral recumbency.

A key to facilitating exposure and pin placement is performing curvilinear incisions on each side of the ilia to facilitate exposure and pin placement. The incisions should start at the cranial ventral iliac spine extending vertically in a dorsal direction and curving caudally to follow the dorsal margin of the ilial shaft to a few centimeters cranial the acetabulum (Figure 60-5). This incisional technique provides good visibility of the sacral articular surface with minimal skin interference during implant placement. The dorsal medial skin edges of both incisions can be sutured to each other thus everting the skin to increase exposure. A more limited surgical approach can be used for single ilial pin placement (commonly performed on the contralateral side). Strong gluteal fascia overlies the iliac spine at the origin of the middle gluteal muscle. Sharply incising over the lateral aspect of the iliac spine and reflecting the middle gluteal muscle caudally provides good visibility and retains the integrity of the tissue for surgical closure. When trans-sacral implants are utilized, the incision is expanded and muscle elevation will include the origin of the

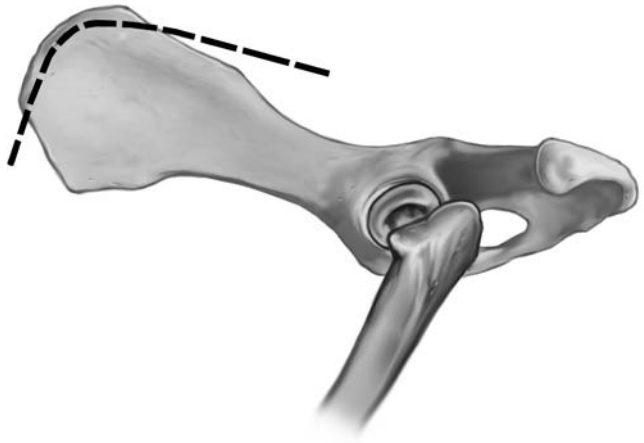

Figure 60-5. (surgical approach) A curvilinear incision is made over the ilium starting at the cranial ventral iliac spine and advancing in a dorsal direction and curving caudally to follow the dorsal margin of the ilial shaft. This incision provides good visibility of the sacral articular surface with minimal skin interference during implant placement. A more limited approach is used for simple ilial pin placement.

deep gluteal muscle. Surgical closure includes reestablishing the gluteal fascia attachment which provides good mechanical strength, minimizes suture interference with functional muscle, and provides coverage of implants. The epaxial fascia and dorsal sacroiliac ligaments when disrupted are closed in a similar manner. The subcutaneous tissue and skin are closed in a traditional matter.

Cement Tips

The following surgical techniques utilize composite fixation in which a small quantity of polymethylmethacrylate (PMMA) bone cement is used to bond the metal implants forming a rigid brace that is firmly attached to the ilia. Care must be taken to ensure aseptic technique when using bone cement, since skin contamination could result in infection and colonization of the PMMA which is difficult to treat; for this reason prophylactic peri-operative antibiotics are commonly administered. A stockinette or towel can be sutured into the incisional edge to improve visibility and minimize skin exposure. Frequent lavage with sterile saline is encouraged. A 20 g packet of PMMA is sufficient for both sides. Setting of the PMMA following addition of the polymer powder to the liquid monomer takes approximately 8 to 15 minutes. The PMMA is typically mixed for 1 to 2 minutes prior to application and applied in a viscous liquid stage. Application of the cement with a syringe provides better control with less spillage. Screws are inserted into the lateral ilium with 3 to 4 mm of the screw head exposed above the bone surface to allow bonding to the PMMA. A flat instrument (such as a periosteal elevator) is used to form and mold the PMMA around the implants, but only a small quantity is required. A commercially available trans-ilial rod with nuts is also available which avoids the use of PMMA and the necessity for a contralateral surgical approach (IMEX Veterinary, Inc.).

Axial Sacral Fractures

The sacrum consists of an osseous spinal canal and multiple foramina which protect the cauda equina and associated ventral and dorsal spinal nerves (Figure 60-6). When the structural integrity of the sacrum is compromised, placing an implant such as a lag screw across the fracture risks inadvertent nerve root damage. Fixation across a sacral fracture may induce nerve trauma directly, by displacement or compression. Forty-three percent of patients undergoing sacral fracture fixation with traditional techniques had neurologic deficits following surgery that were not noted prior to surgery (Kuntz 1995). Trans-ilial pin fixation relies on stabilization anchored at multiple points between contralateral ilia without necessitating placing implants through or compression across the sacrum.

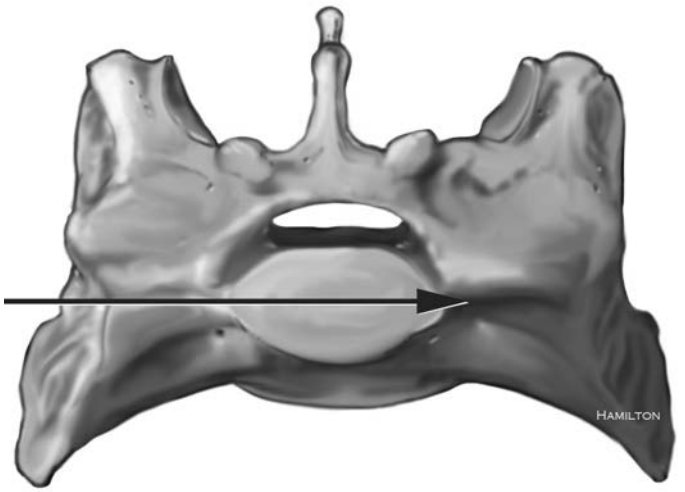

Figure 60-6. The sacrum contains nerve roots that contribute to the pelvic, pudendal and perineal nerves as well as components of the sciatic nerve. Disruption of these osseous canals can produce neurologic dysfunction either through the initial injury or additional surgical trauma. The particular architecture of the sacrum provides only small corridors for substantial bone engagement used for surgical fixation.

Surgical Technique

Following surgical approach and alignment of the pelvis, two pins are placed transversely through both ilia dorsal to the sacrum (Figure 60-7). One pin is placed directly behind the lumbosacral diarthrodial joint resting on the dorsal surface of the sacrum and engaging both ilia at the caudal iliac spine. The second pin is placed transversely, cranially and parallel to the first pin engaging both ilia in the cranial dorsal iliac spine (approximately 2.5 cm cranial to the first pin in a 35 Kg dog). The fixation and pin penetration can be visualized to ensure adequate ilial bone pentration through the thick dorsal caudal iliac spine. The pin is typically driven with a power drill. A blunt instrument can be used to direct the penetration of the contralateral ilium which commonly requires ventral deflection of the pin for maximal bone engagement. Fracture alignment can be additionally adjusted during the placement of pins. Compression at the cranial pin location will displace the caudal pelvic alignment laterally correcting medial displacement which is common in these injuries. The pins are bent at a 90° angle against the lateral surface of the ilium and cut to a length so when rotated they

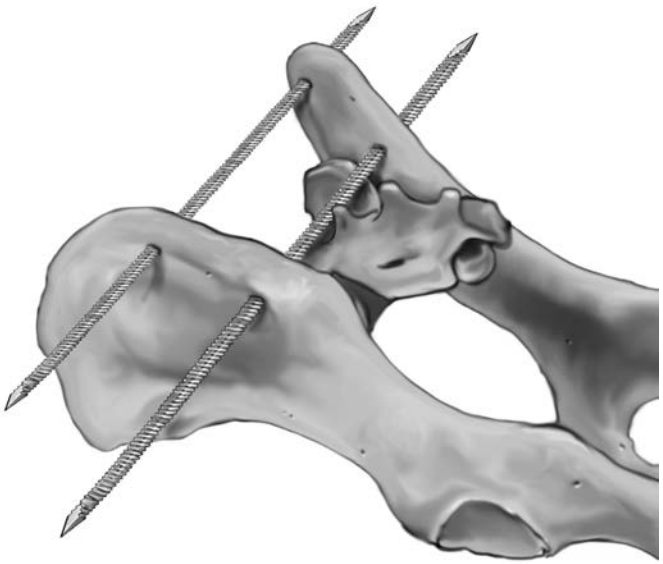

Figure 60-7. Trans-ilial brace: Two trans-ilial pins placed transversely through both ilia dorsal to the sacrum. One pin is placed directly behind the lumbosacral diarthrodial joint contacting the dorsal surface of the sacrum and penetrating both ilia at the caudal iliac spine. The second pin (arrow) transversely and parallel to the first engaging both ilia, but cranial to the first in the cranial dorsal iliac spine.

will overlap (approximately 2 cm). Two screws are applied to the lateral surface of the ilia and polymethylmethacrylate is applied and molded to the pin and screw construct on each side. The ilium is subjected to torsional and fulcrum forces transferred through the acetabulum during weight-bearing. The two trans-ilial pins are intended to provide a rigid brace with multiple points of fixation which counteract weight-bearing forces. Minimal pelvic displacement and good early weight-bearing were observed in dogs with sacral injuries, including comminuted sacral fractures, using this fixation. Anatomic reduction is not required for rigid fixation, thus intentional malalignment can be maintained when desired (i.e. prevention of further nerve root manipulation and possible entrapment).

Unilateral Abaxial Sacral Fractures and Sacroiliac Luxations

Abaxial sacral injuries occur lateral to the sacral foramina and include fractures of the wing of the sacrum and separation of the sacroiliac joint. Placement of implants through the sacral body or dorsal to the spinal canal through the ilia will provide mechanical support that is unlikely to cause additional neurologic injury. Traditional lag screw fixation through the ilium and into the sacral body with greater than 60% depth of penetration across the sacrum provides reasonable stability with 88% success achieved with ideal implant placement (DeCamp 1985) using open reduction or 100% success with fluoroscopic guidance in closed fixations (Tomlinson 1999). However, sacroiliac luxations often occur with fractures that obscure traditional landmarks making identification of the sacral body more challenging without the aid of fluoroscopy. In one study only 33% of lag screws were placed in the sacral body. Trans-ilial pin fixation can be used to reinforce stability of traditional lag screw repairs especially in polytrauma cases in which early increased stress across the repair is anticipated or in which lag screw fixation may be problematic. Single trans-ilial pin fixation has also been used as a less invasive alternative in juvenile patients with painful, less severe sacroiliac luxations.

Surgical Technique

In this technique, sacroiliac lag screw fixation is placed by traditional surgical technique into the sacral body and reinforced with a trans-ilial pin. The sacroiliac joint is exposed through a dorsal approach. The lateral surface of the sacrum is exposed by ventrolateral retraction of the ilial wing. Careful placement of a blunt Hohmann retractor under the ventral surface of the sacrum provides excellent retraction of the ilial wing and provides exposure of the lateral sacral surface. Care should be used to ensure the tip of the Hohmann remains lateral and does not penetrate medially. The landmarks of the lateral surface of the sacrum should be visible. These include the crescent shaped articular surface, a fibrocartilaginous dorsal articular surface, and a ventral edge of the sacrum (Figure 60-8). A line is visualized from the craniodorsal point of the sacral wing to the ventral point of the wing. The point of drill bit entry is just caudal to the line at 60% of the distance from dorsal to ventral (slightly caudoventral to the halfway point). Difficult placement of the transsacram screw hole can occur due to many reasons including loss of visible landmarks (most commonly due to fracturing of the craniodorsal landmark) and incorrect orientation of the transsacral screw hole (most commonly due to tilting of the sacral that arises during retraction or loss of proper patient position). The sacral wing notch and articular surface can be used as additional landmarks to confirm an ideal drill entry point. The

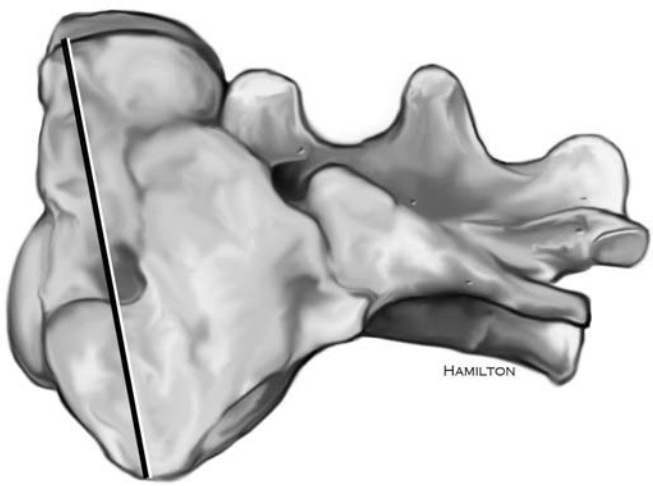

Figure 60-8. The lateral surface of the sacrum: The landmarks of the lateral surface includes the crescent shaped articular surface, a fibrocartilaginous dorsal articular surface, and the ventral edge of the sacrum. The ideal entry point for engagement of the sacral body can be identified by drawing a line from the from the craniodorsal point of the sacral wing to the ventral point of the wing. The point of drill bit entry is just caudal to this line at 60% of the distance from dorsal to ventral. The sacral wing notch and articular surface can be used as additional landmarks to confirm ideal drill entry point. The orientation of the drill must compensate for the offset of the sacral surface to achieve maximal bone engagement.

orientation of the sacral drill hole can be aided within surgery by observing the lateral surface of the sacrum. A small Steinman pin (5/64 in.) can be used in place of a drill bit. The additional pin length, as compared to a drill bit, serves for better assessment of pin orientation with less interference with regional structures and additionally, trans-ilial pin penetration helps assure proper pin placement. Remember that the pin direction is not perpendicular to the surface of the lateral sacral surface since the lateral surface of the sacrum is tilted caudodorsal approximately 15 degrees. Aligning the pin perpendicular to the lateral surface of the sacrum typically causes the pin to breach the ventral surface of the sacrum or to enter the lumbosacral disk space. Pin placement should be perpendicular to the axis of the dog, but retraction can alter the orientation of the sacrum. Thus, some relaxation of the retraction can correct disorientation especially if hard retraction is being utilized.

Following placement of the screw pilot hole into the sacrum, a guide hole is placed through the ilial wing at the level of the sacroilial articulation on the medial aspect of the displaced ilium. The articular surface on the medial side of the ilium is palpable and can be used to assist guide-hole placement. Remember the ilium is also oriented obliquely so the guide hole should be tilted approximately 15 degrees from the saggital axis of the ilial wing and enters more ventrally than expected (approximately 1/3 the distance from the ventral border). The guide-hole diameter needs to be greater than the outside thread diameter of the screw to provide lag compression. A washer can be used in combination with the screw to ensure good compression across the sacroiliac joint especially in younger dogs with softer bone. Depth of screw purchase is estimated from pre-operative radiographs and a screw length is chosen that crosses greater than 60% of sacral width including the thickness of the ilium. The screw is placed through the guide hole in the ilium and lined up with the pilot hole in the sacrum. The sacroiliac joint is reduced as the screw is driven into the sacral body. Reduction most commonly requires caudal retraction and occasional rotation of the ilium. Symmetry and reduction can be ensured by palpation of the contralateral ilial wing prior to final tightening of the screw which will compress the sacroiliac joint.

Difficult reductions can also be aided by temporarily replacing the screw with a pin. The pin (with chuck) is placed through the ilial guide hole into the sacral pilot hole and used as a lever to reduce and align the sacroiliac joint. The pin provides a mechanical lever (no screw and driver interface) and the smooth pin surface allows it to slide without resistance. The sacroiliac joint is temporarily stabilized with an additional sacroiliac pin which is later removed after the original pin is again replaced with a screw or converted to a trans-sacral pin brace (see next section).

When additional stability is desired, a trans-ilial pin can be added intra-operatively. This requires a limited contralateral dorsal surgical approach to expose the dorsolateral aspect of the ilial wing. A Steinmann pin is driven transversely through both ilia, over the dorsal surface of the sacrum just behind the lumbosacral articulation. The pin location can be verified visually and by digital palpation to ensure that the ilia are well engaged and the pin contacts the dorsal surface of the sacrum. The ends of the

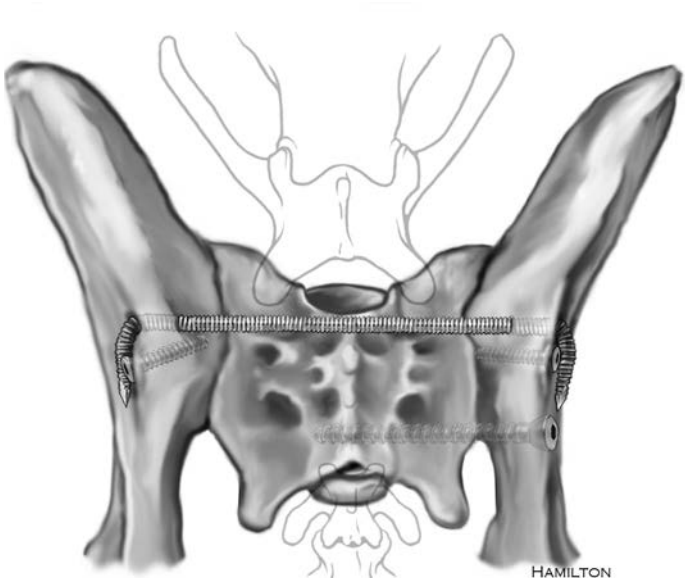

Figure 60-9. Trans-ilial pin fixation used in combination with traditional sacroiliac lag screw fixation. A sacroiliac screw is first placed through the ilium and into the sacral body using lag screw technique. When additional stability is desired a trans-ilial pin is driven transversely through both ilia, over the dorsal surface of the sacrum just behind the lumbosacral articulation. The ends of the pin are bent over and an additional screw is placed through the lateral surface of the ilia and polymethylmethacrylate (not shown) is applied incorporating the pins and neighboring screws. A limited dorsal approach to the contralateral ilial wing is required.

Steinmann pins are bent over at the level of the ilial surface. One or two additional screws are placed through the lateral surface of the ilia adjacent to the pin and polymethylmethacrylate is applied incorporating the pins and neighboring screws (Figure 60-9).

Bilateral Sacral Iliac Luxations and Fractures

Repair of bilateral abaxial sacral injuries can be challenging due to anatomic limits in ideal bone purchase. Placing two lag screws into the sacral body with greater than 60% purchase can be problematic due to interference of the two converging screws in a very small target. Single screw techniques theoretically have some advantages, but become problematic due to technical difficulty and availability of proper implants in many practices (proper screw length and nut availability). Trans-sacral pin placement is relatively simple. It avoids the use of a bone tap, decreasing the opportunity for damage to the cauda equina. The pin orientation within the sacral body can be verified intra-operatively by comparing the exit points of the pin in the lateral surfaces of the sacrum. The pin is easily replaced if ideal orientation is not achieved. Reduction of the sacroiliac joint does not require alignment of drill holes which can be fickle with screw placement. Trans-sacral pin placement is done following reduction of the sacroiliac joint by simply advancing the pin through the ilium. Complete reduction can be achieved during bending of the pin using a chuck, but a trans-ilial pin is placed to provide additional stability. This fixation engages multiple cortices providing good quality bone purchase and stability, thus decreasing the chance of the implant fracturing out of the sacrum which can occur with screws. The trans-sacral pin is relatively uncomplicated to place and a viable alternative

to placing bilateral lag screws in dogs with bilateral injuries, therefore simplifying the surgical technique and shortening operative time.

Surgical Technique

The lateral surfaces of the sacrum are exposed and visualized. The center of the sacral body is identified by visualizing a line from the craniodorsal point of the sacral wing to the ventral point of the wing (See Figure 60-8). The point of pin entry is just caudal to this line at 60% of the distance from dorsal to ventral (slightly caudoventral to the halfway point). The sacral wing notch or the crescent shaped articular cartilage can be used as additional landmarks which is especially helpful when landmarks are obscured due to trauma. The pin is advanced transversely across the sacrum and should exit at the same location on the opposite lateral surface of the sacrum (Figure 60-10). A "C" shaped drill guide is helpful in providing accurate drill orientation. Once proper trans-sacral pin placement is established, the pin is retracted on one side of the sacroiliac joint to allow unilateral sacroiliac reduction. Sacroiliac reduction is achieved and the trans-sacral pin is advanced through the ilium. The drill is replaced on the opposite end of the pin and the pin is retracted in the opposite direction to allow reduction of the contralateral sacroiliac joint. The pin is then advanced across this ilium just as before, but in the opposite direction.

Following trans-sacral pin placement, a trans-ilial pin is placed with the Steinmann pin driven transversely through both ilia, contacting the dorsal surface of the sacrum just caudal to the lumbosacral articulation (as previously described). The pin location can be verified visually and by digital palpation to ensure that the ilia are well engaged and the pin contacts the dorsal surface of the sacrum. The ends of the Steinmann pins are bent over at approximately 90 degrees and cut so that the pins can be rotated to overlap. One to two additional screws are placed into the lateral surface of the ilial wing adjacent to the overlapping pins. PMMA is applied to incorporate the pins and screws into a composite fixation.

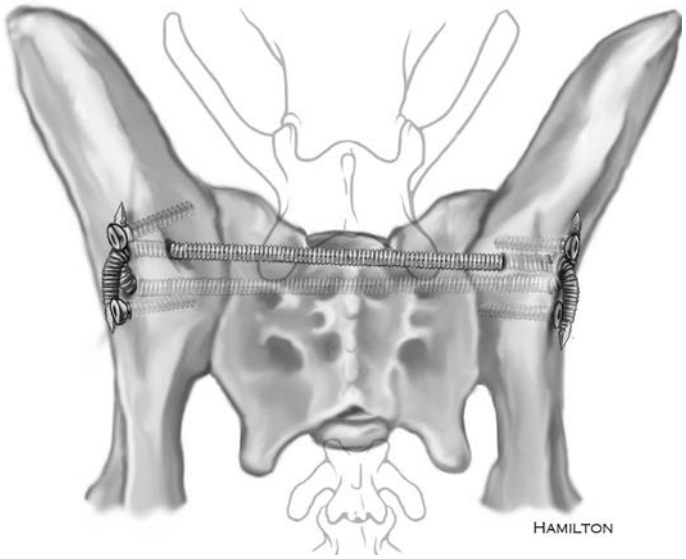

Figure 60-10. Combined trans-ilial and trans-sacral pin fixation can be used for bilateral sacral injuries. One pin is placed transversely through the sacrum and associated sacroiliac joint and ilia. A second pin is placed dorsal to the first pin transversely contacting the dorsal surface of the sacrum penetrating the thick ilial wing slightly caudal of the lumbosacral joint. The two pins are bent over ninety degrees, cut and rotated until they overlap. Screws are placed in the lateral surface of the ilium and polymethylmethacrylate (not shown) is applied to incorporate the implants into a component fixation.

Post-Operative Care

The trans-ilial pin provides a rigid fixation with low morbidity, so early weight-bearing is anticipated. Enforced restricted activity is recommended for six weeks. However, aggressive physical therapy has been performed for concurrent injuries in many patients. Pin migration, implant discomfort or infection has not been commonly associated with this technique and implant retrieval is seldom required.

Repair of Ilial Fractures

Charisse D. Davidson, Timothy M. Lenehan, and Guy B. Tarvin

Introduction

It has been reported that 20 to 30% of all fractures in small animals are pelvic fractures and of these 18 to 46% are ilial in the canine.[1,2] In dogs, pelvic fractures are commonly the result of vehicular trauma, while in cats, falls from a great height are the most common cause. Due to the nature of these injuries, it is essential that other organ systems be assessed and treated appropriately before repair of the orthopedic injuries is initiated. Pelvic fractures have been associated with abdominal trauma, (urinary tract

and abdominal organs), thoracic injury, and peripheral nervous system insult. In particular, cranial or craniomedial displacement of the iliac bone has been associated with damage to the L6 and L7 nerve roots and injury to the lumbosacral trunk.[3]

The lumbosacral trunk is composed of the ventral branches of the last two lumbar and first two sacral nerves and it runs caudally along the medial surface of the ilium. The ischiatic nerve begins when the second sacral nerve joins the lumbosacral trunk. Although the ischiatic nerve is located medial to the ilium it is less closely associated with bone and therefore less susceptible to direct injury (Figure 60-11). Ischiatic nerve injury is more often associated with acetabular fractures and secondary fibrosis associated with the healing of ischial fractures.[3] Cutaneous, sensory, and voluntary motor deficits associated with the L6, L7, S1 and S2 nerve roots are the most common peripheral nerve deficits associated with pelvic fractures. However depression of the sciatic reflex (cranial tibial reflex) and decreased sensation of the lateral digit of the affected limb may also be present.

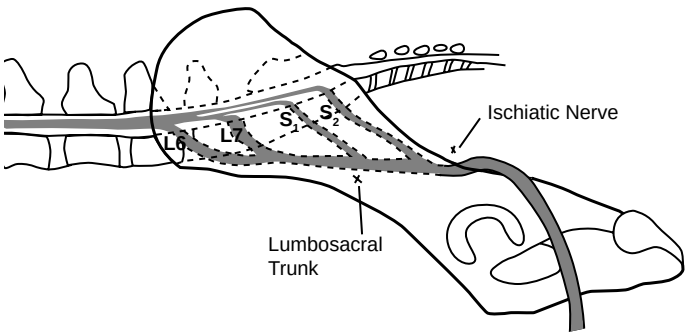

Figure 60-11. The lumbosacral trunk is composed of the ventral braches of the last two lumbar and first two sacral nerves and it runs along the medial surface of the ilium.

Classification of Ilial Fractures

Ilial fractures have been classified as either ilial body fractures with an interruption of the weight bearing arch or ilial wing fractures which are sustained cranial to the sacroiliac joint whereby the weight bearing arch is left intact.[4] Ilial wing fractures have been further classified as either cranial avulsion fractures (where the most cranial part of the ilial wing is separated from the ilial body at the insertion site of the sartorius and tensor fascia latae muscles) or central ilial wing fractures (where the separation occurs in the region on the middle gluteal muscle insertion). Ilial fractures can be further described as simple or multifragmentary, unilateral or bilateral. Very often they are associated with other pelvic fractures.

For most ilial fractures, a lateral approach allows optimal visualization of all portions of the ilium (Figure 60-12).[5] The patient is placed in lateral recumbency with the affected side up, and the limb is prepared for aseptic surgery. A skin incision is made starting cranially at the center of the iliac crest and continued caudally in a straight line to the greater trochanter. The subcutaneous fat and fascia are incised along the same line. The tensor fascia lata is reflected cranially to expose the middle gluteal muscle. Dissection is continued in a cranial direction between the tensor fascia lata and middle gluteal muscle to the wing of the ilium. Elevation and retraction of the middle and deep gluteal muscles exposes the wing and body of the ilium.

If exposure of the ventral ilium or sacroiliac joint is needed this can be accomplished by a ventral extension of the above approach.[6] The iliacus muscle is incised along its origin at the ventromedial border of the ilium. The iliacus muscle is elevated subperiosteally allowing exposure of the ventral ilium and/or digital palpation of the sacroiliac joint and lumbosacral trunk. The lateral approach to the ilium can also be extended caudally and combined with either a craniolateral, dorsal approach, or a caudal approach to the coxofemoral joint, allowing access to the acetabulum and ischium when indicated.

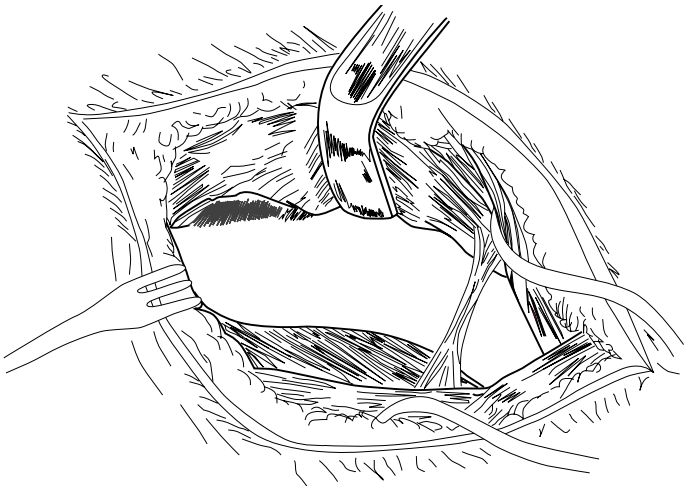

Figure 60-12. Lateral approach and exposure of the ilium.

Repair Options

Open reduction and internal fixation of ilial fractures is indicated when the weight bearing portion of the ilium is involved (ilial body fractures), when there is gross displacement of the fracture fragments, when the diameter of the pelvic canal is compromised, when the fracture impinges on the lumbosacral trunk, if there is gross pelvic instability(as is often the case with bilateral pelvic fractures) or when there are concurrent fractures of the ipsilateral acetabulum, ishium, and/or pubis. Precise reduction and rigid fixation will allow for early ambulation and healing. This in turn reduces complications associated with conservative management and prolonged recumbancy.

Plate fixation is the most common method of repair. Lag screw fixation has also been advocated and may also be useful to supplement plate fixation when needed. Pin/ wire fixation +/- polymethymethacrylate, external skeletal fixation, and mini-plate fixation are also possible but have been associated with increased morbidity and complication rates.[2,7]

Bone Plating

Stabilization of ilial fractures using a laterally placed bone plate is the most common repair technique used and the simplest to perform. The ilium is a wide, flat bone and lends itself readily to plating. The ilial fragments should be of sufficient length to allow at least two bone screws proximally and distally. Reduction can

be accomplished by grasping the fragment ends with Verbrugge or speedlock forceps and bringing the ends into proper alignment; however, further manipulation is often needed. One technique that can be used when the hip joint is intact but the ischium is broken, is to grasp the greater trochanter with Lewin forceps and then manipulate the distal ilial fragment into reduction (Figure 60-13). Alternatively, if the hemipelvis is intact, Kern bone-holding forceps or an intramedullary pin can be placed in the tuber ischium to allow manipulation of the distal segment. Once the fracture has been reduced, bone holding forceps are applied, or an assistant maintains reduction while the plate is contoured and applied.

In some cases, the aforementioned reduction techniques are insufficient because of muscle contracture. In these patients the plate may be contoured, using the radiograph of the intact opposite side as a guide when possible, and is applied only to the distal fragment. The fragment ends are brought as close to reduction as possible. A Verbrugge clamp then is used to complete reduction, and the plate is secured to the proximal segment (Figure 60-14 A, B and C).[8]

During drilling, measuring with a depth gauge, and tapping of the screw holes, care must be taken not to injure medial structures such as the rectum and lumbosacral trunk. Optimally, at least one screw in the proximal segment should engage the wing or body of the sacrum. Although this maneuver results in greater holding power, care should be taken, just as in the repair of sacroiliac dislocation, to avoid penetrating the spinal canal in that area. Traversing the sacroiliac joint with a screw may lead to degenerative sacroiliitis, however to date there are no significant reports of this phenomenon in the dog.

If needed, rigidity of the repair can be increased by the addition of a mini or cuttable plate or intrafragmentary screws to the ventral (tension-side) of the ilium (Figure 60-15). Ventral fixation can be applied prior to the lateral plating to maintain reduction during plating.[2,7] Steinmann pins placed through the contoured plate screw-holes can also be used to maintain reduction. Pin size should not be greater that the diameter of the drill bit for the screws to be used. As plating proceeds the pins are removed and replaced with screws.

Fractures of the ilium with concurrent sacroiliac luxations are best treated with plate fixation. The ventral aspect of the ilium is exposed as described previously. Blunt dissection, preferably with the finger, is directed along the medial face of the ilium until the articular surface of the sacral body and ilium are palpated (Figure 60-16 A and B). Once the sacroiliac luxation has been reduced, a small Kirschner wire can be inserted through the ilium and into the sacral body to maintain reduction. The plate is applied as previously described for ilial fractures. If possible, one of the plate screws is placed thru the sacroiliac joint in a lag fashion to afford compression of the ilium to the sacrum. If the fracture precludes this, the sacroiliac luxation is reduced with a lag screw and the iliac fracture is reduced and plated separately.

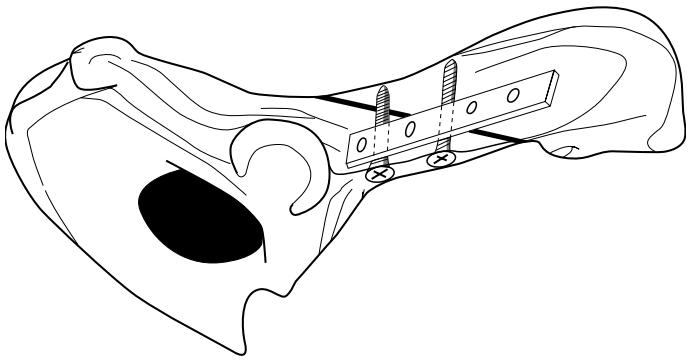

Figure 60-15. Rigidity of the repair can be increased by addition of interfragmentary screws to the ventral aspect of the ilium.

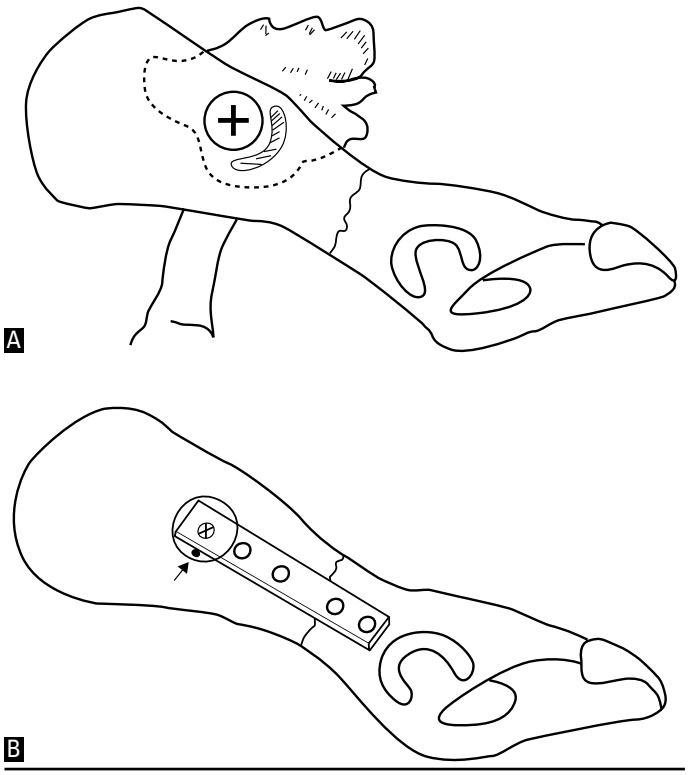

Figure 60-16. Repair of concurrent ilial fracture and sacroiliac luxation. **A.** The index finger is used to palpate the sacrum from the ventrolateral approach. This helps to reduce the sacroiliac luxation and in screw placement. **B.** After a small pin *(arrow)* is placed, the plate is applied to the ilium. The most rostral screw is placed through the ilium and into the sacrum.

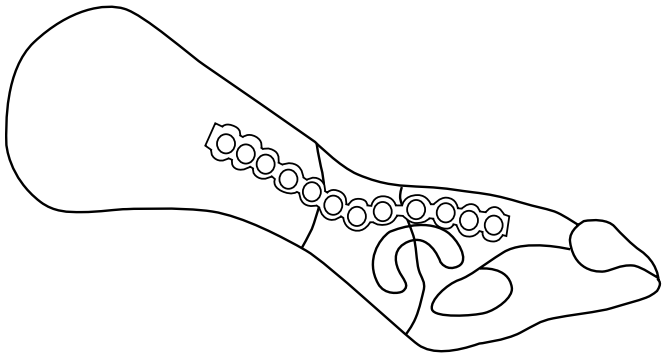

Figure 60-17. Fixation of segmental ilial fractures with an acetabular component can be achieved with a reconstruction plate contoured to match the dorsal aspect of the acetabulum.

Additional exposure via trochanteric osteotomy may be needed when repairing ilial fractures near the acetabulum or segmental ilial fractures with an acetabular component. Fixation of these fractures is achieved with a bone plate or a reconstruction plate contoured to match the dorsal aspect of the acetabulum (Figure 60-17).

Alternatives to Plating

When plating equipment is unavailable, some fractures of the ilium are amenable to lag screw fixation or pinning. Long oblique fractures of the ilial body can be effectively stabilized with two lag screws. The ventral aspect of the ilium is exposed

as described previously and the iliacus muscle is retracted medially. Screws are inserted in a ventral to dorsal direction across the fracture line resulting in compression. When applied properly to the appropriate fracture, lag screw fixation may be mechanically equivalent to plate fixation.[7]

Although mechanically inferior, pinning can be successful in fractures involving the proximal or midbody area of the ilium in small dogs and cats. Fractures distal to the midbody of the ilium do not often permit sufficient length of the insertion of the pins to provide adequate stability.

Insertion of each pin is started in the proximal fragment near the cranial dorsomedial aspect of the wing of the ilium. The pin is driven down the shaft of the ilium and into the distal segment (Figure 60-18. A and B). A pin of identical length is used to check the distance traversed. The hip joint should also be palpated to determine whether the implant has entered the joint. If so, the pin is retracted until no palpable evidence of joint invasion is noted. At least two pins should be driven in a similar manner to improve rotational stability. Ilial pinning is technically difficult because the medullary cavity of the ilium is narrow, and the cortex is often penetrated during pin insertion.

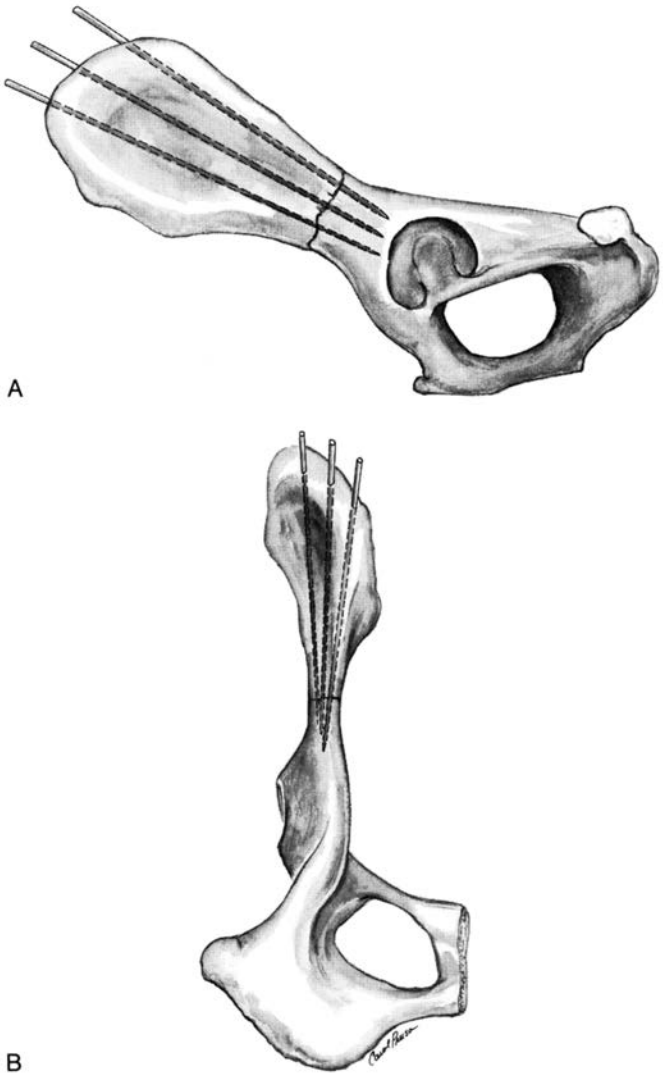

Figure 60-18. A and **B.** Placement of pins for repair of ilial fractures.

Hemicerclage wiring also can be used in smaller dogs and cats to aid in stability in fractures of the ilial midbody.

Postoperative Care

Postoperative radiographs (ventrodorsal, lateral, and oblique hemipelvic) are indicated to evaluate the implants and reduction. Appropriate steps should be taken if errors in reduction have occurred. If adequate fixation is accomplished, no special aftercare is required. Appropriate bedding and nursing care, along with confinement for 4 to 8 weeks, are advised. Physical and radiographic assessment at 4 and 8 weeks post-operatively are recommended to evaluate implant stability and fracture healing. Surgical procedures can be staged approximately 1 to 2 days apart if the animal's condition disallows simultaneous fixation of both sides.

Surgical Repair of Acetabular Fractures

Marvin L. Olmstead

Introduction

One of the principles of joint fracture repair is that the weight bearing articular surface must be reconstructed so that it is as anatomically correct as possible. This reduces the injured joint's risk of developing osteoarthritis. The acetabulum is one half of the coxo-femoral joint and its cranial 2/3's are generally considered its primary weight bearing area. Optimal surgical repair should restore normal joint mechanics and gliding motion.

Surgical treatment of acetabular fractures involves four steps: exposure of the fracture site, reduction of the fracture, fracture stabilization and closure. Several different approaches and

surgical techniques have proven effective to successfully complete these steps.

Surgical Technique

Acetabular fractures are approached either by a trochanteric osteotomy or the caudal approach. In most cases the author prefers the caudal approach. The caudal approach provides exposure of the acetabulum equal to a trochanteric osteotomy, does not require creation of a femoral fracture and is more quickly closed than a trochanteric osteotomy.

With both approaches, the superficial gluteal muscle is first isolated, incised at its insertion and reflected dorsally. If the surgeon is performing an osteotomy of the greater trochanter, it is started at the level of the third trochanter and extended dorsally to the junction of the greater trochanter and the femoral neck. The middle and deep gluteal muscles are reflected dorsally with the greater trochanter. The caudal portion of the deep gluteal and the gemellus muscles are elevated with a periosteal elevator from their origin over the dorsal rim of the acetabulum. This exposes the fracture site. The sciatic nerve is identified and protected. Following repair of the fracture, the greater trochanter is reattached to the proximal femur with the tension band technique (Figure 60-19). The remaining layers are closed routinely.

In the caudal approach, after the superficial gluteal muscle is incised and retracted dorsally, the external and internal obturator muscles and gemelli muscle, are incised at their insertion in the trochanteric fossa, tagged and retracted caudo-dorsally. Elevation of these muscles exposes the caudal acetabulum. The muscles can be used to protect the sciatic nerve. The caudal portion of the deep gluteal and gemellus muscles are elevated exposing the dorsal aspect of the acetabular rim. The caudal ilium is exposed by inserting a Hohmann retractor under the middle and the deep gluteal muscles and hooking its tip just cranial to the acetabulum on the ventral border of the ilium. Pushing the retractor's handle ventrally displaces the middle and deep gluteal muscles distally. Maintaining the hip in an extended and internally rotated position provides maximal exposure to the acetabular rim (Figure 60-20). After the fracture is stabilized with a fixation device, the external and internal obturator and gemelli muscles are sutured to fascial tissue over the lateral surface of the trochanter near their original insertion point. The remaining tissues are closed routinely.

The acetabulum must be anatomically reduced if a successful outcome is to be achieved. The caudal bone segment is often displaced cranially and medially. The fragment can be moved to a caudal position by one of two methods. An intramedullary pin is driven ventral to dorsal through the ischium just cranial to the ischial rim while the hip joint is flexed. The pin should penetrate the skin dorsal and ventral to the ischium. Pin chucks are attached to the exposed ends the pin and used as handles to pull the fracture segment caudally (Figure 60-21). Limited rotation of the segment is provided with this method. Another method for providing caudal traction uses a large Kern bone holding clamp. An incision wide

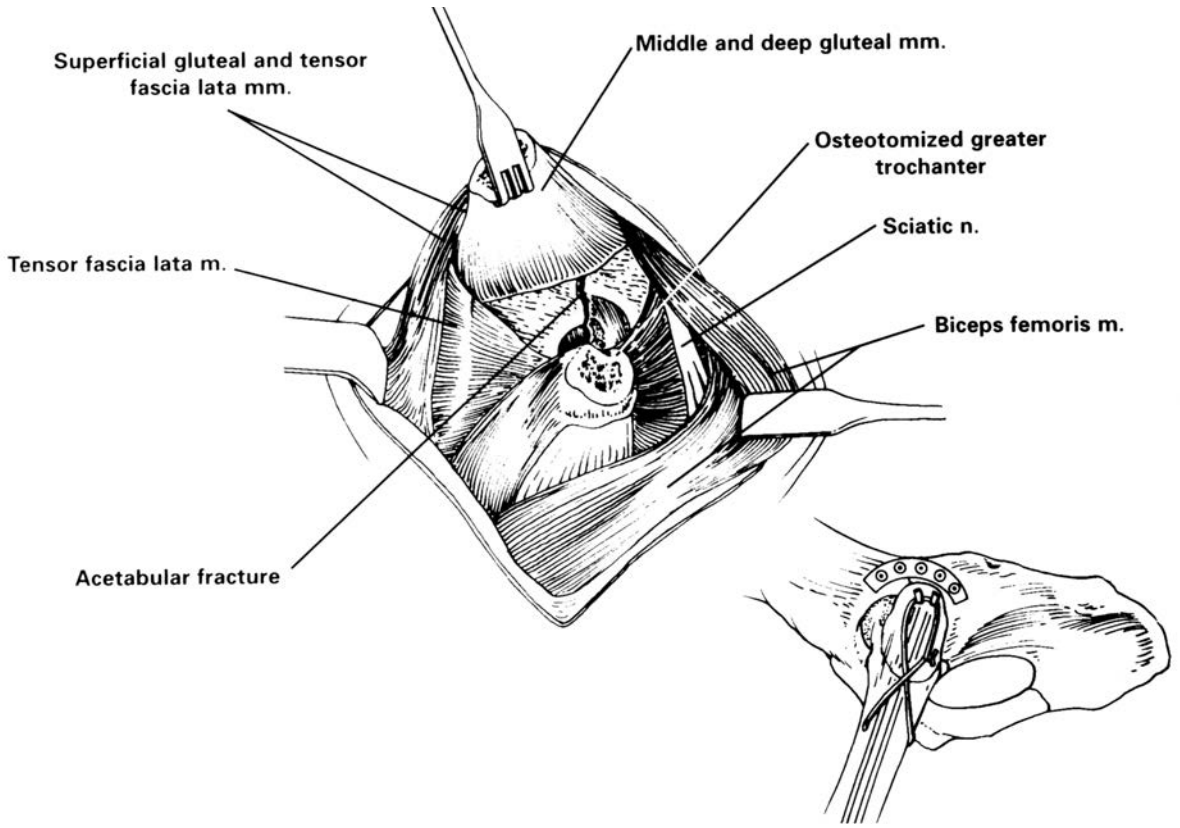

Figure 60-19. The trochanteric osteotomy approach is used to expose fractures of the acetabulum. The sciatic nerve is isolated before the osteotomy is preformed. Two pins and a tension band wire reattach the trochanter following fracture repair. (Olmstead, ML. Small Animal Orthopedics, pg 223, 1995).

enough to allow insertion of the end of the clamp is made parallel with the ischial rim. Because the fixation teeth of the Kern clamp provide 4 points of fixation, this instrument can be used for both caudal retraction and rotation of the segment (Figure 60-22). If the fracture segments are collapsed medially, the Lahey retractor is helpful in repositioning the fragments laterally. A Lahey retractor, which is blunt, strong, and bent 90° at its end, is passed along the medial wall of the free segment. The retractor's tip is maintained on the bone's surface as it is passed along the medial wall to avoid compromising the sciatic nerve. Pulling laterally moves the fracture segments laterally (Figure 60-23).

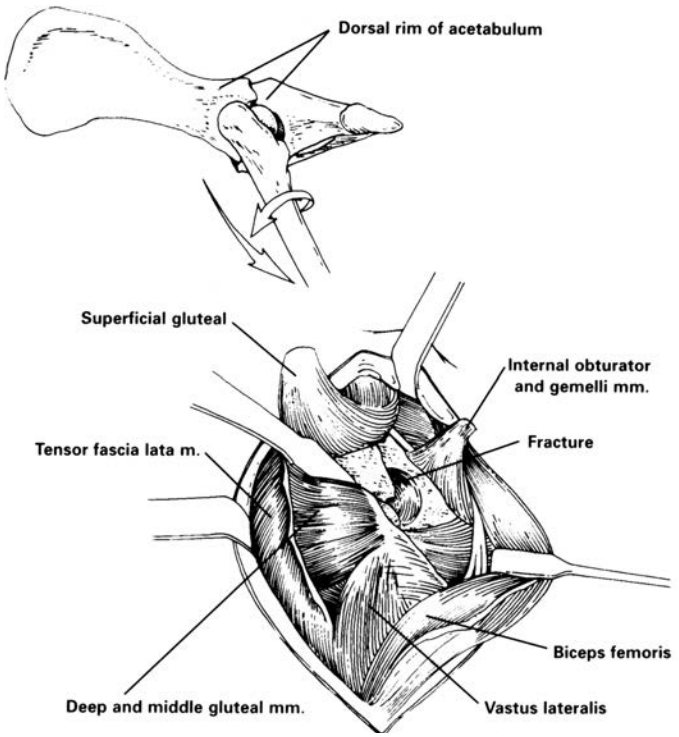

Figure 60-20. The external rotators of the hip are incised at their insertion in the trochanteric fossa during a caudal approach. These muscles are retracted caudally protecting the sciatic nerve. Extension and internal rotation of the femur enhances fracture exposure. These muscles are retracted ventrally by a Hohmann retractor placed under the middle and deep gluteal muscles and hooked on the ventral edge of the ilium. (Olmstead, ML. Small Animal Orthopedics, pg 222, 1995).

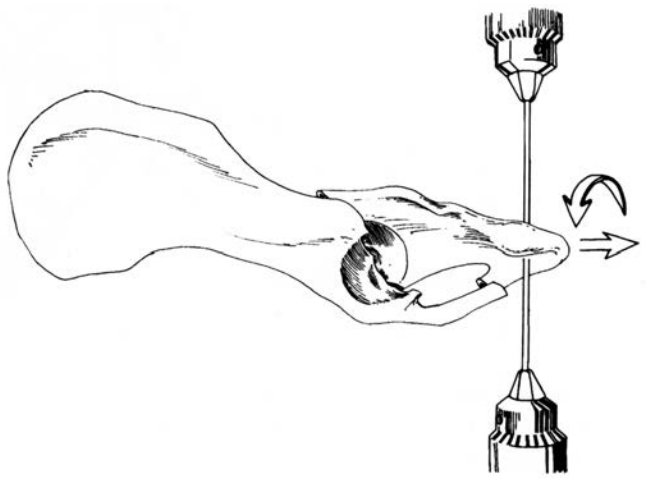

Figure 60-21. An intramedullary pin driven through the ischium can be used for caudal traction and minimal rotation of the free pelvic segment. (Olmstead, ML. Small Animal Orthopedics, pg 225, 1995).

Acetabular fracture reduction is maintained by manually holding the fragments in place until the permanent stabilization procedure is completed. Reduction of an acetabular surface can be evaluated visually through an incision in the joint capsule or an existing capsular tear by applying ventral traction on the greater trochanter. This will pull the femoral head out of the acetabulum enough so the articular surface of the acetabulum can be observed.

Non-plating surgical techniques for repair of acetabular fractures have not proven to be as effective as bone plates. They also have not consistently provided the clinical results obtained with bone plates. Two different sizes of C-shaped acetabular plates, mini fragment plates and standard Dynamic Compression Plates® [Synthes (USA), Paoli, Pennsylvania] have been used successfully to stabilize acetabular fractures. Some surgeons use reconstruction plates for acetabular fractures because they can be bent easily in several different planes.

Bone plates must be anatomically contoured to the dorsal rim of the acetabulum. The bone fragments will shift in position as the screws are tightened if the plate is not properly contoured. The C-shaped acetabular plates are easily contoured to the acetabulum's dorsal surface. Mini plates are also easy to bend because they are thin. However, this makes them relatively weak and limits the size of animal in which they can be used. The acetabulum's dorsal surface is used for plate placement

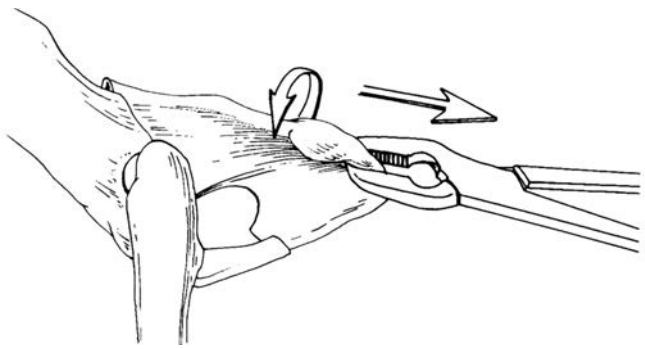

Figure 60-22. A Kern bone holding clamp applied to ischium through an incision over the tuber ischia is used to rotate and caudally retract the free segment. (Olmstead, ML. Small Animal Orthopedics, pg 226, 1995).

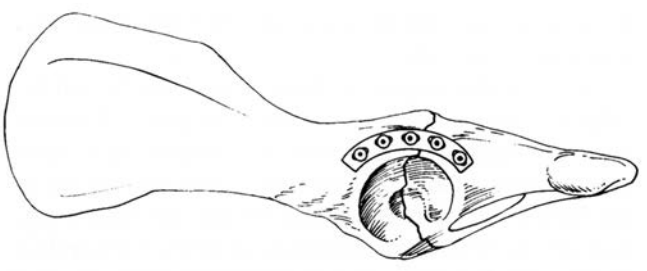

Figure 60-23. Bone plates are placed over the dorsal rim of the acetabulum because it is acetabulum's most accessible area, largest visible bone surface and tension surface. (Olmstead, ML. Small Animal Orthopedics, pg 227, 1995).

because adequate bone is present there and this is the tension surface of the bone. In all acetabular fractures at least two screws should be located on either side of the fracture line, and they should be angled so that they do not penetrate the articular cartilage surface (Figure 60-24).

One of the most difficult fractures to stabilize is one that has a component of the medial wall of the acetabulum fractured out. If a large section of this wall is involved, the femoral head will displace medially into the pelvic canal. If the fracture segment containing the medial wall extends far enough cranially, a lag screw and/or intramedullary pin fixation of the ilial segment are used to stabilize the fragment. If the fragment can not be stabilized, a slight over-bending of the plate closing the diameter of the articular surface, makes it more difficult for the femoral head to displace medially. If the femoral head cannot be prevented from displacing medially, a salvage procedure, excision arthroplasty, should be considered. For severe acetabular fractures where reconstruction is not possible excision arthroplasty may also be performed. This procedure is done only as a last resort as it sacrifices joint function but is intended to save limb function.

The weight bearing surface of the acetabulum, its cranial 2/3's, must be reconstructed if its integrity is to be maintained. Repair of fractures in the caudal 1/3 of the acetabulum is controversial. Although unrepaired fractures in this area will result in coxofemoral osteoarthritis, it has not been definitively proven that repairing fractures in this area will improve the patients' recovery. Although osteoarthritis may be present, limb function may be unaffected. Due to their small size, fractures of the caudal 1/3 of the acetabulum can be difficult to adequately stabilize. With a caudal fracture the sciatic nerve is at greater risk of injury during surgery then when the fracture is located more cranially.

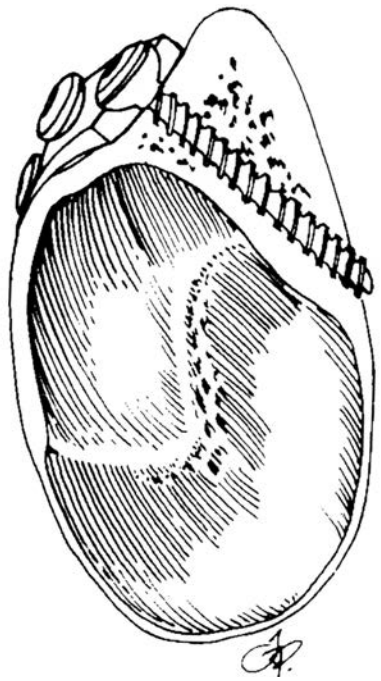

Figure 60-24. This cut-away view of the acetabulum shows a bone screw directed through the plate in a direction that does not violate the articular surface. (Olmstead, ML. Small Animal Orthopedics, pg 227, 1995).

When both a fracture of the ilium and the acetabulum are present, the author prefers to repair the ilial shaft first. Repair of the ilium is often done with a stronger fixation system than is used on the acetabulum because usually more screws and a longer and stronger plate can be applied to the ilium. The reconstruction of the ilium does not have to be as anatomically exact as reconstruction of the acetabulum. When the acetabulum is repaired last it will be fixed to a solidly stabilized ilial segment. Also, its fixation will not be subjected to additional loads that would be generated during manipulation of the ilial fragments if the ilium were fixed last.

Treatment of Coxofemoral Luxations

James L. Tomlinson

Introduction

Coxofemoral luxation is a common injury suffered by both dogs and cats after various forms of trauma to the pelvis. The hip joint is the most commonly luxated joint in dogs and cats. In most coxofemoral luxations the femoral head is displaced cranial and dorsal to the acetabulum. In about 10% of hip luxations, the femoral head is displaced either ventrally or caudodorsally.

The severity of tissue damage associated with hip luxations varies. In all luxations, the round ligament and part of the joint capsule are torn. In more severe cases, part of the gluteal musculature also may be torn. Small avulsion fractures of the femoral head where the round ligament attaches are common. Erosion of the cartilage of the femoral head sometimes results from the femoral head's rubbing on the ilium, especially in more chronic cases. On rare occasions, portions of the dorsal rim of the acetabulum are fractured off.

Diagnosis of a coxofemoral luxation usually is simple. Most animals have a history of trauma such as having been hit by a

car. The animal does not bear weight on the leg and stands with the adducted and externally rotated with a craniodorsal luxation. On physical examination, a greater than normal distance can be palpated between the greater trochanter of the femur and the tuber ischiadicum. The "thumb test" also is useful in diagnosing a craniodorsal luxation. To perform this test, the animal is placed in lateral recumbency with the affected leg up. The examiner stands behind the animal and places the thumb of the hand closest to the spine in the depression between the greater trochanter of the femur and the tuber ischiadicum while the other hand is grasping the stifle joint. The leg is then externally rotated. In a normal animal, the greater trochanter of the femur should pinch or displace the thumb from the depression between the greater trochanter of the femur and the tuber ischiadicum during rotation, whereas in an animal with a dislocated hip, the thumb is not pinched or displaced. A third way to evaluate a patient for a luxated hip is to extend the animal's legs out caudally while the animal is in either dorsal or lateral recumbency. With a craniodorsal luxation, the affected limb appears shorter than the normal leg; with a ventral luxation, the leg appears longer. Radiographs are needed to confirm the diagnosis, because animals with fractures of the femoral head or neck present with clinical signs similar to those of animals with luxations. The radiographs should be evaluated for direction of luxation, avulsion fractures of the femoral head, other pelvic fractures, and hip dysplasia.

Surgical Options

Closed reduction with application of a non weight bearing sling is the method of choice for most acute luxations. An Ehmer sling is applied after closed reduction as described in Chapter 63. Failure rates for coxofemoral luxations treated by closed reduction have been reported to be as high as 50 to 70%.[1,2]

Open reduction is indicated for acute luxations that will not remain reduced closed, irreducible acute luxations, chronic luxations, luxations associated with avulsion fractures of the femoral head, and luxations associated with other fractures (ipsilateral pelvis, femur, or tibia). Animals with moderate-to-severe degenerative changes of the hip are not candidates for open or closed reduction. Other methods of treatment should be used with such animals.

Numerous methods for open reduction of coxofemoral luxations have been devised including DeVita pinning, Yarbough pinning, use of Knowles toggle pin, joint capsule imbrication with trochanteric transposition, acetabular rim extension, transacetabular pinning, and retention suturing with joint capsule imbrication. The goal of open reduction of a coxofemoral luxation is to reestablish normal function and conformation of the hip. Once healing is complete, the anatomic shape of the hip joint and fibrosis of the joint capsule hold the hip in place.

Surgical Techniques

The techniques for performing joint capsule imbrication with transposition of the greater trochanter, toggle pinning, transacetabular pinning and retention suturing are described in this section.

Open reduction of coxofemoral luxations can be performed by one of two surgical approaches to the joint. Transacetabular pinning, toggle pinning and single retention suturing are best performed through a craniolateral approach,[3] except in patients with chronic luxations. Double retention suturing, and joint capsule imbrication with transposition of the greater trochanter are performed through a dorsal approach by osteotomy of the greater trochanter of the femur.[3] With acute craniodorsal luxations, the femoral head is easily identified during the approach. If the luxation is chronic, the femoral head is surrounded by a fibrous pseudo-joint capsule. With acute craniodorsal luxations, the acetabulum is caudoventral to the femoral head and may be difficult to find, especially in chronic luxations. The acetabulum may have joint capsule, blood, or fibrin clots, remnants of the round ligament, avulsed pieces of the femoral head, and fibrous tissue (chronic luxations) within the joint. The joint must be cleaned out before the femoral head can be reduced into the acetabulum. The joint capsule should be preserved for later suturing. The femoral head can be retracted caudal to the acetabulum with a Hohmann retractor by hooking the tip of the retractor on the caudal edge of the acetabulum and prying caudally against the proximal metaphysis of the femur. Care must be taken not to entrap the sciatic nerve under the retractor.

Joint Capsule Imbrication with Transposition of the Greater Trochanter

Joint capsule imbrication with transposition of the greater trochanter of the femur is a useful method for treating patients with acute luxations, chronic luxations, and luxations with concurrent lesions such as acetabular fractures that require an approach to the hip by osteotomy of the greater trochanter of the femur.

The animal is placed in lateral recumbency with the affected hip up and is prepared for aseptic surgery. The luxated joint is exposed through a dorsal approach by osteotomy of the greater trochanter of the femur.[3]

Great care must be taken during this approach to preserve the joint capsule for later suturing.

After the femoral head has been identified and the acetabulum cleared of debris, the luxation is reduced. If adequate joint capsule is present on both sides of the joint, a simple interrupted or horizontal mattress pattern of 3-0 or 2-0 polypropylene or PDS is used to appose the joint capsule (Figure 60-25A). Placement of sterile towels on the medial side of the leg is beneficial to hold the leg in abduction during the imbrication to relieve the pressure on the joint capsule. If insufficient joint capsule is present on the acetabular side of the joint, the joint capsule can still be attached by using screws or tissue anchors (IMEX™ Veterinary, Inc. 1001 McKesson Drive, Longview, Texas 75604) to secure the suture on the acetabular side (Figure 60-25B). Once the joint capsule repair is completed, the greater trochanter is replaced in a position caudal and distal to its normal position (See Figure 60-25B). By positioning the greater trochanter caudal and distal to its normal location, the gluteal muscles try to abduct and internally rotate the femur thus making it more difficult for the femoral head to luxate. The greater trochanter is attached using a tension band device.

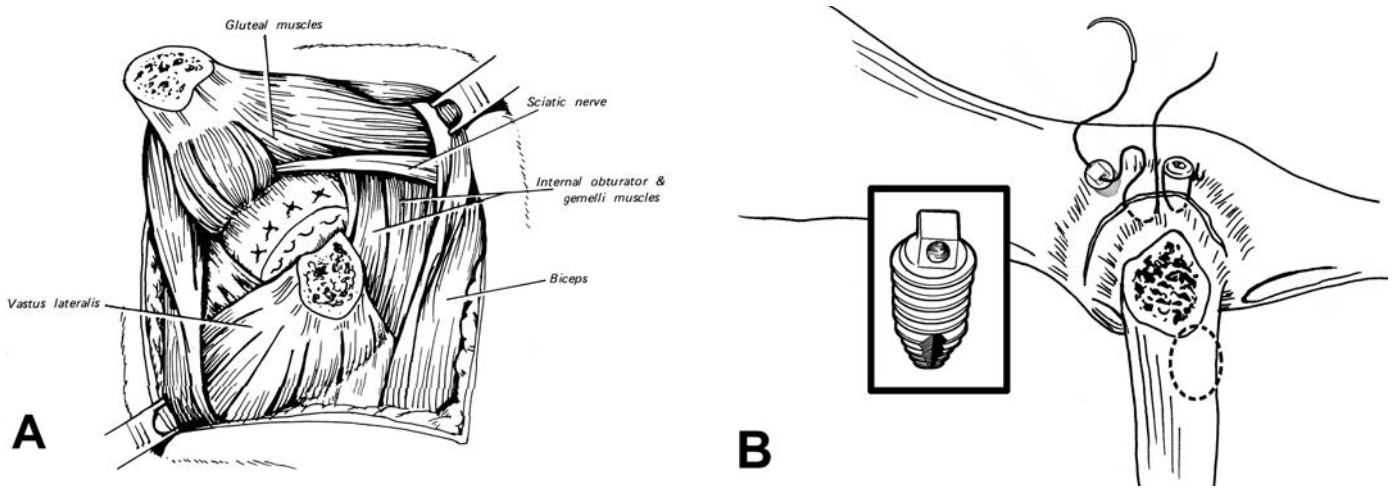

Figure 60-25. Imbrication of coxofemoral joint capsule. **A.** When sufficient joint capsule is present, nonabsorbable sutures are placed in a horizontal mattress pattern. (From Brinker WO, Piermattei DL, Flo GL, eds. Handbook of small animal orthopedics and fracture treatment. Philadelphia: WB Saunders, 1983;272.) **B.** When insufficient joint capsule is present on the acetabular side for suturing, bone screws or tissue anchors can be used to secure the suture on the acetabular side of the joint. The insert shows a tissue anchor. The suture is passed through the joint capsule on the femoral head side of the joint and tied. The dotted line on the femur illustrates where the greater trochanter of the femur is reattached with a tension band device distal and caudal to its normal location.

Toggle Pinning

Toggle pinning is an old technique for open reduction of coxofemoral luxations that is still useful today. One of the benefits of using this technique to repair coxofemoral luxations is that the dog can be allowed to walk on the leg after surgery.[4] Having a leg that can bear weight is very important for dogs with multiple leg injuries. Recent advancements in the equipment that is available for performing toggle pinning has simplified the technique and made it something that is realistic to do in small animal practices. Toggle pins, surgical buttons, an aiming device, and a suture passer that simplifies the procedure are commercially available (IMEX™ Veterinary, Inc.1001 McKesson Drive, Longview, Texas 75604). A cranial lateral approach to the hip is performed.[3] Some surgeons prefer to approach the hip through an approach that osteotomizes the greater trochanter of the femur to provide greater exposure of the joint. In most cases, the cranial lateral approach to the hip provides adequate exposure to perform the surgery with less morbidity for the dog. Once the femoral head and acetabulum are exposed, blood clots and remnants of the round ligament are removed from the acetabulum. Any joint capsule that remains needs to be preserved for suturing. A hole is drilled through the acetabular fossa from lateral to medial with a drill bit or pin slightly larger than the diameter of the toggle pin (Figure 60-26). The toggle pin with suture is passed through the hole so that the toggle pin anchors on the medial wall of the acetabulum (Figure 60-27). Using the aiming device, a hole is drilled through the femur from an area just below the greater trochanter of the femur up the femoral neck and exits at the fovea capitus (the area where the round ligament normally attaches to the femoral head) (Figure 60-28). An alternative to using the aiming devise is to externally rotate the femur until the fovea capitus of the femoral head is visualized. The hole is then drilled from the fovea capitus down the femoral head and neck so that it exits slightly below the greater trochanter. Two types of suture material are used for this procedure. The first is fiber wire (IMEX™ Veterinary, Inc. 1001 McKesson Drive, Longview, Texas 75604) which has a small diameter but is very strong. The second

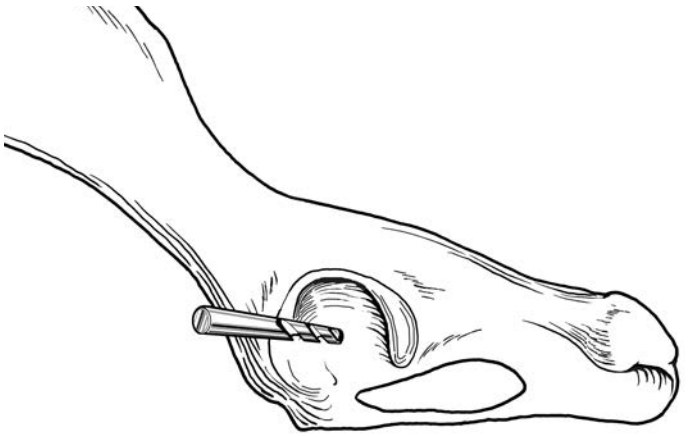

Figure 60-26. A hole is drilled through the acetabular fossa from lateral to medial so that the toggle pin and suture can be anchored on the medial side of the acetabulum.

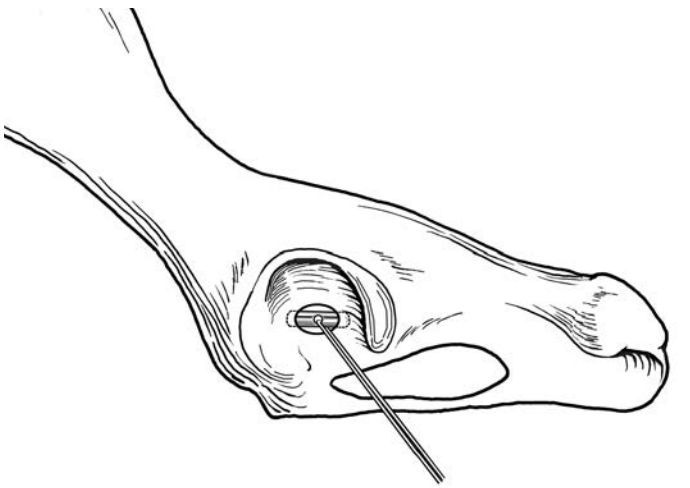

Figure 60-27. The toggle pin with suture attached is passed through the hole in the acetabulum and anchored on the medial side of the acetabulum.

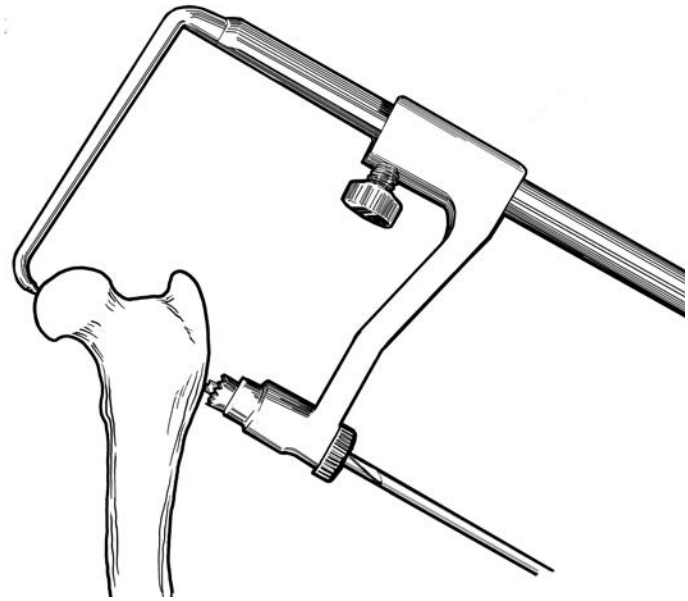

Figure 60-28. Using an aiming devise, a hole is drilled from an area just distal to the greater trochanter, up the femoral neck and out the fovea capitus.

type of suture is the same heavy leader line suture material many veterinarian use for cruciate repair. The suture is passed through the tunnel from the femoral head to the lateral side of the femur (Figure 60-29). A suture passer facilitates passing the suture if fiber wire type of suture is being used. Heavy nylon suture will slide through the hole without need for the suture passer. The easiest method of anchoring the suture on the lateral side of the femur is with a surgical button. The suture is passed through the two holes in the surgical button. The femoral head is reduced into the acetabulum and the suture tied over the button (Figure 60-30). If possible, the joint capsule is sutured into apposition. Closure of the surgical site is routine. The animal is allowed to bear weight on the leg in a controlled manner after surgery.

Transacetabular Pinning

Transacetabular pinning is a practical and successful procedure for repair of coxofemoral luxations. The best results are obtained when this procedure is used for acute luxations in nondysplastic patients, although I have used this procedure successfully for chronic luxations. The only equipment needed is standard operating instruments, Jacob's pin chuck, and intramedullary pins.

The animal is placed in lateral recumbency on the operating table with the affected leg suspended from an intravenous pole. The leg is scrubbed and draped for aseptic surgery. For acute luxations, the hip is exposed through a craniolateral approach.[3] For chronic luxations, a dorsal approach to the hip by osteotomy of the greater trochanter of the femur[3] may be needed. Once the femoral head is exposed and the acetabulum is cleaned of debris, the luxation is reduced temporarily. The hip is reluxated, and the femur is rotated externally until the fovea capitis of the femoral head is visible (Figure 60-31A).

An intramedullary pin, with a diameter that is two-thirds to three-fourths that of the fovea capitis, is selected. The pin is advanced

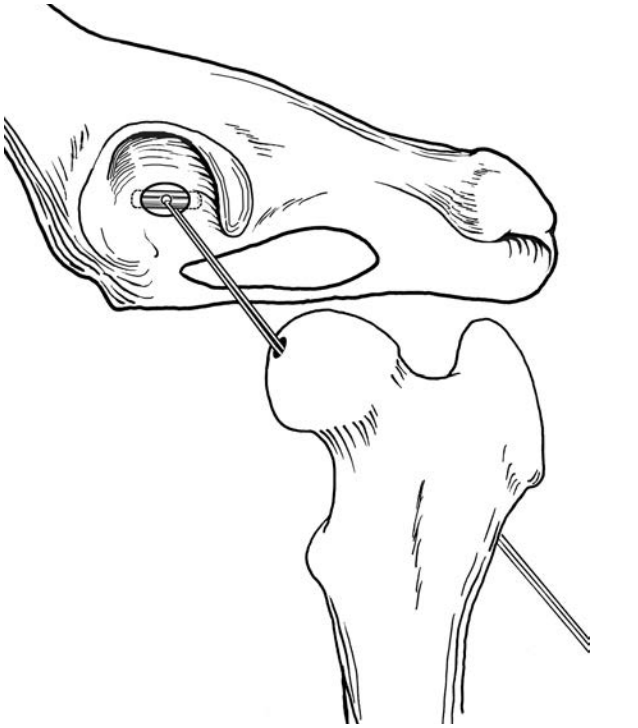

Figure 60-29. The end of the suture is now passed through the femoral tunnel starting at the femoral head and exiting at the lateral side of the femur.

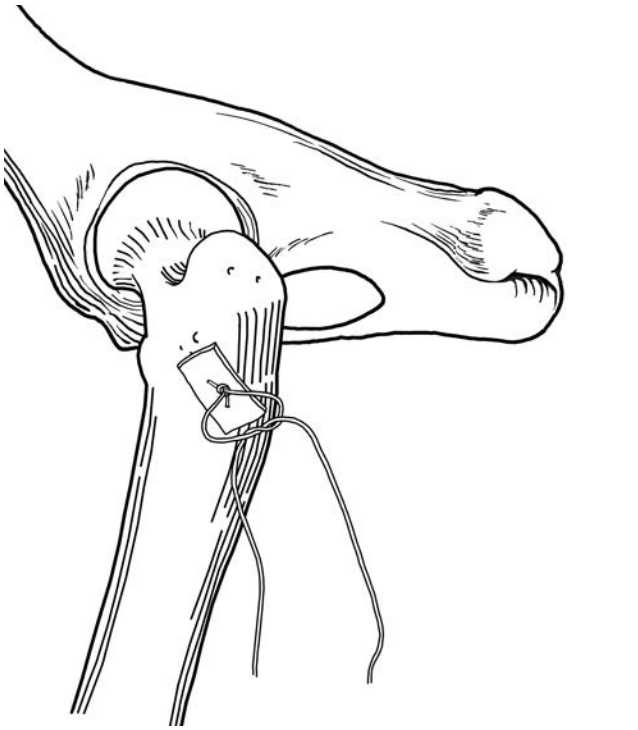

Figure 60-30. The femoral head is reduced and the suture passed through holes in a surgical button. The surgical button is placed under the vastus muscles. The suture is tightened so that the femoral head can not luxate.

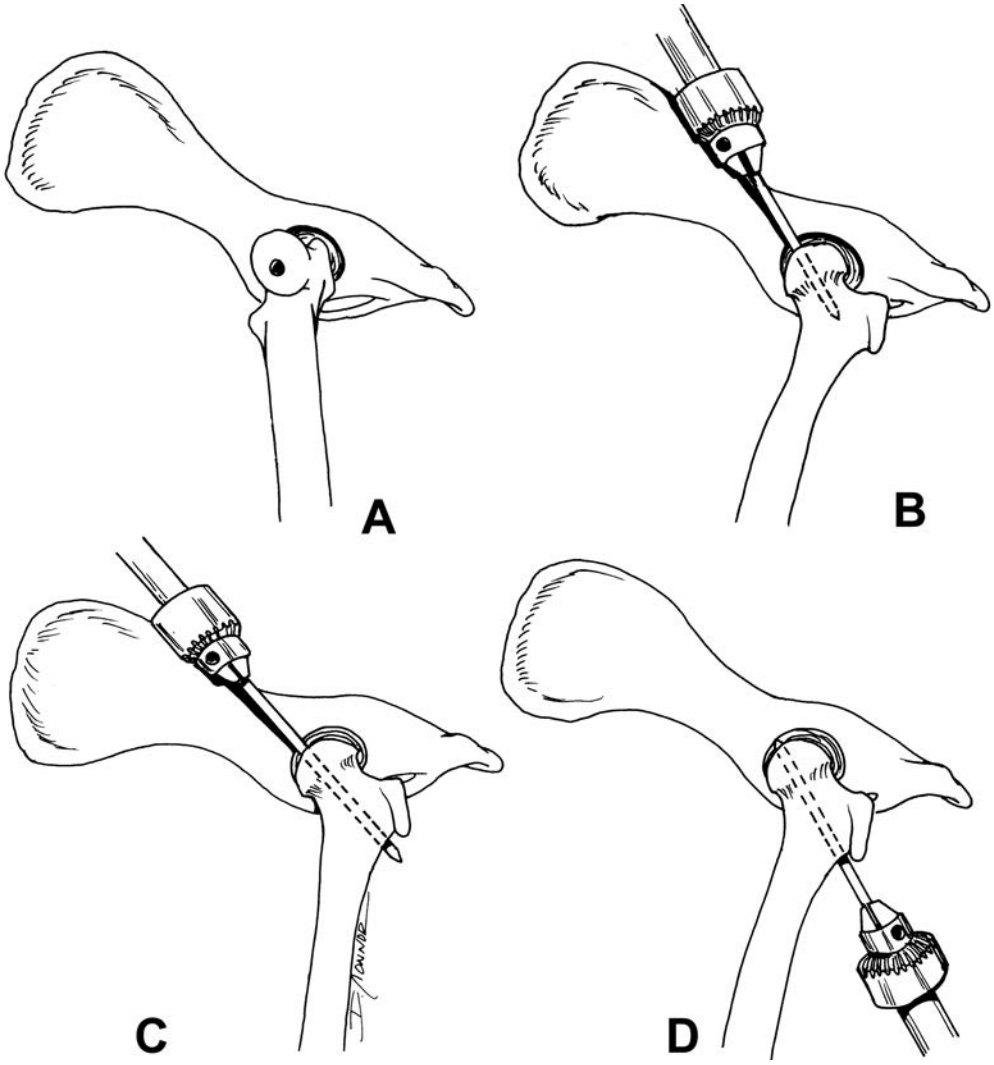

Figure 60-31. Placement of transacetabular pin. After exposure of the femoral head, the leg is rotated to bring the fovea capitis into view. **A.** An intramedullary pin is placed on the fovia capitis. **B.** The pin is advanced through the head and neck of the femur. **C.** The pin exits at the level of the third trochanter. **D.** The pin is adjusted until the end is flush with the fovea capitus.

from the fovea capitis, down the femoral neck, and out the cortex of the third trochanter of the femur (Figure 60-31B and C). The pin is adjusted until the tip is flush with fovea capitis (Figure 60-31D). After the luxation is reduced, the femur is placed parallel to the table top and at a 90° angle to the spine. The pin is driven across the acetabulum while firm downward pressure is applied to the greater trochanter of the femur. If inadequate pressure is applied to the greater trochanter, the femoral head will back part way out of the acetabulum. The pin is driven approximately 1cm into the pelvic canal for the average-size dog. An assistant can palpate the pin rectally to determine whether it has been driven the correct distance. Care must be taken not to puncture the colon. Once the pin has been driven the correct distance, the end of the pin is bent over and cut off (Figure 60-32A, B, and C). Bending the pin over prevents it from migrating further into the pelvic canal.

Postoperatively, the hip is radiographed to check for proper pin placement and reduction of the luxation. The leg is placed in a non-weight bearing sling (Ehmer or Robinson), and the animal is discharged with instructions for limited exercise until the pin is removed. The pin should be removed in 14 to 21 days; the animal's activity is restricted for 3 weeks after pin removal.

Complications associated with transacetabular pinning include pin migration and breakage and reluxation of the hip. Pin migration and breakage generally result from failure of the owner to keep a sling on the animal. The owner should be instructed to return the animal immediately if the sling comes off.

Retention Suturing

Retention suturing can be a valuable technique by itself when the joint capsule is missing or traumatized to such an extent that it will not effectively hold sutures. Retention suturing can be combined with other methods of repair also. Two methods for retention suturing have been described. The single-suture method[5] is started by drilling a hole dorsal to ventral at the attachment of the rectus femoris to the ventral aspect of the ilium (Figure 60-33A). An alternative method of anchoring the suture in the ilium is with a tissue anchor. A second hole is drilled cranial to caudal through the greater trochanter of the femur (after the trochanter is reattached) at about the level of attachment of the deep gluteal tendon (Figure 60-33B). Heavy nonabsorbable suture material (No. 5 Ethibond or nylon leader line [Ethicon, Inc., Somerville, NJ]) is threaded through the holes, and the suture is

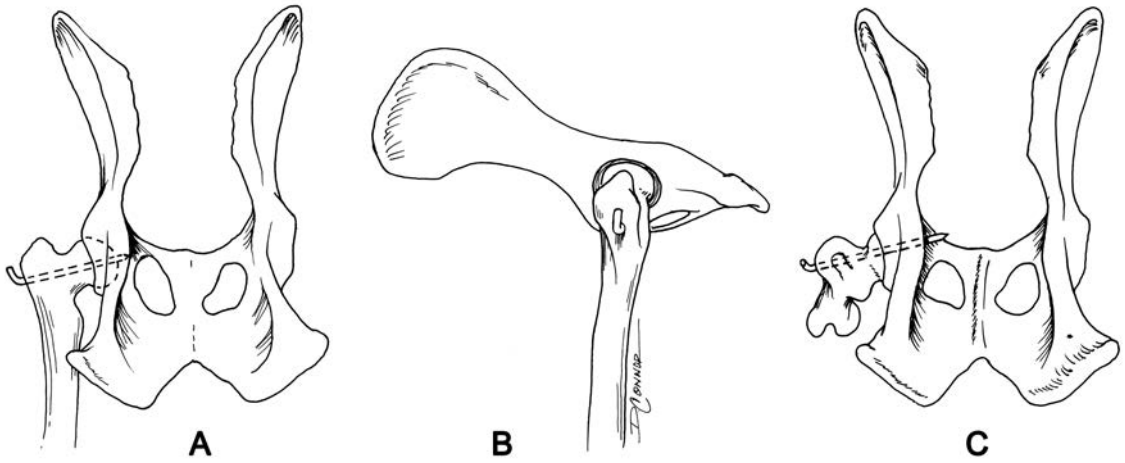

Figure 60-32. A-C. Final placement of transacetabular pin after reduction of joint. Note that the pin extends about 1 cm into the pelvic canal for a large dog and that the end of the pin in bent over to prevent medical migration of the pin.

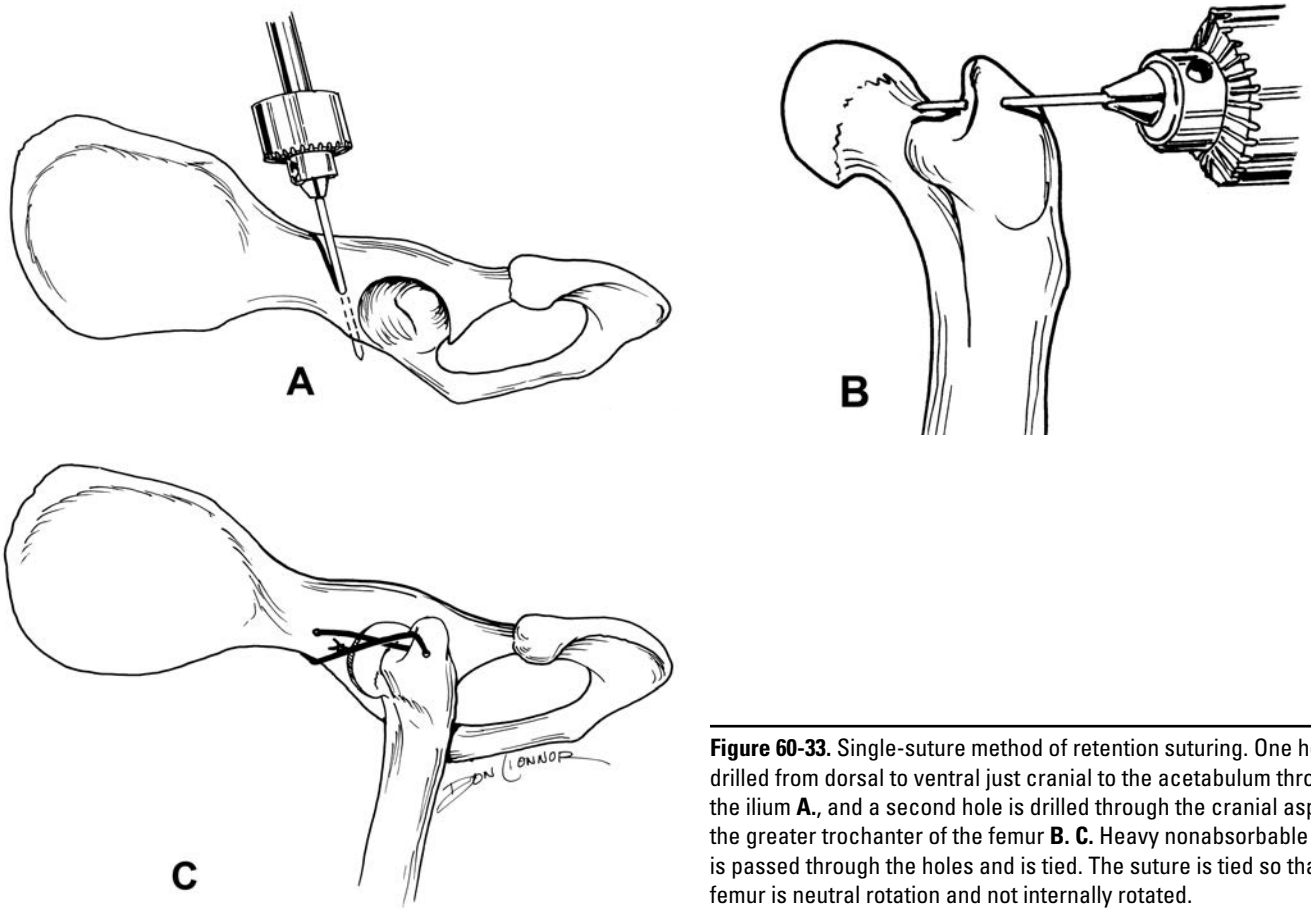

Figure 60-33. Single-suture method of retention suturing. One hole is drilled from dorsal to ventral just cranial to the acetabulum through the ilium **A.**, and a second hole is drilled through the cranial aspect of the greater trochanter of the femur **B. C.** Heavy nonabsorbable suture is passed through the holes and is tied. The suture is tied so that the femur is neutral rotation and not internally rotated.

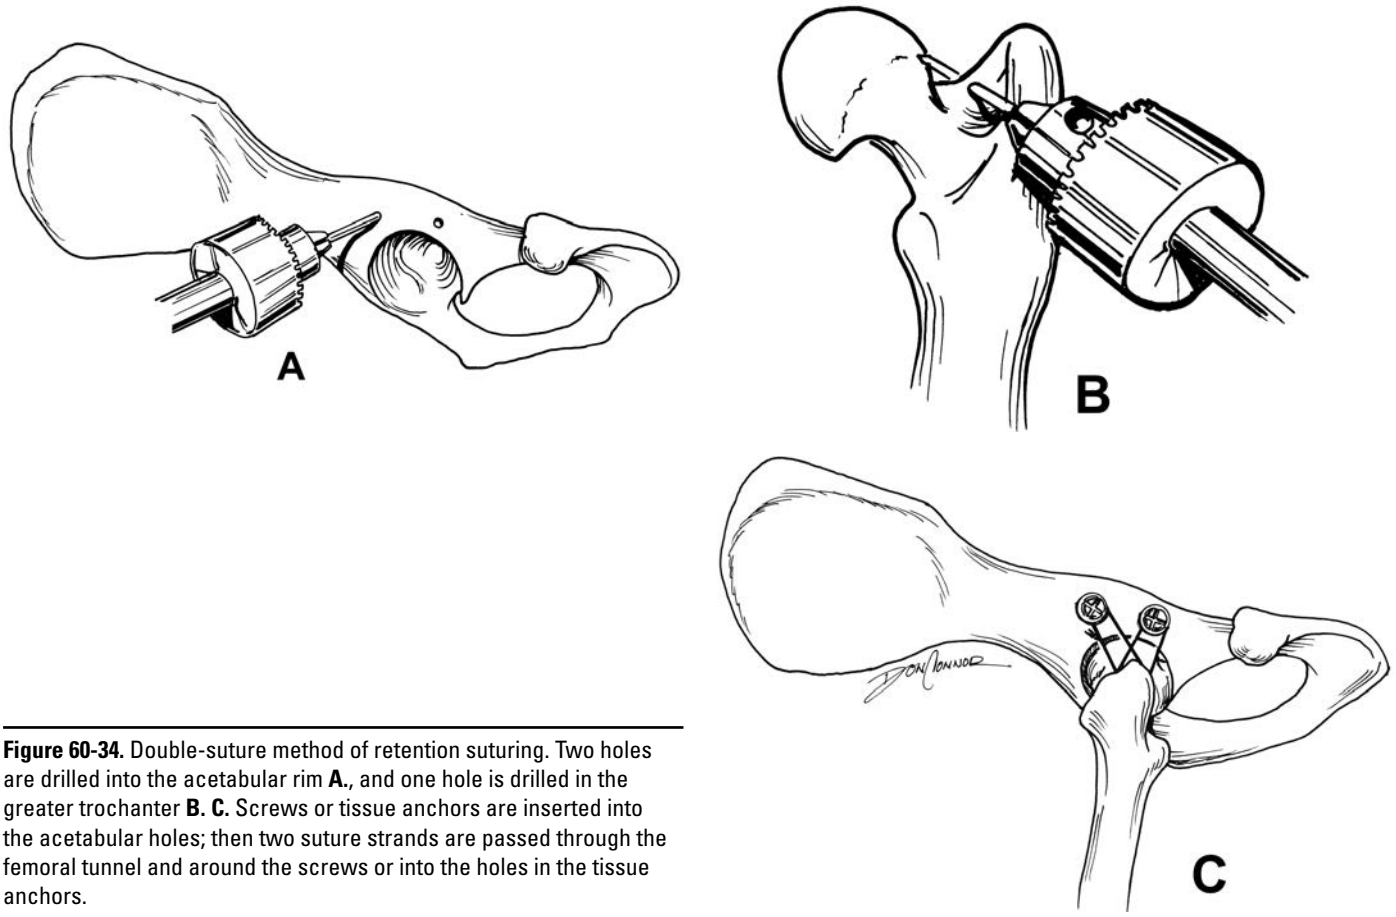

Figure 60-34. Double-suture method of retention suturing. Two holes are drilled into the acetabular rim **A.**, and one hole is drilled in the greater trochanter **B. C.** Screws or tissue anchors are inserted into the acetabular holes; then two suture strands are passed through the femoral tunnel and around the screws or into the holes in the tissue anchors.

tightened (Figure 60-33C). The suture should not be tightened to the extent that flexion and extension of the hip are restricted or that the leg is internally rotated. Over tightening of the suture will result in poor leg function and suture breakage.

In the double-suture method, two sutures are passed from the greater trochanter to the dorsal rim of the acetabulum.[6] Two holes are drilled in the dorsal acetabular rim at the 11 and 1 o'clock positions (Figure 60-34A) and a third hole is drilled cranially to caudally through the greater trochanter of the femur (Figure 60-34B). After screws or tissue anchors are inserted into the holes in the acetabular rim, two strands of heavy nonabsorbable suture material are passed through the femoral tunnel. One strand is passed around the cranial acetabular screw or through the hole in the tissue anchor and the other around the caudal screw or hole in the tissue anchor. The sutures are then tightened (Figure 60-34C). Spiked washers (Synthes, Paoli, PA) may be needed to hold the sutures in place if screws are used. The greater trochanter is reattached with two Kirschner wires and a tension band wire.

With either retention suture technique, the animal is placed in a non weight bearing sling for 2 to 3 weeks postoperatively with exercise restriction. Once the sling is removed, the animal is slowly returned to normal exercise over the next month.

Diagnostic Tests

Barclay Slocum and Theresa Devine Slocum

Clinical Observations

"Boxy" Hips

The observation of gait is important to distinguish between functional abnormalities such as ataxia, and conformational abnormalities. "Boxy" hips are a change in shape of the rump from smooth and rounded to that of a rounded square (Figure 60-40), caused by a luxated hip.

Observation Procedure

The patient is observed from behind during walking. The examiner notes the width between the animal's feet in the transverse plane. The normal patient places the foot beneath the hip joint, which is 7 to 10 cm apart on a dog the size of a Labrador retriever. This is called base normal. On the same dog with boxy hips, the feet will be 2 to 5 cm apart, which is called base narrow. Some patients walk base narrow, convert to base wide (feet are 12 to 15 cm apart), and oscillate between the two (Figure 60-41).

The second characteristic to notice is the contour of the rump from behind. The rump of the normal dog is smooth and rounded, sloping ventrally from the caudal vertebrae, as the contour is traced laterally. The dog with "boxy" hips has minimal or no slope from the caudal vertebrae as the contour of the rump is traced laterally, and then it is round (with a smaller radius of curvature) as the contour curves around the greater trochanter to continue along the lateral thigh. Occasionally, the trochanter intermittently protrudes, causing the shape to change between the two contours (Figure 60-42).

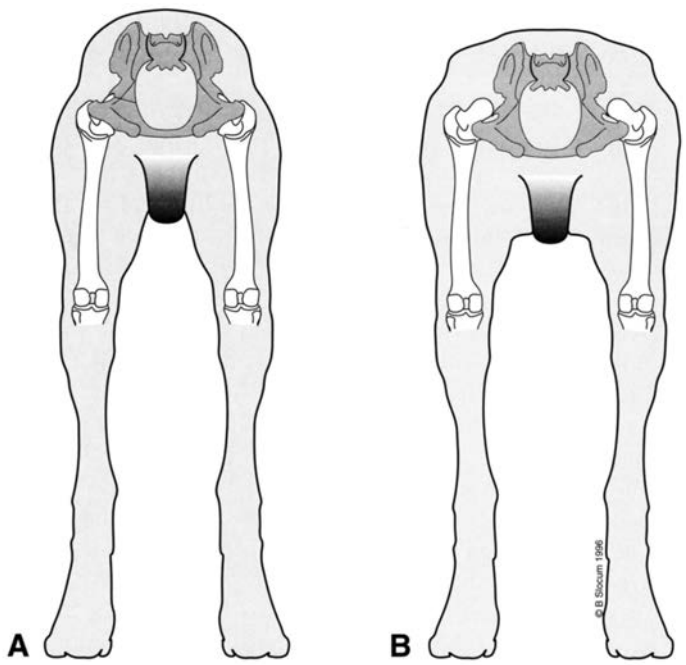

Figure 60-40. A. The contour of the normal rump is like a beautifully arched doorway. **B.** The contour of the rump of a dysplastic dog with luxated hips is like a rectangular doorway.

The difference between normal and "boxy" hips is the difference between a normally reduced femoral head and a luxated femoral head. In the luxated hip, the femoral head has translated laterally and dorsally. This projects the greater trochanter laterally and dor-sally and gives the contour of the rump the "boxy" appearance of a rounded square. The luxated hip is supported by the joint capsule, rather than by the acetabulum. Abduction is limited because the adductor muscles, especially the pectineus, are excessively lengthened by the amount of displacement of the femoral head when abduction occurs. This abduction of the luxated femoral head creates extra forces on the already stretched and inflamed joint capsule, which causes the patient pain. The dog limits the amount of this abduction by walking base narrow (See Figure 60-41).

The reduced or normal position of the hip in the acetabulum is nonpainful. Because the increased slope of the acetabulum in the dysplastic hip allows the femoral head to drift into the luxated position, the patient has two means of reducing the femoral head into the acetabulum. The combined muscle forces of the hip abductors and rotators can create sufficient pull to reduce the femoral head, but this force must be sustained to maintain reduction. These muscles are not created with the purpose of maintaining the reduced hip. As these muscles fatigue, the hip again luxates.

The second means of creating hip reduction is to abduct the hip, a maneuver that redirects the axial muscle forces of the femur into the acetabulum. This requires minimal abductor forces to hold the hip in the reduced position, but the foot is not under the femoral head. The patient must walk base wide to maintain reduction of the luxated hip (See Figure 60-41). This base wide effect has been observed in several circumstances. Some dogs shift from a base narrow gait to a base wide gait and back, as the discomfort of luxation dictates a base wide configuration for comfort. Some dogs shift to base wide to go up stairs. Some dogs hesitate slightly before jumping into a car or the bed of a pickup truck, to go base wide and relocate the hip before jumping.

The presence of "boxy" hips indicates that the hips are luxated and are in a severe and rapid stage of degeneration. If the dog is young, these hips may be saved and made functional by a pelvic osteotomy. Most frequently, dogs are presented beyond this stage.

"Bunny Hopping" Gait

The observation of gait is important in the determination of functional abnormalities such as ataxia and conformational abnormalities. "Bunny hopping" gait is a running gait in which the patient runs with both feet in adduction, simultaneously.

Observation Procedure

The patient is observed from behind during running. The examiner notes the width between the feet in the transverse plane. The normal patient places the foot beneath the hip joint, which is 7 to 10 cm apart on a dog the size of a Labrador retriever. On the same dog with a "bunny hopping" gait, the feet are 2 to 5 cm apart, and use of the hind limbs is simultaneous (Figure 60-43).

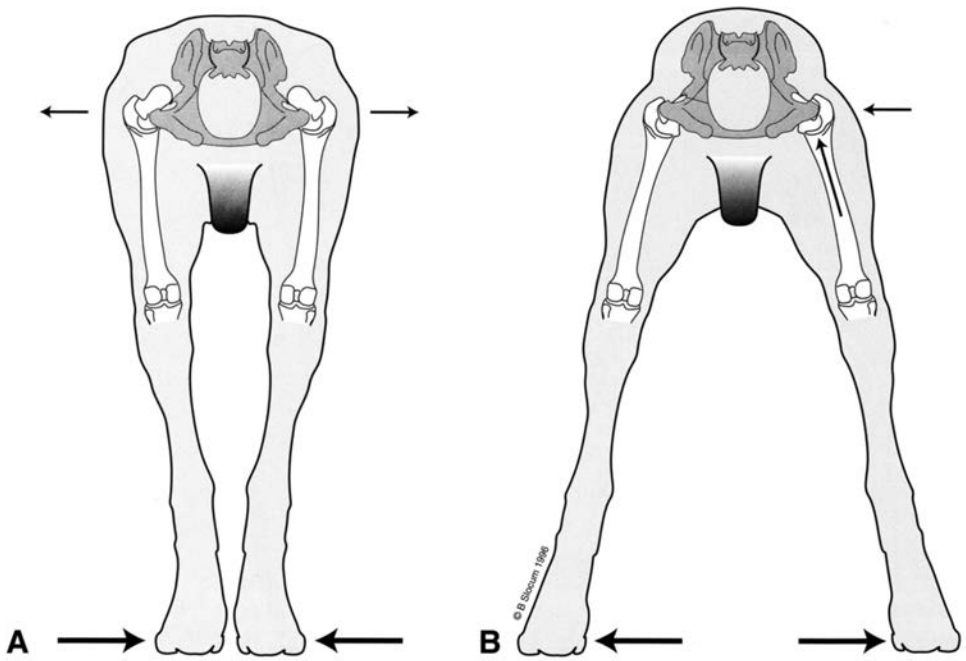

Figure 60-41. A. The dysplastic dog with luxated hips is likely to stand with the feet together, base narrow. **B.** The dysplastic dog with reduced hips stands with the feet apart, base wide, to direct the axial femoral force into the acetabulum and ease hip reduction.

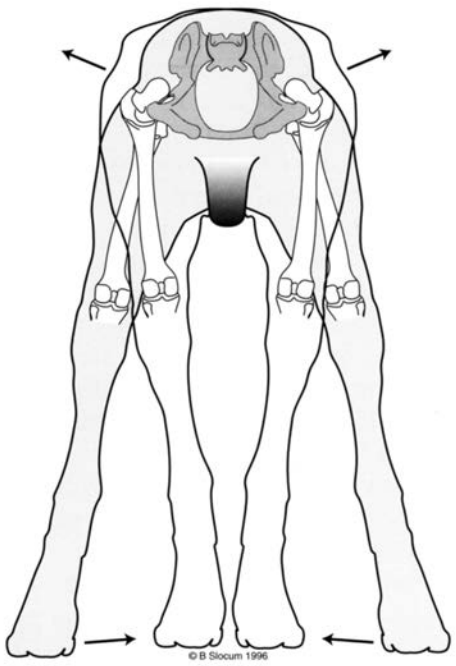

Figure 60-42. As the dog goes from a base wide to a base narrow stance, the width of the rump may increase as the hips luxate. As the dog goes from a base narrow to a base wide stance, the width of the rump may decrease as the hips reduce. This is called a base shift.

The difference between the normal running and "bunny hopping" gait is that, in the normal gait, the feet are apart by approximately the width of the hip joints, and one hind foot is used slightly before the other. In the "bunny hopping" gait, the feet are placed close together and are used together, with the back performing the greater part of extension. The difference between the hips in the normal and "bunny hopping" gait is the difference between a normally reduced femoral head and a luxated femoral head. The luxated hip is supported by the joint capsule rather than by the acetabulum and is therefore limited in its abduction. When the femoral head is laterally displaced, the adductor muscles are excessively lengthened. Abduction of the luxated fem oral head creates large forces on the already inflamed joint capsule. This causes the patient pain and a base narrow gait. The patient seems to be incapable of reducing the femoral head into the acetabulum by either abductor and rotator muscle forces or abduction of the hip. By using both limbs together, the forces are greatly reduced in each hip.

The presence of a "bunny hopping" gait indicates that the hips are luxated and are in a severe and rapid stage of degeneration. These hips are usually beyond reconstruction by means of a pelvic osteotomy unless the patient is young and the severe luxation is a recent occurrence.

"Clunking" Hips

The observation of gait is important in the determination of functional abnormalities. "Clunking" hips are a result of the hip relocating from the luxated position to the reduced position during ambulation.

Observation Procedure

The client often brings the "clunking" of the hips to the attention of the orthopedist. The patient is observed during walking. The examiner's hand can be placed on the animal's rump to feel the hip being reduced during ambulation. One can also hear the "clunk" of reduction (Figure 60-44). A positive observation of "clunking" hips is to experience the feel of the "clunk" and to hear the "clunking" sound.

The presence of a "clunk" in a hip means that the hip begins in a luxated position, and the femoral head falls into an acetabulum of some depth. The combined muscle force of the hip abductors

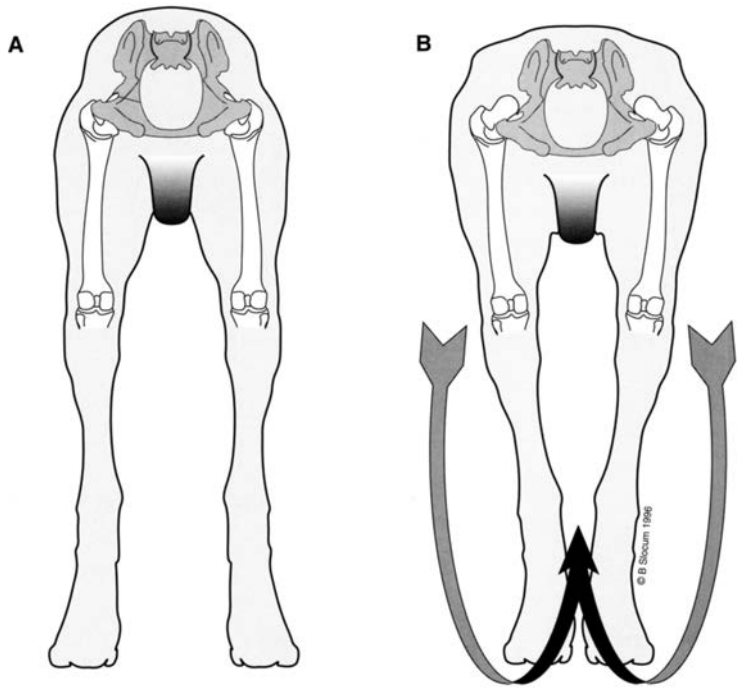

Figure 60-43. A. Normal. **B.** "Bunny hopping" is an abnormality of gait that occurs when hips are luxated. Both rear limbs are used simultaneously during extension to limit hip pain. The back is hyperextended, to assist in lengthening the stride.

and rotators can create sufficient pull to reduce the femoral head, but this force must be sustained to maintain reduction. Because these muscles are not created with the purpose of maintaining hip reduction, they soon fatigue, and the hip again luxates. The reduced or normal position of the hip in the acetabulum is nonpainful, but the increased slope of the acetabulum in the dysplastic hip allows the femoral head to drift into the luxated position.

The presence of a "clunking" hip, whether by direct observation or by client observation, clearly indicates an orthopedic emergency in which the patient should be placed under absolute rest conditions until the hips can be evaluated and treated. If the hips are "clunking," then usually enough acetabulum is left to reseat the femoral head. A pelvic osteotomy will be successful if the acetabulum has not filled with osteophytes and the dorsal acetabular rim (DAR) still has sufficient integrity and depth to maintain the femoral head in the acetabulum after pelvic osteotomy.

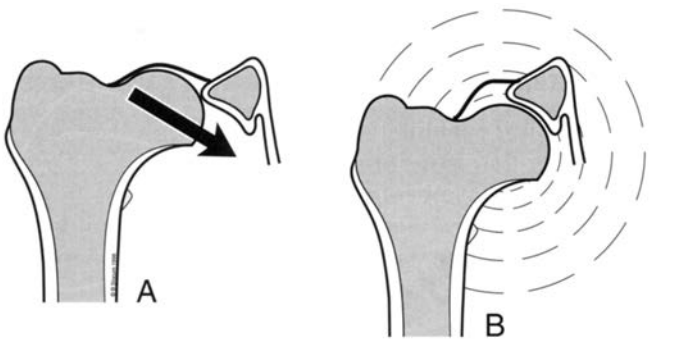

Figure 60-44. A. The "clunking" sound emanating from the hip is generated by the luxated hip, rapidly returning to the acetabulum *(arrow)* during ambulation. **B.** When the femoral head seats in the bottom of the acetabulum, a "clunking" sound is heard, and this corresponds to the vibration felt as the medial translation of the greater trochanter is palpated during ambulation.

The DAR is under immediate trauma by the femoral head because the femoral head just proximal to the ligament of the femoral head is incongruent with the acetabulum and is concentrating forces on the DAR and the adjacent joint capsule. If the DAR breaks down, then the "clunk" will cease. The femoral head remains permanently in the luxated position in the dorsal joint capsule. Acetabular filling follows breakdown of the DAR because it is secondary to the inflammation generated by the breakdown process at the DAR. The hip will stop "clunking" if the hip is neglected because acetabular filling occurs. The window of opportunity to correct this patient's acetabular hip dysplasia by pelvic osteotomy is lost if dorsal acetabular breakdown or acetabular filling occurs. Under these circumstances, the attending veterinarian has lost the chance to reconstruct the patient's hip.

The presence of "clunking" hips indicates that the hips are luxated and are in a severe and rapid stage of degeneration. If the dog is young, these hips may be saved and made functional by a pelvic osteotomy; however, immediate action must be taken to identify the source of damage accurately and to correct the incongruity.

Stand Test

The stand test creates extension of the hip and lordosis of the spine (Figure 60-45). This test is a functional exercise that stresses the spine (especially the L7-S1 with cauda equina impingement) and hip in extension. Because the interaction to perform this test is between the owner and the patient, resistance to the test is

minimal, and the results are reliable. If the owner is unable to handle the patient, or if the patient intimidates the owner, then the test should be bypassed to avoid injury.

Testing Procedure

Clear and specific instructions to the owner are the basis of this test:

1. "Allow your dog to stand on all four legs and face you."
2. "Pick up your dog by the front legs as if you are going to dance with him or her. All the way up."

The patient and owner are observed from the side. Some patients (but few) refuse to stand facing the owner because they have been disciplined for jumping up on the owner.

The normal dog stands in this position without discomfort and enjoys the attention. The dog does not attempt to get down. The dog extends to be closer to the owner. The dog's back and hips are extended and flat as the dog stretches to reach the owner's face.

The abnormal dog stands in this position with discomfort and does not enjoy the test. The dog attempts to get down. The dog does not extend to be closer to the owner and shifts body weight to the side to return to the ground. The dog's back and hips are maintained in flexion, and the dog attempts to disengage from this activity. The dog may even mock bite at the owner's hand as the owner holds the dog's forelimbs.

The stand test stresses the hips and spine of the patient by forced extension. Dogs with abnormal hips respond differently, depending on the degree of inflammation and fibrosis. Young dogs with stretched joint capsules that have little inflammation give the response of a normal dog. The young dog with highly inflamed joints and joint capsules adamantly resists the test. Older dogs with capsular fibrosis of chronic hip dysplasia simply cannot flex at the hips and stand with their rump sticking out.

Dogs with an abnormal spine also vary in their response, depending on the degree of inflammation. The patient with a highly inflamed spine from a disease such as discospondylitis fights this test violently. Dogs with cauda equina syndrome resist to a lesser degree. Patients with mild spondylosis do not fight the test, but they prefer to stand with their rump sticking out.

Even though the stand test is not pathognomonic for a disease, it consistently regionalizes the problem to the back or hip. It is an easy test to perform to demonstrate a problem in these regions.

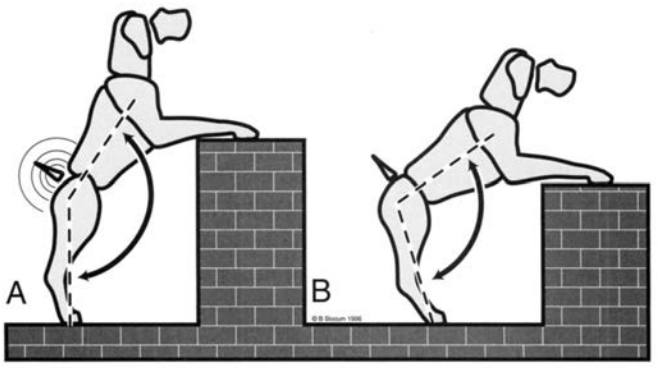

Figure 60-45. The stand test is performed by picking up the front legs of a standing dog. **A.** A normal dog extends the hips and back to relish the attention of the owner. **B.** The abnormal dog protrudes the rump in an attempt to maintain flexion of the hip and back. The abnormal dog usually attempts to return to the standing on all four legs and may even mock bite the hands holding the dog.

Physical Examination in an Awake Patient

Abduction External Rotation Test

The physical examination is the primary means of demonstrating that a patient's lameness or soreness is coming from the hip, lower lumbar spine, or lumbosacral disc. The abduction external rotation test is not specific to hip dysplasia, but it suggests dorsal joint capsule inflammation. Because this test creates discomfort in the hip, the owner should be forewarned of the patient's possible pain response. Only enough external rotation to elicit a response is necessary. This should be the last test performed on the caudal portion of the dog if patient cooperation is expected.

Testing Procedure

The orthopedist is caudal to the patient while an animal health technician restrains the patient's head. The right and left hips are tested independently. The examiner's right hand holds the patient's right stifle. The stifle is used to flex and externally rotate the right hip. The hip is abducted, externally rotated, and extended simultaneously. A negative response from the patient is indifference. A positive response from the patient varies, depending on the dog's personality, from guarding the hip against manipulation, to vocalization, to attempting to bite the operator.

The abduction external rotation test stresses the attachment of the joint capsule at the DAR, to stimulate a pain response in the inflamed hip. The hip inflammation is caused by repeated tearing of the joint capsule as the femoral head translates laterally and dor-sally. The final dorsal migration of the femoral head creates the capsular tearing. After the repeated tearing of the capsule dorsally, the capsule thickens and attempts to heal by fibrosis. The normal joint capsule at the DAR is thin and almost transparent, but it is stout cranially and caudally.

A positive response from the patient indicates that inflammation is present. This test does not quantify the amount of inflammation. The acute tearing of the young patient is usually painful, because it is complete and creates a tremendous stretching on the cranial and caudal capsule. The tearing of the older patient's joint capsule is usually not so extensive. The joint capsule with a more chronic disorder supports the femoral head by hypertrophy and fibrosis. This test is also positive if the lower lumbar spine or lumbosacral disc is inflamed by causing a torsion of the affected inflamed disc.

Hip Extension Test

This physical examination is a primary means of demonstrating that lameness is emanating from the hip or back. This test is not specific to the hip because it tests the dog's response not

only to the inflamed and thickened joint capsule, but also to the contracted iliopsoas and lower back inflammation. Because the hip extension test creates discomfort, the owner should be forewarned of the possibility of aggressive or painful behavior.

Testing Procedure
The orthopedist is caudal to the patient while an animal health technician restrains the patient's head. The right and left hips are tested independently. For testing a small dog's right hip, the operator places his or her fingers around the cranial thigh and the thumb on the dorsal ischial table. The patient's hip is extended by pulling the examiner's fingers to the thumb. For large dogs, the fingers of the right hand are placed around the cranial right thigh at the stifle, and the left hand is placed over the dog's rump. The operator extends the dog's hip by pulling the femur caudally, while the left hand prevents the dog moving away from the doctor. The left hip is similarly tested. A negative response from the patient is indifference. A positive response from the patient varies, depending on the dog's personality, from guarding the hip against manipulation, to vocalization, to attempting to bite the operator.

The hip extension test tightens the joint capsule around the neck of the femur. This stretches an inflamed joint capsule like wringing a mop. The hip inflammation is present because of repeated tearing of the joint capsule as the femoral head translates laterally and dorsally. After the repeated tearing of the capsule dorsally, the inflamed capsule thickens and attempts to heal by fibrosis. A positive response from the patient indicates that hip joint capsule inflammation is present. This test does not quantify how much inflammation is present, only that it is present. This test may show discomfort of the lower lumbar spine or lumbosacral disc inflammation by extending the lower back.

The stand test creates similar conditions of hip extension and lordosis (back extension), but in the stand test, the patient extends only as far as comfort allows. Interpretation of the hip extension test and the stand test is similar.

Hip Subluxation Test

This physical examination is a primary means of demonstrating that a patient's lameness or soreness is coming from the hip. This test is specific to the dysplastic hip because it tests the dog's response to the inflamed dorsal joint capsule. The owner should be forewarned that the patient may create its own discomfort by contracting the muscles that force the femoral head against the irritated joint capsule. This should be the last test performed on the caudal portion of the dog, if patient cooperation is expected.

Testing Procedure
The orthopedist is on the side of the hip to be tested, while an animal health technician restrains the patient's head. The right and left hips are tested independently. For the right hip, the fingers of the examiner's right hand are placed medial to the proximal femur from cranially, and the right thumb is placed on the right ilium. For large dogs, it may be helpful to prevent the hip from abducting by placing the left hand on the lateral stifle. The examiner pulls laterally on the femur and pushes medially on the ilium with the thumb at the same time. A negative response from the patient is indifference. A positive response from the patient varies from guarding the hip against further manipulation, to vocalization, to attempting to bite, depending on the dog's personality. The left hip is similarly tested.

The hip subluxation test stresses the attachment of the joint capsule at the DAR. As the hip subluxates laterally by the examiner's lateral pressure on the proximal femur, the patient contracts the thigh muscles to protect the hip against the anticipated pain. This muscular contraction causes the hip to translate dorsally into the inflamed dorsal joint capsule. This causes a positive pain response. The hip inflammation is present because of repeated stretching of the joint capsule as the femoral head translates laterally. The dorsal migration of the femoral head after lateral translation creates the capsular tearing and high inflammation in the diseased hip.

The normal joint capsule at the DAR is thin and almost transparent, but it is stout cranially and caudally. After repeated stretching and tearing of the capsule dorsally, the capsule thickens and attempts to heal by fibrosis. A positive response from the patient indicates that inflammation is present. This test does not quantitate the amount of inflammation. The acute stretching in the young patient is usually painful because it creates a tremendous stretching on the cranial and caudal capsules. The acute tearing of the dorsal joint capsule resulting from dorsal translation in the young patient is usually painful because it lacks capsular support of the more chronic cases. The per incident tearing of the older patient joint capsule is usually not so extensive, and the joint capsule with a more chronic disorder has the support of hypertrophy and fibrosis cranially and caudally.

The hip subluxation test is useful in distinguishing between hip and back pain because it is specific to the hip and independent of the lower lumbar spine or lumbosacral disc inflammation.

Iliopsoas Testing

This physical examination is a primary means of demonstrating that lameness is emanating from the iliopsoas muscle. This test is specific to the iliopsoas because it tests the dog's response to the inflamed iliopsoas muscle. Because iliopsoas testing creates discomfort, the owner should be forewarned of the possibility of aggressive or painful behavior.

Testing Procedure
The orthopedist is lateral to the patient while an animal health technician restrains the patient's head. The right and left hips are tested independently. For testing a dog's right iliopsoas muscle, the operator places his or her fingers around the patient's cranial thigh and applies digital pressure over the iliopsoas just caudal to the origin of the pectineus muscle. The iliopsoas muscle is further tested by extending the hip and digital palpation. In addition, the iliopsoas muscle is tested further by extending the hip plus digital palpation of the muscle with internal rotation of the hip. The left hip is similarly tested. A negative response from the patient is indifference. A positive response from the patient varies, depending on the dog's personality, from guarding the hip against manipulation, to vocalization, to attempting to bite the operator.

The direct digital palpation of the iliopsoas muscle causes pain in the inflamed muscle. Extension of the hip causes pain by stretching the inflamed muscle. The internal rotation of the hip also lengthens the inflamed iliopsoas muscle. The pain experienced by the patient is in direct proportion to the amount of inflammation, digital pressure, and stretching of the muscle. This test does not quantify the degree of inflammation. The digital test and internal rotation test are specific to the iliopsoas muscle.

Physical Examination in an Anesthetized Patient

Angles of Reduction and Subluxation

The meaning of hip palpation has been incompletely understood because of imprecise definition and measurement. The Ortolani sign occurs during hip abduction and is created when the femoral head is reduced into the acetabulum from a luxated position with a "shift" or "clunk." The angle of reduction is the measurement of the angle of abduction from the sagittal plane to the physical position at which hip reduction occurs.

The Barlow sign is a palpation event during which the femoral head is luxated from the acetabulum. The Barlow sign occurs during hip adduction and is created when the femoral head is luxated from the acetabulum into a position of joint capsular support with a "shift." The angle of subluxation is the angle between the sagittal plane and the physical event of hip luxation at which the hip first begins to luxate. By definition, the angle of subluxation is measured as positive if the hip is lateral to the sagittal plane when subluxation occurs (Figure 60-46) and negative if the hip is medial to the sagittal plane when subluxation occurs.

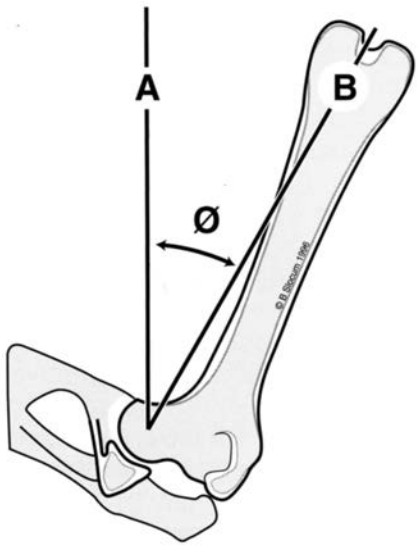

Figure 60-46. Measuring hip angle *(Ø)* is done in dorsal recumbency with the sagittal plane *(A)* as vertical. The femoral axis *(B)* is between the center of the femoral head and the center of the intercondylar notch where it meets the articular surface of the trochlear sulcus. Ø is positive when the hip is abducted; that is, the distal femur is lateral to the sagittal plane as shown; Ø is negative when the hip is adducted, and the distal femur is medial to the sagittal plane.

Techniques of Measurement

The patient is anesthetized and is placed in dorsal recumbency.

Angle of Reduction

The stifle is brought to the starting position of vertical, without hip flexion or extension, by using a medially directed force of the operator's hand on the lateral stifle. Axial femoral compression by the operator is not necessary in the immature patient, although it may clarify the angle at which reduction occurs in a patient with a chronic case. The hip is then abducted slowly by reducing the medially directed force at the stifle. When hip reduction occurs, abduction is stopped. Reduction of the hip is detected in three possible ways: a "clunk" is heard; a shift of the patient's limb is seen or palpated; or the event can be recorded by cineradiography. In chronic hip dysplasia, a "fast spot" or rapid abduction is palpated, instead of a "clunk," as the hip reduces under the influence of abduction.

The angle of reduction is measured by the Canine Electronic Goniometer (Slocum Enterprises, Eugene, OR), which was designed for this purpose. The probe is placed just caudal to the attachment of the pectineus on the iliopectineal eminence. The side of the goniometer is touched to the medial side of the stifle (Figure 60-47 and 60-48). The angle of reduction is read directly from the digital readout with accuracy to 0.1° (Figure 60-49).

Angle of Subluxation

To obtain the angle of subluxation, the stifle is slowly returned to vertical from the abducted position at which the angle of reduction was taken. The hip is adducted slowly by increasing the medially directed force at the stifle. When the hip begins to luxate (subluxate), adduction is stopped. Here again, axial femoral compression by the operator is not necessary, but it may clarify the angle at which subluxation occurs in patients with a chronic disorder.

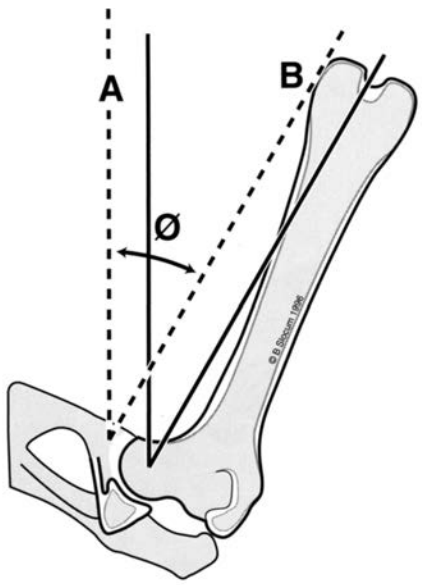

Figure 60-47. The axis of measurement for the Canine Electronic Goniometer *(dotted line, B)* is parallel to the defined axis (solid line). Because the sagittal plane *(A)* is defined by gravity, the angle Ø remains the same.

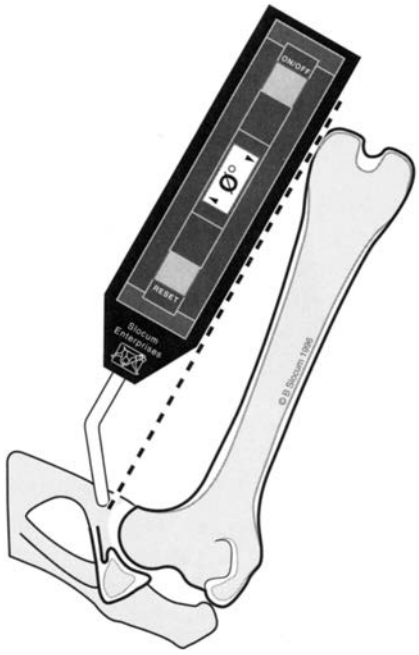

Figure 60-48. The Canine Electronic Goniometer measures the angle with respect to gravity, the sagittal plane is 0°, obtained in dorsal recumbency of the patient. The probe is placed just caudal to the iliopectineal eminence; the body of the goniometer is touched to the medial femoral condyle, and the angle Ø is recorded from the digital readout.

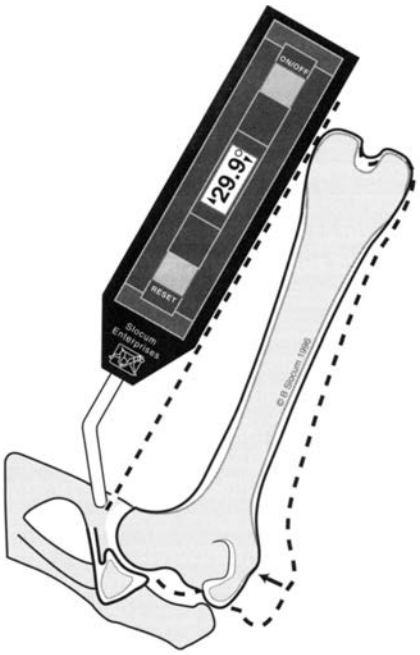

Figure 60-49. The angle of reduction is measured, 29.9° in this example, immediately after the abduction event of hip reduction *(arrow)*.

Luxation of the hip is detected in three ways: a "shift" is palpated; a "shift" is seen; or the event can be recorded by cineradiography. In cases of chronic hip dysplasia, a "fast spot" or rapid abduction is palpated, instead of a "shift," as the hip luxates under the influence of adduction. The angle of subluxation is measured by the Canine Electronic Goniometer. The probe is placed just caudal to the attachment of the pectineus on the iliopectineal eminence. The side of the goniometer is touched to the medial side of the stifle (Figure 60-50), and the measurements are recorded. The measurements of the angles of reduction and subluxation are repeated on the other hip.

Two angles are measured for each hip, the angle of reduction and the angle of subluxation. The format for recording this information is (angle of reduction/the angle of subluxation), that is, AR/AS = 29.9°/14.5°. The angle of reduction is always greater than the angle of subluxation.

The angle of reduction represents joint laxity, that is, the stretching of the joint capsule and its tearing from the DAR. The greater the angle of reduction, the greater is the stretching of the joint capsule dorsally. The stretching of the joint capsule dorsally determines where the DAR will contact the femoral head. The physical contact point between the rim and the femoral head determines the amount of abduction necessary before the axial force of the femur (the direction not the magnitude) is directed medial to that contact point. The femoral head falls into the acetabulum when that condition exists (Figure 60-51). For this reason, abduction is necessary to create hip reduction.

When the stretching of the joint capsule is small, the contact point is almost dorsal on the femoral head when the limb is in the sagittal plane. As the joint capsule stretches, the femoral head is allowed to translate laterally and then dorsally, and the point of contact between the DAR and the head moves further medially on the femoral head. The lateral and dorsal translation of the femoral head is limited by the ligament of the femoral head. This causes the contact point of the DAR and the femoral head to be just dorsal to the fovea capitis. This is the outer limit of capsular stretching without damage to the teres ligament. When the femoral head rests in this position, all the forces transmitted to the DAR from the femoral head have to do so through

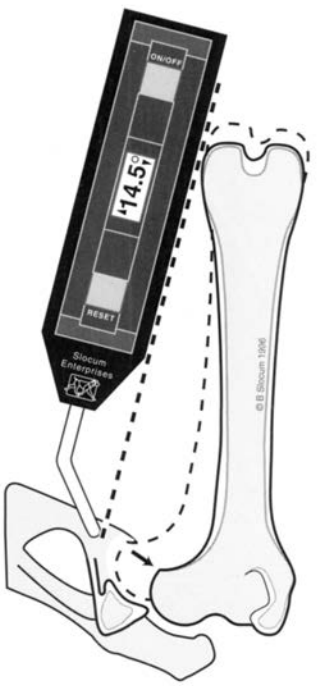

Figure 60-50. The angle of subluxation is measured, 14.5° in this example, immediately after the adduction event of hip luxation *(arrow)*.

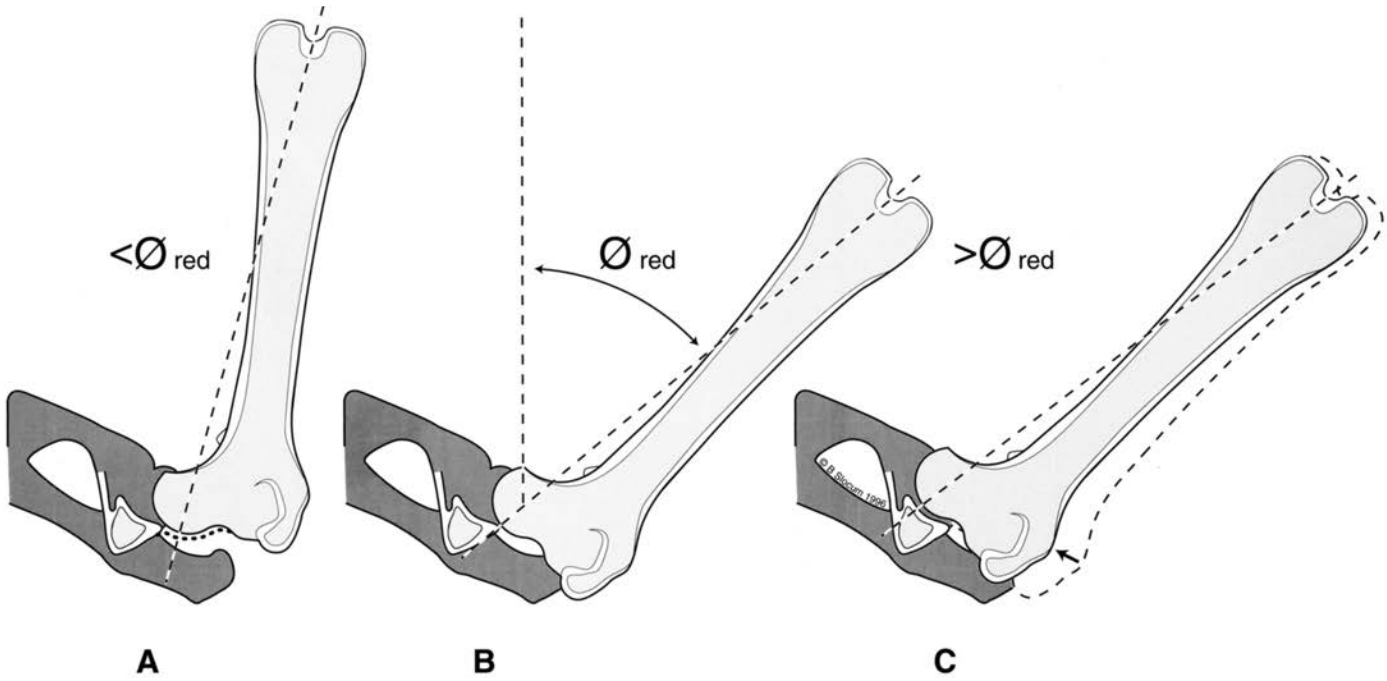

Figure 60-51. A. Hip reduction by abduction begins (less than $Ø^{red}$) with the femoral head resting and stable in the dorsal joint capsule *(dotted line)* (hip luxated) and the acetabulum contacting the femoral head medial to the axial line of femoral force between the joints *(dashed line)*. **B.** As the hip is abducted, the joint capsule supporting the femoral neck through the cranial and caudal ligaments causes the femoral head and the dorsal acetabular rim to contact along the axial line at angle $Ø^{red}$, which makes the hip unstable. **C.** Any further abduction (greater than $Ø^{red}$) causes the femoral head to contact the dorsal acetabular rim lateral to the axial line of force, and the femoral head shifts into the acetabulum *(arrow)*. The femoral head is now stable within the confines of the acetabulum when greater than $Ø^{red}$.

a reduced area of contact. This extreme force per unit area of contact between the femoral head and the DAR damages the cartilage of the femoral head just above the fovea capitis. This damage begins with fibrillation of the cartilage and ends with bone rubbing on bone and distortion of both the femoral head and acetabulum as end-stage events. The angle of reduction increases further only with stretching of the teres ligament or breakdown of the dorsal acetabulum. The angle of reduction decreases with capsular fibrosis and osteophyte production on the DAR that initiates capsular stabilization by resisting further dorsal translation.

The angle of subluxation represents the functional slope of the acetabulum beneath the dorsal rim. The actual slope of the DAR may be less than the angle of subluxation, if the ligament of the femoral head is redundant or the acetabulum is filling with osteophytes. For subluxation of the hip to occur, the femoral head and the acetabulum must interact, but not the joint capsule (Figure 60-52). The direction of the axial femoral force is into the acetabulum following the measurement of the angle of reduction. As the hip is adducted, the axial femoral force becomes normal to the DAR slope that was the last position of stability. Any further adduction of the hip directs the axial femoral force lateral to the perpendicular of the DAR surface, and so the femoral head translates laterally to rest in the joint capsule. In the normal hip, no significant joint capsule laxity exists to allow enough lateral translation of the femoral head for subluxation. All hips have some laxity, as clearly established by Penn-Hip. PennHip is a commercial registry which reads distraction and compression hip radiographs for hip laxity. The laxity is normalized to the femoral head and expressed as the Compression Index, C.I. (C.I. = displacement of the femoral head divided by the radius of the femoral head.) C.I. < 0.30 is normal for most breeds.

As some normal puppies undergo rapid growth between 4 and 6 months of age, the adductor muscle mass (and moment) overpowers the abductor muscles because of the temporary lack of adductor muscle length. As a consequence, the relative hip adduction directs the axial femoral force lateral to the DAR, and the femoral head is contained in its lateral translation by the joint capsule. The joint capsule is stretched, producing joint laxity. The result is an increased angle of reduction and distractive index of PennHip. In such patients, the angle of reduction is high because of the lax joint capsule, but the DAR angle is normal. The angle of subluxation may be 0° or negative because the DAR slope is normal. Such laxity is not hip dysplasia, because the conformation of the hip is normal and the stretched capsule is temporary, whereas hip laxity, caused by capsular stretching that accompanies acetabular hip dysplasia, is secondary to an increased slope of the DAR (the cause of stretching) and remain until the slope of the DAR is normalized by a pelvic osteotomy. This example of rapid growth syndrome in puppies with lax capsules that allow hip luxation confirms our clinical experience that hip joints can be lax without being pathologic. In addition, these puppies have become certified by OFA as normal when trauma to the hip is prevented by conservative management during 5 to 12 months of age. The angle of subluxation may even be a negative number in the nonpathologic hip or after a pelvic osteotomy.

In the pathologic hip, the angle of reduction is easily palpated in the young patient (6 months), but it may be difficult to palpate in

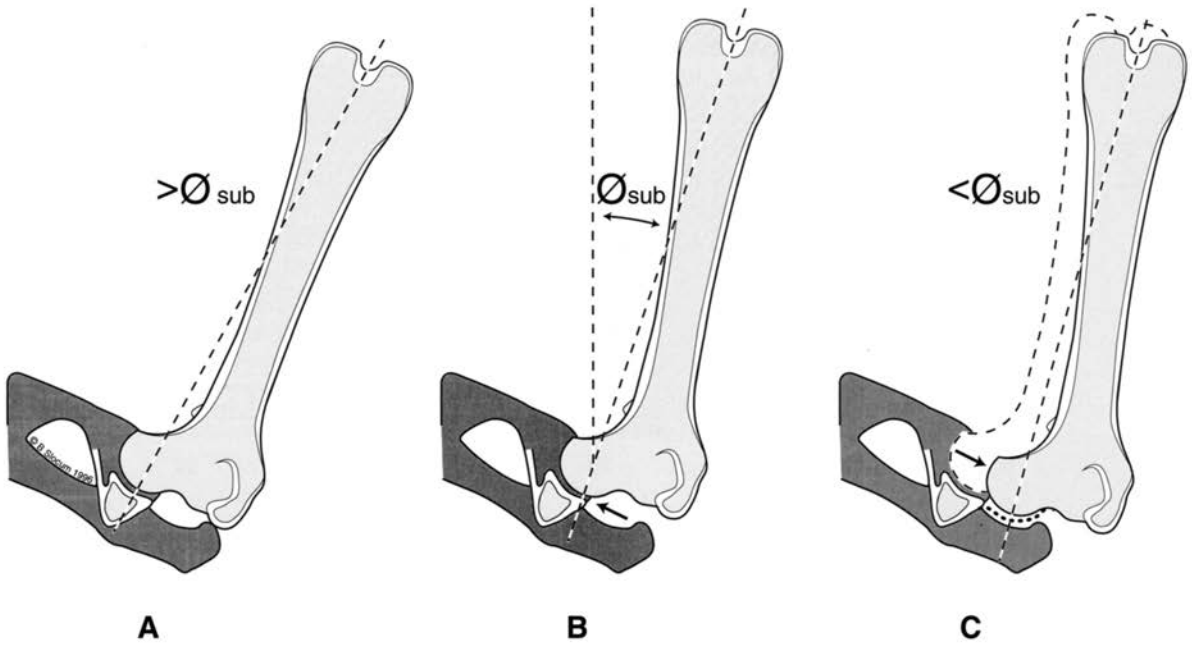

Figure 60-52. A. Hip luxation by adduction begins (greater than $Ø^{sub}$) with the femoral head resting and stable in the acetabulum and the femoral head contacting the dorsal acetabular rim lateral to the axial line of femoral force between joints *(dashed line).* **B.** As the hip is adducted, the femoral head contacts the dorsal acetabular rim at $Ø^{sub}$ along the axial line, and the hip is unstable. **C.** Any further adduction (less than $Ø^{sub}$) causes the femoral head to contact the dorsal acetabular rim medial to the axial line of force, and the femoral head luxates *(arrow)* into the joint capsule *(dotted line).*

the older patient (often by 2 years). The angle of reduction usually increases until the patient reaches the limit of stretching of the teres ligament and the joint capsule. Once the femoral head rests in the luxated position, the acetabulum fills with osteophytes, even though the femoral head may occasionally reduce. The joint capsule becomes fibrotic and thickened. As this dysplastic process progresses, the angle of reduction begins to decrease and finally becomes difficult to palpate.

In the pathologic hip, the angle of subluxation is greater than 0° and slowly increases, but it never decreases. This increasing angle is caused by the increased DAR slope because of acetabular filling and teres ligament redundancy. As the angle of reduction decreases and the angle of subluxation increases, one sees a single angle at which the femoral head shifts between capsular support and acetabular support. This is called the angle of translation (Figure 60-53).

Simply stated, a great difference between the angle of reduction and the angle of subluxation (i.e., 40/5) indicates a healthy hip with a stretched joint capsule, or a young dog's hip in the early stages of hip dysplasia that can be readily repaired with good results and no arthritis. A moderate difference between the angle of reduction and the angle of subluxation (i.e., 30/15) indicates a hip in immediate need of a pelvic osteotomy, but the status of the articular cartilage and acetabular filling needs to be assessed. A small difference between the angle of reduction and the angle of subluxation (i.e., 25/22) indicates a hip that is filling with osteophytes and is no longer a candidate for a pelvic osteotomy. A small difference between the angle of reduction and the angle of subluxation in the near-0° range (i.e., 10/0) indicates a normal hip with some capsular stretching with no need for surgical intervention.

The angle of reduction and the angle of subluxation are critical parts of the hip evaluation and are excellent indicators of status of hip health, especially at 6 months of age. Hip palpation at the time of neutering is a perfect opportunity to assess the patient for future hip problems, because it gives the owners information about whether their pet is at risk for hip dysplasia.

Ortolani Sign

The Ortolani sign is a palpation finding which was originally used in human medicine as an indicator of hip dysplasia. This sign occurs when the luxated hip enters the acetabulum with a "clunk."

Testing Procedure

The anesthetized patient is placed in dorsal recumbency. The palm of the operator's left hand is lightly placed on the lateral side of the patient's flexed right stifle. The left thumb is placed over the medial femoral condyle adjacent to the patella. The starting position is hip adduction without flexion or extension. In this position, the hip luxates from the acetabulum. The hip is slowly abducted.

If a "shift" or "clunk" in the hip is palpated, then the Ortolani sign is positive. If no "shift" or "clunk" in the hip is palpated, then the Ortolani sign is negative. The process is also repeated for the left hip by using the operator's right hand on the patient's left stifle.

The "shift" or "clunk" palpated in the hip is the reduction of the femoral head. Reduction of the femoral head into the acetabulum can only occur if the joint capsule has been stretched. A positive Ortolani sign means that the joint capsule is stretched. A negative Ortolani sign means either that the joint capsule is not

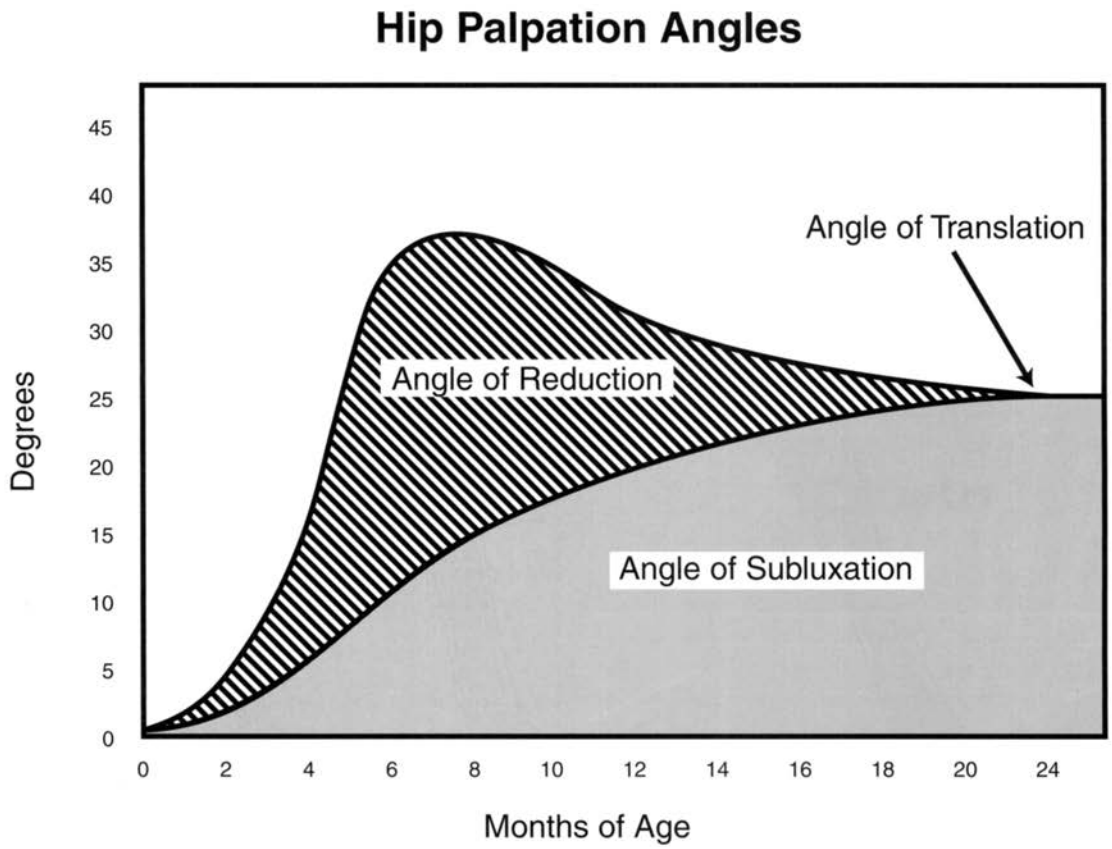

Figure 60-53. The natural progression of the angles of reduction and subluxation over time in the moderately dysplastic dog has repeatable characteristics. Early (0 to 7 months) joint capsular stretching is accompanied by a rapid increase in the angle of reduction. As time passes, the capsule becomes thickened and stabilizes the hip. The angle of subluxation, which is a function of femoral head and acetabular interaction, represents dorsal acetabular damage, acetabular filling, and ligamentum teres redundancy. The angle of subluxation increases most rapidly in the early adolescent period (5 to 8 months), when the acetabulum is subjected to high force per unit area by the luxating femoral head in the lax joint capsule. As filling of the acetabulum occurs by osteophytes forming under the influence of inflammation within the joint and the joint capsule thickens, the rate of increase of the angle of subluxation slows. The angle of subluxation continues to increase until the angle of reduction equals the angle of subluxation, called the angle of translation (AT). At the AT, the femoral head is supported by the capsule when Ø is less than AT, and the femoral head is supported by the acetabulum when Ø is greater than AT.

stretched or that the hip is not reducible into the acetabulum. Chronic fibrosis of the joint capsule often makes the transition from luxation to reduction so subtle as to go undetected.

The Ortolani sign does not represent hip dysplasia, but it indicates joint capsule stretching, which often accompanies hip dysplasia. Joint laxity is not hip dysplasia, but it is one secondary manifestation of the hip dysplastic process. Joint laxity occurs when the joint capsule is stretched. Joint capsule stretching has many causes, the most common being hip dysplasia.

To reduce the hip, the femoral head must enter the acetabulum. The angle of abduction at which the head begins to enter the acetabulum during hip abduction is the angle of reduction. This angle is the angle at which the femoral head becomes stable and relocates because of the axial compressive force direction. The angle of reduction depends on the amount of stretching of the joint capsule.

Barlow Sign

The Barlow sign is a palpation finding originally used in human medicine as an indicator of hip dysplasia. This sign occurs when the reduced hip leaves the acetabulum.

Testing Procedure

The anesthetized patient is placed in dorsal recumbency. The palm of the operator's left hand is placed lightly on the lateral side of the patient's flexed right stifle. The left thumb is placed over the medial femoral condyle adjacent to the patella. The starting position is hip abduction without flexion or extension. This position reduces the hip into the acetabulum. The hip is slowly adducted.

If a "shift" of the femoral head is palpated, then the Barlow sign is positive. If no "shift" of the femoral head is palpated, then the Barlow sign is negative. The process is also repeated for the left hip by using the operator's right hand on the patient's left stifle.

The "shift" palpated with the Barlow sign is luxation of the femoral head. Luxation of the femoral head from the acetabulum can only occur if the joint capsule has been stretched. A positive Barlow sign means that the joint capsule is stretched. A negative Barlow sign means either the joint capsule is not stretched or the hip will not reduce into the acetabulum. If the hip has chronic disease with a thickened joint capsule, the shift may be so subtle that it is missed by the operator.

The Barlow sign does not represent hip dysplasia, but it indicates joint capsule stretching, which often accompanies hip dysplasia. Joint laxity is not hip dysplasia, but it is a secondary manifestation of the hip dysplastic process. Joint laxity occurs when the joint capsule is stretched. Joint capsule stretching has many causes, and the most common cause of joint laxity is hip dysplasia.

To luxate the hip, the femoral head must leave the acetabulum. The angle of adduction at which the head begins to leave the acetabulum during hip adduction is the angle of subluxation. This angle is the angle at which the femoral head becomes unstable because of the axial compressive force direction and luxates. The angle of subluxation depends on the functional slope of the DAR.

Bardens Palpation

Bardens recognized laxity in the hip joints of 8-week-old puppies and discovered that those puppies were dysplastic as adults. Later, Brown studied the laxity of hips in rottweiler puppies by the Bardens method and confirmed that laxity and hip dysplasia were associated. Recently, laxity testing has been addressed by radiography and statistical analysis and has been shown to be present in hip dysplasia.

Bardens Palpation

The anesthetized 6- to 8-week-old puppy is placed in right lateral recumbency for testing of the left (up) hip (Figure 60-54). The operator's right hand is the measuring hand and the left hand is the testing hand. The thumb of the operator's right hand is placed on the left lateral prominence of the patient's tuber ischiadi-cum. The middle finger of the operator's right hand is placed on the left wing of the ilium. The index finger of the operator's left hand is placed on the left greater trochanter. The patient's left femur is grasped just below the greater trochanter by the left hand of the operator. A medial to lateral force is exerted on the proximal femur by the left hand that translates the greater trochanter laterally. This translation is recorded and measured.

For testing of the right hip, the operator's left hand is the measuring hand and the right hand is the testing hand. The experienced operator can distinguish among four groups of lateral hip translation: 1 to 2 mm; 3 to 4 mm; 5 to 6 mm; and greater than 6 mm:

Normal hip: 1 to 2 mm
Borderline hip: 3 to 4 mm
Dysplastic hip: 5 to 6 mm
Severely dysplastic hip: more than 6 mm

Although the Bardens palpation has never been well accepted as a definitive index of hip dysplasia, it is useful as a general indicator of hip dysplasia. The Bardens palpation has four main objectives. First, the method requires a skilled operator who can detect and measure the lateral laxity accurately. This makes the test difficult to generalize to all veterinarians. Second, the patient must be between 6 and 8 weeks of age to achieve uniformity in the population and the dysplastic process. Third, the scientific correlation of confirmation between the Bardens palpation and degree of hip dysplasia in the mature patient has not been clearly established. Fourth, hip laxity is not hip dysplasia but rather one measurable aspect of hip dysplasia and is dependent on joint capsule stretching. As we develop better means of measuring the lateral translation with accuracy and repeatability, this test may become the basis for future decisions about hip dysplasia.

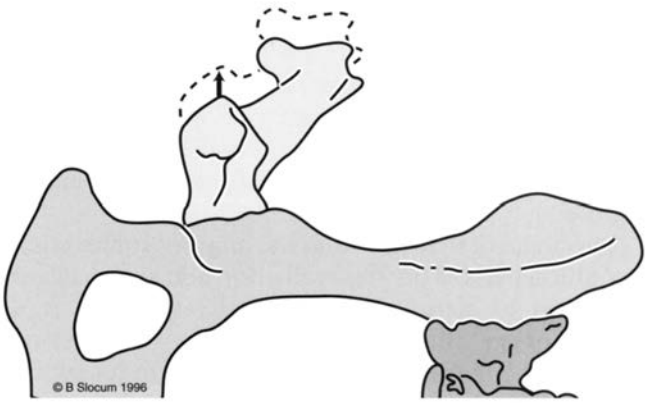

Figure 60-54. Bardens palpation of the left hip (up) requires the patient to be in right lateral recumbency. The left proximal trochanter is translated laterally *(dotted femur)* by a medial-to-lateral force on the proximal femur with the left hand. The right hand calibrates the amount of translation *(arrow)*.

Axial Compression Test of the Hip

The axial compression test is an intraoperative test for hip stability. Hip stability is achieved when the reduced hip remains in the acetabulum on axial compression of the femur in the sagittal plane.

Testing Procedure

To test the left hip, the patient is placed in right lateral recumbency. The examiner's right hand is placed on the dorsal rump of the patient. The left hand gently grasps the stifle and applies axial compression of the femur in the sagittal plane to the reduced hip (Figure 60-55).

If a "shift" of the femoral head is palpated as the hip luxates from the acetabulum, then the axial compression test is positive and the hip is unstable. If no "shift" of the femoral head is palpated, then the axial compression test is negative and the hip is stable. When the test is applied to the right hip, the operator's right hand is on the patient's stifle, and the left hand is on the rump.

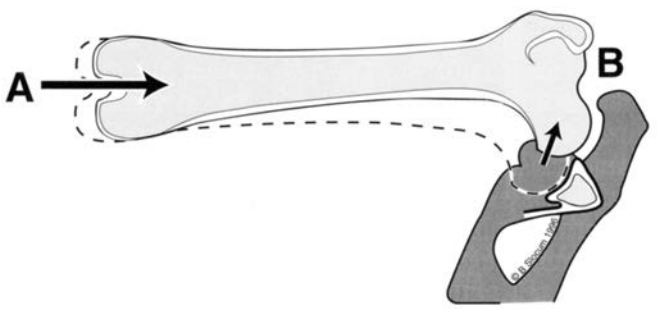

Figure 60-55. The axial compression test *(A)* is positive and the hip is unstable if a dorsolateral translation of the femoral head *(small arrow)* is detected by a lateral movement of the greater trochanter *(B)*. The test is negative, and the hip is stable, if no translation is noted.

The palpated "shift" is luxation of the femoral head. Luxation of the femoral head from the acetabulum can only occur if the slope of the DAR is too great to contain the head, if acetabular filling is present, or if the femoral head has a redundant ligament. No "shift" means that the DAR is able to contain the femoral head. Surgically, it means the axial rotation of the acetabular segment by pelvic osteotomy is sufficient. A hip joint is either stable or unstable to axial compression in the sagittal plane. If a hip is stable in the sagittal plane, additional rotation of the acetabular segment by pelvic osteotomy will only limit abduction of the hip and cause hip degeneration.

Radiographic Characteristics of Hip Dysplasia

Theresa Devine Slocum and Barclay Slocum

Evaluation of the canine hip for hip dysplasia involves gathering information on the history and attitude of the dog from the owner, performing a series of hip function assessment tests on the awake and anesthetized dog, and obtaining a three-dimensional view of the hip joint by radiographs. Examination of the dog for hip dysplasia is an important service to predict the physical ability of the young dog (6 months of age and older) to meet the owners' expectations for function and to provide the appropriate treatment for a dysplas-tic dog. Although hip dysplasia is defined by many authors as a congenital, bilateral, degenerative joint disease, or as hip laxity, limitations of these definitions are recognized clinically as we expand our knowledge of the disease and separate acetabular hip dysplasia from femoral hip dysplasia. The most important aspect of any definition is to acknowledge that hip dysplasia is a dynamic process, and any view of the disease is a window at one point in its progression.

Most cases of dysplasia involve acetabular hip dysplasia, which is characterized by excessive slope of the dorsal rim of the acetabulum, and its secondary osteo-arthritic changes. Because the major forces of the hip run parallel to the long axis of the femur, the contact between the femoral head and the acetabulum should be perpendicular to the axial femoral forces for a stable hip joint. In the young puppy, the femoral head presses into the pliable acetabulum to form a deep socket. After 4 months, the formation of the acetabulum is becoming complete. If the acetabulum is shallow because of insufficient magnitude or direction of forces pushing the femoral head into the developing acetabulum, the joint capsule becomes stretched or, worse, the cartilaginous labrum becomes fractured. With insufficient dorsal support to the femoral head, muscular forces must be relied on to stabilize the joint by forcing the head into the acetabulum. As the muscles become fatigued, the joint capsule becomes stretched, and the dorsal rim becomes damaged. The femoral head resides in an incongruent subluxated position. As the restraints to subluxation, the joint capsule and teres ligament, stretch and tear, the vicious cycle of osteoarthritis becomes evident. When the hip cannot be maintained in the acetabulum, yet is within the joint capsule, the hip is considered luxated. When the acetabulum fills with osteophytes and the femoral head cannot be congruent with the acetabulum, the hip has irreducible luxating hip dysplasia. A dislocated hip occurs when the hip is outside the traumatically torn joint capsule. As the stages of acetabular dysplasia progress, the treatment and prognosis for the hip must also match the degenerative process. Physical and radiographic information must be combined to provide the best evaluation of the canine hip.

The hip is a three degree of freedom joint, which means that it allows rotation about three orthogonal axes but no translation along those axes. Normal movements are flexion-extension, internal rotation-external rotation, and adduction-abduction. The dog is examined at a walk, trot, and run. Leg alignment, stride length, and movement in the sagittal plane are all noted. With the dog standing, the hip is slowly flexed and extended. A thickened and inflamed joint capsule causes the patient discomfort, and extension is resisted. Similarly, dysplastic patients usually refuse to stand erect with the hip in an extended position. The leg is abducted and externally rotated. Any apprehension indicates irritation to the inflamed tissue between the femoral neck and the dorsal rim of the acetabulum. Inability to abduct the leg indicates a contracted pectineus muscle. With the patient under anesthesia, the hip is palpated to reveal the viability of the cartilage of the femoral head and the acetabulum. With the dog in dorsal recumbency, the angle of reduction (the angle from vertical when reduction occurs during abduction) is measured; this angle is an indicator of joint capsule laxity. The greater the angle of reduction, the greater is the stretching or tearing from the dorsal acetabular rim (DAR) that has occurred to the joint capsule. The angle of subluxation (the angle from vertical when the luxation occurs during adduction) is measured. This angle increases proportionally to the damage to the dorsal rim of the

acetabulum and acetabular filling. The trochanteric compression test reveals the preferred position of the femoral head with respect to the acetabulum; normally, it is within the acetabulum. A normal dog shows no apprehension or pain during the physical examination and enjoys the attention. Under anesthesia, a dog with normal hips demonstrates no angle of reduction or subluxation and has a negative trochanteric compression test.

Clinically, our radiographic examination uses six radiographic views: ventrodorsal, lateral, DAR, frog, compressed ventrodorsal, and distracted ventrodorsal views. The ventrodorsal, lateral, and DAR views are orthogonal and therefore give a "three-dimensional" study of the hip (Figure 60-56A and B). Because positioning is essential in evaluating these radiographs, the dog is anesthetized for this portion of the examination. In the normal hip, the ventrodorsal view shows the femoral head to be deeply seated under the acetabulum with at least 50% coverage by the dorsal rim. Congruence exists between the subchondral bone of femoral head and the cranial acetabulum. Any torsion of the femur or anteversion of the femoral head is readily recognized with this view. The ventrodorsal view is useful for determining pelvic torsion, which often mimics unilateral hip dysplasia and is usually associated with a transitional vertebra. In the sublux-ated hip, the femoral head is partially covered by the dorsal rim of the acetabulum. One sees incomplete congruence of the joint and cupping of the acetabulum. In the luxated hip, the femoral head resides outside the acetabulum, and there is no congruence of the hip joint. As the disease process worsens, one can see a thickening of the neck of the femur and, occasionally, dorsal acetabular osteophytes forming.

The frog view is useful to determine acetabular filling with osteophytes (Figure 60-57). The examiner must not lever the femoral head out of the acetabulum by abduction beyond 45°. The normal hip joint rests easily in the socket, whereas in the dysplastic hip, the femoral head is unable to seat fully in the acetabulum. This is indicative of filling of the acetabulum with osteophytes or a redundant teres ligament. As the dysplastic process progresses, the frog view demonstrates this condition.

The lateral radiograph of the pelvis and lower lumbar spine is useful for differentiating hip dysplasia from spondylitic bridging at L7-S1, which is often associated with the painful cauda equina syndrome. A normal hip shows congruence and concentricity of the femoral head within the acetabulum. In the dysplastic hip, the concentricity of the femoral head becomes less visible, and rather than a "white-black-white" description of normal congruence, a "white-gray-gray" description is common. Dorsal acetabular osteophytes are often seen as a white line over the femoral head.

Perhaps the most informative radiographic view is the DAR view. The dog is placed in a sternal recumbency with the hind legs pulled cranially to rest along the side of the thorax. A circumferential belt holds the stifles against the torso. Four-inch elevation of the hocks provides hamstring tension that causes enough rotation on most dogs to allow the x-ray beam to pass through the longitudinal axis of the pelvis. This view enables us to see the weightbearing portion of the acetabulum in cross section. In normal dogs, the DAR view shows the dorsal rim of the acetabulum to be sharply pointed. The femoral head is well seated and is covered by the acetabulum. When measured, the DAR angle is 7.5° or less, from a line perpendicular to the long axis of the pelvis. Normal hips have a combined left and right DAR measurement of 15° or less. Congruence of the hip joint is apparent with this view. A dog with normal hips continues to have a normal DAR angle throughout its lifetime.

As the hip is damaged by dysplasia, sclerosis of the rim can be seen on the DAR radiograph. The shape of the rim progresses from slightly rounded to blunted and broken off. Concurrently, the slope of the rim becomes increased. The dorsal acetabular osteophytes, so difficult to visualize on the ventrodorsal radiograph, are obvious with the DAR view. The femoral head moves dorsally and laterally, and filling of the acetabulum occurs. As the process of dysplasia progresses, the osteoarthritic changes can be seen clearly with this view. Lack of congruity and loss of cartilage are easily noted. When measured on the DAR view, dogs with hip dysplasia have a combined DAR slope of 20° or more. The slope continues to increase as the dysplastic changes occur.

The importance of the DAR view is that it corresponds to hip palpation under anesthesia and provides the information necessary to determine the treatment of choice for the individual dog. As stress is placed on the DAR with the early stages of dysplasia, the rim shows slight rounding. On palpation, the hip makes a smooth transition from the subluxated position into the acetabulum, indicating integrity of articular cartilage of the head and acetabulum and minimal stretching of the joint capsule. As frequent intermittent subluxation occurs, palpation reveals smooth cartilage and a stretched joint capsule, noted by a "clunk" as the hip moves from subluxation to reduction. The acutely luxating femoral head causes a bevel to the rim, characteristic of a torn joint capsule and a worn labrum. With palpation, this correlates to a fine granular crepitus of articular cartilage fibrillation and abrupt dorsal translation of the femoral head. In chronic conditions, no distinct transition between reduction and subluxation is palpated because of acetabular filling and capsular fibrosis. The DAR radiograph measurement provides the amount of pelvic rotation for a triple pelvic osteotomy in patients that still have cartilage on the femoral head. This measurement is the amount of rotation necessary for support of the femoral head by the acetabulum. If the DAR measurement shows a 20° slope, then a 20° Canine Pelvic Osteotomy Plate (Slocum Enterprises, Eugene, OR) is necessary for corrective surgery. Postsurgically, a tomogram of the DAR allows visualization of the amount of rotation performed with pelvic osteotomy. Overrotation can be prevented as a result of this radiographic technique.

Femoral dysplasia on physical examination has the same characteristics as acetabular dysplasia; however, it is most easily differentiated radiographically, and with palpation under anesthesia. The ventrodorsal radiograph shows a shortened femoral neck and a lack of coverage and congruity in the hip joint. In the early stages of femoral dysplasia, the hip may have an angle of reduction of less than 10° and an angle of subluxation of less than 0° on palpation. The lateral radiograph shows femoral head anteversion. The DAR view may appear normal if

			E. Loss of articular cartilage seen by narrowing of joint space

Figure 60-56B. Three-dimensional radiographic matrix findings for normal hip, subluxating hip dysplasia, reducible luxating hip dysplasia, and irreducible hip dysplasia.

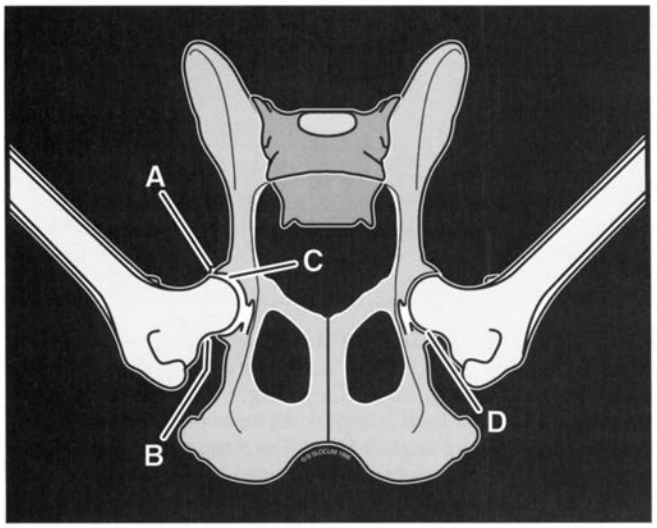

Figure 60-57. A frog view is taken with the hips in 45° of abduction. The normal hip has a narrow cartilage line *(D)* and no osteophytes, whereas the dysplastic hip may have a dorsal acetabular osteophyte *(A)*, a femoral neck osteophyte *(B)*, and a wide cartilage space *(C)*, indicating acetabular filling by osteophytes or redundant ligamentum teres.

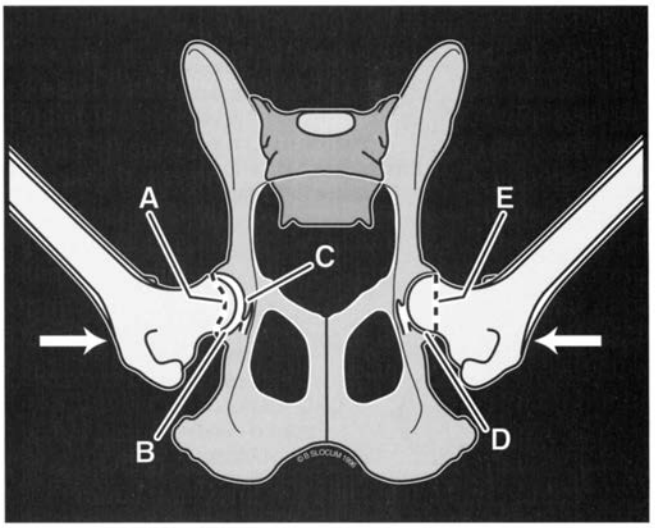

Figure 60-58. A compression view is a ventrodorsal view with the hips in 0° of abduction, no flexion, and a medial force on both greater trochanters *(white arrows)*. The normal hip has a narrow cartilage line *(D)*, no osteophytes, and a linear dorsal acetabular rim *(E)* viewed through the femoral head, whereas the dysplastic hip may have a cupped dorsal acetabular rim *(A)*, a wide cartilage space *(B)*, which indicates acetabular filling by osteophytes or redundant ligamentum teres, and ventral acetabular filling osteophytes *(C)*.

damage to the rim has not yet occurred. As the hip degenerates because of lack of support from the acetabulum, the dorsal rim becomes blunted. As a result, we then observe radiographically the same characteristics as acetabular dysplasia. Correct diagnosis of early femoral dysplasia is critical to the success of surgical treatment. If medially directed muscle force is insufficient to hold the hip in the acetabulum, an excessive amount of pelvic rotation will correct the situation but will lead to femoral neck impingement and reduced abduction. Femoral neck lengthening is the surgical treatment of choice. As the disease process continues, both femoral neck lengthening and pelvic osteotomy are necessary to obtain return of normal function. When both operations are necessary, a much lower rotation of the pelvis is adequate for correct coverage of the femoral head with acetabular stability.

Radiographic views taken using compression (Figure 60-58) and distraction (Figure 60-59) provide information on hip laxity. Bardens[1] first proposed a wedge technique to demonstrate radiographic joint laxity in the early 1960s, along with palpation. Radiographic techniques were further defined by Belkoff and associates in 1989[2], using a distraction device. Although this device allows passive laxity to be seen radiographi-cally, this has been used by Stoll[3] as a measure of the amount of femoral neck lengthening necessary when the dorsal acetabular slope has been reduced to 0°. Because passive capsular laxity is present in both dysplastic and nondysplastic hips, it should be considered a secondary indicator of hip dysplasia (Figures 60-60 and 60-61). The distraction displacement index is an indicator of passive joint laxity. Smith and colleagues[4] determined that a distraction index of 0.30 is the dividing line between normal hips and hips predisposed to hip dysplasia. Some dysplastic hips, however, have a distraction index less than 0.30, and some hips with a distraction index greater than 0.30 fail to show other dysplastic characteristics. The compression displacement index is an indicator of acetabular filling. In the clinical situation, laxity

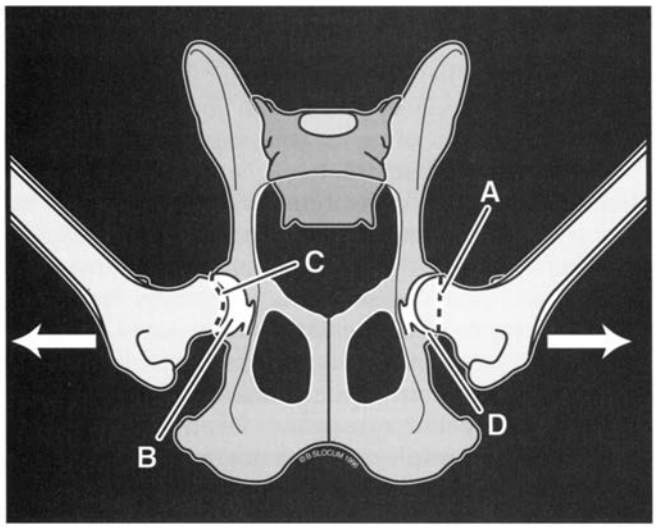

Figure 60-59. A distraction view is a ventrodorsal view with the hips in 0° of abduction, no flexion, and a lateral force on both proximal femurs *(white arrows)*. The normal hip has a narrow cartilage line *(D)*, no osteophytes, and linear dorsal a acetabular rim *(A)* viewed through the femoral head, whereas the abnormal hip may have a cupped dorsal acetabular rim *(C)* and a wide cartilage space *(B)*, which indicates a stretched joint capsule but not necessarily hip dysplasia.

of the joint capsule is palpated and measured as the angle of reduction. The angle of subluxation is a measure of the functional slope of the dorsal acetabulum because it is the result of interaction between the acetabulum and the femoral head.

In summary, correct evaluation of the hip joint is essential to understand the progression of hip dysplasia and to recognize the choice points of intervention. Physical and radiographic examination of dogs 6 months of age and older can provide accurate

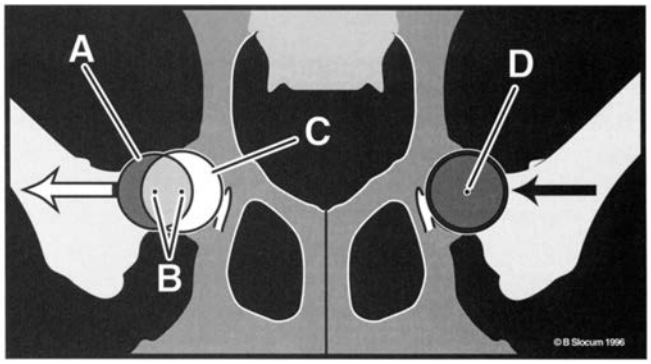

Figure 60-60. Lateral distraction of the femur *(white arrow)* causes lateral translation of the femoral head. The circle that overlies the acetabular subchondral bone *(C)* is larger than the circle that overlies the femoral head subchondral bone *(A)*. The centers of the two circles *(B)* are displaced by *d*. The distraction displacement index is equal to the displacement divided by the radius of *A, r: (DDI = d ÷ r)*. Medial compression of the greater trochanter *(black arrow)* causes the circles overlying the acetabular and femoral head subchondral bone of the hip to be concentric and the centers superimposed *(D)*, indicating that this hip is not abnormal. The compression displacement index is equal to the displacement *(d)* divided by the radius of *A, r. (CDI = d ÷ r)*. In the normal hip, *d* = 0; therefore, *CDI* = *d* ÷ *r* = 0.

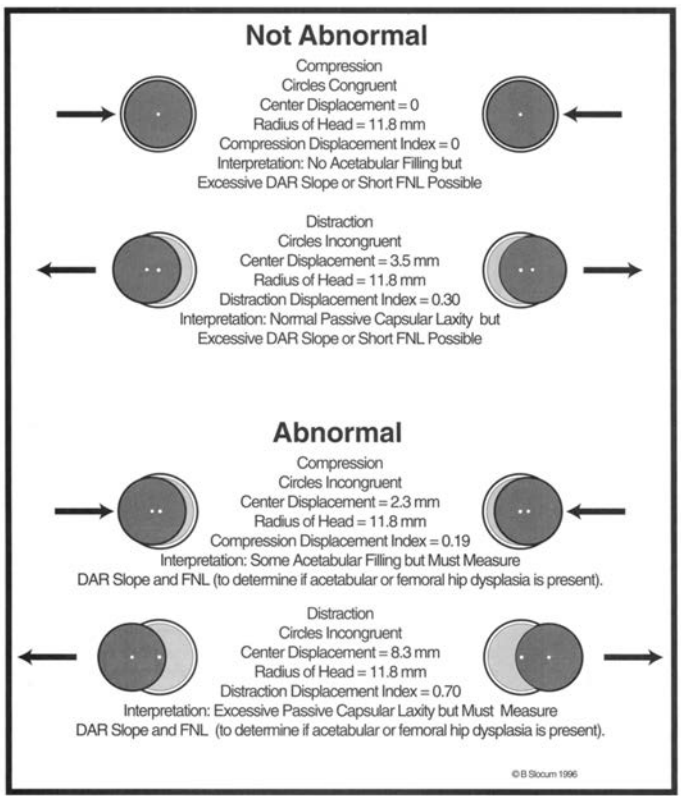

Figure 60-61. Schematic illustration of interpretation of the compression and distraction radiography. *DAR,* dorsal acetabular rim; *FNL,* femoral neck lengthening.

assessment of the hips. The patient can be treated appropriately to provide for the enjoyment and functioning of the dog for the rest of its lifetime.

Definitions of Hip Terms

Barclay Slocum and Theresa Devine Slocum

Acetabular Hip Dysplasia
Acetabular hip dysplasia is the malorientation of the acetabulum in the presence of normal depth. A slope of the dorsal acetabular rim (DAR) greater than 10.0° is considered to be acetabular hip dysplasia. The slope is usually reported as the sum of both the right and left DAR slopes, so a combined slope greater than 20.0° would be dysplastic. (A combined slope of 15.0 to 20.0° is suspect, whereas a combined slope of 15.0° or less is considered normal.) The minimum depth of the normal hip is 50% coverage of the femoral head by the DAR under ideal circumstances.

Angle of Reduction
The angle of reduction is the angle between the sagittal plane and the longitudinal axis of the femur when a "clunk" or shift is palpated as the femoral head enters the acetabulum during abduction of the hip in the anesthetized patient.

Angle of Subluxation
The angle between the sagittal plane and the longitudinal axis of the femur when a "clunk" or shift is palpated as the femoral head leaves the acetabulum during adduction of the hip in the anesthetized patient.

Barden Palpation
Barden palpation is a test for lateral translation of the hip. The lateral translation is a sign of joint capsule stretching: 1 to 2 mm is normal; 3 to 4 mm is suspicious; 4 mm or more is considered dysplastic.

Barlow Sign
The Barlow sign is the "clunk" or shift palpated as the femoral head leaves the acetabulum during adduction of the hip.

Coxarthrosis
Coxarthrosis is a general term for hip degeneration from nondysplastic sources that include, but are not limited to, rapid growth syndrome, osteochondritis dissecans of the lateral femoral condyle and transitional vertebra at the seventh lumbar vertebra or first sacral vertebral segment, osteochondritis dissecans of the femoral head, neurologic or neuromuscular insufficiency, degenerative myelopathy, intervertebral disc disease, autoimmune arthritis of the hip, infection of the hip joint, and neoplasia of the hip. Secondary manifestations of coxarthrosis are joint capsule laxity, tearing of the joint capsule, increase of synovial fluid, acetabular osteophytes, femoral osteophytes, acetabular filling, destruction of the dorsal acetabular rim, teres ligament hypertrophy or degeneration, and articular cartilage fibrillation or eburnation.

Darthroplasty
A DARrthroplasty is a dorsal acetabular rim arthroplasty. The dorsal rim of the acetabulum is augmented by bone graft that supports the joint capsule in cases that have a luxated hip. In essence, a new acetabulum is created to support the luxated hip.

Dislocation
The femoral head is unsupported by and resting outside the torn joint capsule, the ligament of the femoral head is torn, and the femoral head is outside the acetabulum.

Distraction Index
The distraction index is a ratio of the linear distance between the center of the femoral head and the center of the acetabulum with the hip in distraction, to the radius of the femoral head. In most breeds, normal hips have a distraction index up to and including 0.30.

Dorsal Acetabular Rim (DAR)
The DAR rim is that portion of the lateral rim of the acetabulum of about 30° that is crossed by a line through the centers of motion of the hip and stifle in the normal standing patient as viewed in the sagittal plane (lateral radiograph). This portion of acetabular rim is subjected to trauma by the femoral head during the dysplastic process.

Femoral Anteversion
Femoral anteversion is the cranial position of the femoral head when compared with normal. The femoral neck often has a valgus conformation. However, the relationships of other components of the femur are normal. Femoral ante-version alone is considered one form of hip dysplasia. Femoral anteversion in the presence of osteochondritis dissecans (OCD) of the lateral femoral condyle is considered a growth disturbance secondary to the OCD.

Femoral Hip Dysplasia
Femoral hip dysplasia is malorientation of the femoral head with respect to the greater trochanter when the limb is in the sagittal plane.

Femoral Neck Length
Femoral neck length is the distance from the lateral aspect of the greater trochanter to the medial aspect of the femoral head. A short femoral neck is considered one form of hip dysplasia.

Femoral Torsion
Femoral torsion is malorientation of the proximal femur with respect to the distal femur. However, the relationships of the components of the ends of the femur are normal. Femoral torsion is considered one form of hip dysplasia.

Hip Dysplasia
Hip dysplasia is an inherited condition of the hip that leads to the degeneration of the joint. Several anatomic variations from normal provide the biomechanical prerequisites for predictable

and progressive degeneration of the hip. Acetabular hip dysplasia is caused by malorientation or shallowness of the acetabulum. Femoral hip dysplasia is caused by a short femoral neck, anteversion of the femoral neck, or femoral torsion. Secondary manifestations of hip dysplasia are joint capsule laxity, tearing of the joint capsule, increase of synovial fluid, acetabular osteophytes, femoral osteophytes, acetabular filling, destruction of the dorsal acetabular rim, teres ligament hypertrophy or degeneration, and articular cartilage fibrillation or eburnation. These secondary changes are not hip dysplasia, but rather result from hip disorders. Nondysplastic conditions can cause the same secondary manifestations as hip dysplasia.

Juvenile Hip Malformation
Juvenile hip malformation is the hip deformity in which an extraordinarily shallow acetabulum is elongated and fails to match the femoral head. The pathogenesis of this condition is thought to be of neuromuscular origin because these patients usually have poor muscular tone, muscular weakness, and an uncoordinated movement. The condition is usually seen in young German shepherd dogs. Because of the pathogenesis, one could term the problem "neuromuscular hip dysplasia" or developmental coxarthrosis of neuromuscular origin.

Luxation
The femoral head is supported by and resting in the intact joint capsule and is incongruent with and not supported directly by the acetabulum.

Normal Hip
A normal hip has no appreciable laxity of the hip joint capsule, with a distraction index less than or equal to 0.30, and no angle of reduction is palpated. The hip has normal acetabular orientation (combined dorsal acetabular rim slope of up to 15°), normal acetabular depth (at least 50%), normal sacral conformation, normal femoral neck length, normal white-black-white articular line on the lateral radiograph, and no palpable angle of subluxation. The determination of normal hips can be made at 6 months of age.

Ortolani Sign
The Ortolani sign is the "clunk" or shift palpated as the femoral head enters the acetabulum during abduction of the hip.

Pelvic Osteotomy
A pelvic osteotomy is a surgical procedure in which a triple osteotomy of the pelvis (pubis, ischium, and ilium) frees the acetabular segment for rotation about an axis parallel to a line tangent to the dorsal acetabular rim (DAR). The amount of axial rotation brings the slope of the DAR to 0°. Excessive rotation of the pelvic osteotomy causes interference between the DAR and the femoral neck. If the acetabulum is filled with osteophytes, then the articular cartilage of the femoral head will erode, and congruity of the femoral head and acetabulum is improbable.

Pelvic Torsion
Pelvic torsion is a spiral deformity of the entire pelvis around its median axis. It can be identified in the ventrodorsal, lateral, and dorsal acetabular rim radiographs. Pelvic torsion is associated with transitional vertebrae of the first sacral segment and is considered a secondary manifestation of the vertebral abnormality. One hip is usually considered normal, whereas the other is "dysplastic." Because the origin of the problem is the sacral deformity, one should term the problem "sacral hip dysplasia" or coxarthrosis of sacral origin.

Rapid Growth Syndrome
Rapid growth syndrome is laxity of the hip joint capsule in the presence of normal acetabular orientation (combined dorsal acetabular rim slope up to and including 15°), normal acetabular depth (at least 50%), normal sacral conformation, normal femoral neck length, normal white-black-white articular line on the lateral radiograph, and normal angle of subluxation (up to and including 0°). The distraction index is greater than normal (greater than 0.30), and the angle of reduction is present (none is normal). The pathogenesis of this condition is the maldirection of the axial femoral force during a rapid growth spurt at 4 to 6 months of age. This maldirection of the axial femoral force stretches the hip joint capsule, but it is otherwise harmless to the hip. Restricted nutrition reduces the excessively rapid rate of growth and should have a preventive influence on capsular laxity. If the patient applies excessive axial load to the hip in the luxated position, the joint capsule can tear, the dorsal acetabular rim (DAR) can fracture, or the DAR can deform over time. If caught at the joint capsule stretching stage, strict confinement and elimination of play for 4 to 6 weeks allow the stretched joint capsule to contract. Normal hips are obtained on OFA examination at 2 years of age. A femoral neck lengthening is curative if performed before increase of the DAR slope into the pathologic range. If the affected patient is allowed to damage the DAR, then traumatic coxarthrosis will result and secondary manifestations of trauma will later be misdiagnosed as hip dysplasia. Because the origin of the problem is the rapid growth of the distal femur (12 to 15 mm per week for 6 to 8 weeks), one should term the problem "rapid femoral growth hip dysplasia" or coxarthrosis of rapid growth of distal femur origin.

Slope of the Dorsal Acetabular Rim (DAR)
The slope of the DAR is defined as the angle formed by a line normal to the sagittal plane (horizontal line) and a line created by the intersection of the acetabular subchondral bone at the DAR, and a plane defined by the intersection of the horizontal line and line through the centers of motion of the hip and stifle in the normal standing patient as viewed in the sagittal plane. The slope of acetabular subchondral bone at the DAR is linear, based on a study of 25 normal pelves. Clinically, the slope of the DAR is the angle between the tangent to the reduced femoral head at its first point of contact with the acetabulum and the horizontal line as seen on the DAR radiographic view.

Subluxation
The femoral head is incongruent and supported directly by the acetabulum, and it is allowed some lateral translation, but it is prevented from dorsal translation by the intact joint capsule.

Total Hip Replacement
A total hip replacement is a salvage procedure in which the worn acetabulum is replaced by a high-molecular-weight polyethylene

acetabular cup, and the worn femoral head is replaced by a molybdenum-chromium-stainless steel alloy femoral prosthesis. The components are maintained in position by polymethylmethacrylate. The replaced components are devoid of nerve endings and therefore are pain free. This surgical procedure is best used when the femoral head rubs bone on bone with the acetabulum.

Treatment of Hip Dysplasia

Femoral Neck Lengthening

Barclay Slocum and Theresa Devine Slocum

In the biomechanical sense, the femoral neck length is defined as the distance between the lateral limit of the greater trochanter and the medial limit of the femoral head. Both the internal and external rotator muscles attach to the greater trochanter and exert equal moments about the femoral head. The moment is defined as force times distance. By lengthening the femoral neck, the moments become greater, yet internal and external moments are still equal. This creates a greater medially directed resultant force more capable of holding the hip in the acetabulum.

The primary indication for a femoral neck lengthening is a short femoral neck. Short femoral necks are common in some breeds such as the akita, chow, and Tibetan mastiff. These hips are frequently diagnosed as dysplastic (Figure 60-62). Short femoral necks can also occur secondary to trauma to the growing capital physis (Salter type IV), as well as secondary to the surgical manipulation and fixation of a fracture of the capital physis. In dogs less than 6 months of age, rigid internal fixation of a fractured capital physis is likely to result in degeneration of the hip from a shortened femoral neck. Similar patients have no arthritis if the femoral neck is lengthened. If a nondisplaced capital physeal fracture is left undiagnosed or unattended, the femoral neck often resorbs, and a short femoral neck results.

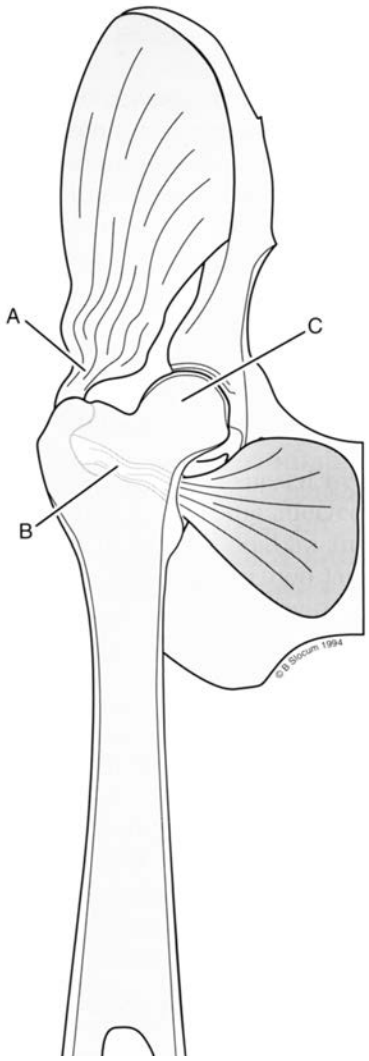

Figure 60-62. In the dysplastic hip, the internal hip rotator group *(A)*, external hip rotator group *(B)*, and joint capsule are lax when the femoral head *(C)* is reduced.

Surgical Technique

The lateral approach to the femur is used to gain access to the lateral, cranial, and medial aspects of the femur. The vastus lateralis is detached from its origin just distal to the greater trochanter and is elevated from the femur as far as the distal lateral circumflex femoral vessels. A small Hohmann retractor is placed beneath the deep gluteal muscle and over the web between the greater trochanter and the femoral head. Two Gelpi retractors are used to separate the biceps femoris and vastus lateralis muscles. External rotation of the hip exposes the proximal femur and the femoral diaphysis for osteotomy.

The greater trochanter is freed from the femoral head by an osteotomy cut in the sagittal plane for two-thirds the length of the femur (Figure 60-63). The cranial cortex of the femur is penetrated by an oscillating saw beginning just proximal to the distal lateral circumflex femoral vessels. The cranial cortical cut is carried prox-imally in the sagittal plane to the Hohmann retractor between the greater trochanter and the femoral head. The cranial cortex is used as a saw guide to direct the osteotomy of the caudal cortex. Because the osteotomy is medial to the external rotator muscle group, little danger exists of traumatizing the sciatic nerve, which lies lateral to these muscles. Considerable hemorrhage is sometimes encountered at the level of the nutrient foramen, but this soon stops with minimal blood loss. If the patient's profile indicates the potential for hemophilia, coagulation potential and von Willebrand factor should be tested before the operation.

Lateralization of the greater trochanter is accomplished by placing a 40-mm cortical screw in only the lateral cortex of the femur at the level of the third trochanter, perpendicular to the sagittal plane. With the limb held in the sagittal plane, the proximal femur is manually moved laterally (Bardens test). The laxity of the Bardens test is decreased by advancement of the screw through the lateral cortex, but not into the medial cortex. Interference of the cancellous surface of the medial segment separates the medial from the lateral cortex, which tightens the rotators as the femoral neck is lengthened. When laxity by Bardens palpation becomes zero, the advancement of the screw is sufficient.

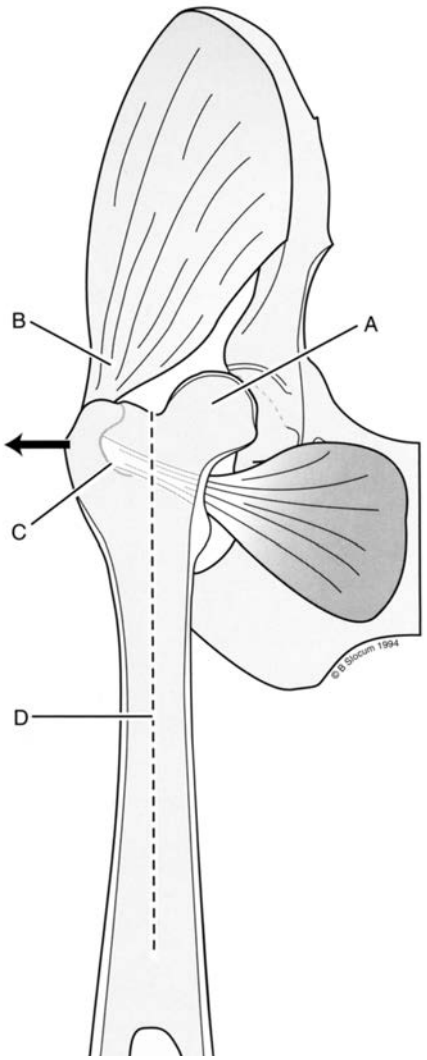

Figure 60-63. When the greater trochanter is moved laterally *(arrow)*, the femoral head *(A)* luxates. The internal *(B)* and external *(C)* hip rotators are no longer lax. A sagittal plane osteotomy *(D)* is made in the femur.

The appropriate Femoral Neck Lengthening Wedge (US Patent No. 4,759,351, Slocum Enterprises, Eugene, OR) is inserted just proximal to the screw to maintain the femoral neck length. A towel clamp or small fragment reduction forceps is used to grasp and manipulate the wedge. The wedge is held in place by predrilling a 2.7-mm (7/64-inch) hole through the lateral cortex, wedge, and medial cortex and then placing a 3.2-mm (1/8-inch) threaded pin into the hole such that the point completely penetrates the medial cortex. A wire passer is used to pass a heavy (1.25-mm or 18-gauge) wire around proximal femur. The wire should be proximal to the lesser trochanter. The point of the pin keeps it from migrating distally. After directly observing the sciatic nerve to ensure that it not entrapped, the wire is securely tightened. The screw is removed.

Another wedge is placed hallway down the osteotomy and is secured in a like manner. Care is taken to avoid driving the wedge distally because this splits the femur. The cerclage wire is proximal to the pin on the lateral cortex and is distal to the pin on the medial cortex, to prevent the pin from migrating. A third pin and cerclage wire are placed at the distal end of the osteotomy (Figure 60-64). No bone graft is necessary because healing takes approximately 5 weeks.

Closure is direct. The vastus lateralis can be reattached with horizontal mattress sutures. Holes can be-drilled in the greater trochanter if greater purchase is necessary. The vastus lateralis is usually attached to the tendon of the deep gluteal muscle cranially.

Procedure for Capital Physeal Fracture

Femoral neck lengthening is indicated for a capital physeal fracture when growth potential has been lost, when chronic capital physeal nonunion has occurred because of the trauma of delayed treatment, or when the young patient has only one opportunity for surgical correction permitted by the owner. In the last circumstance, failure of the capital physis to grow after smooth pin fixation leads to a short femoral neck and degeneration of the hip without opportunity to compensate for this lack of growth surgically. The femoral neck length deficiency may be

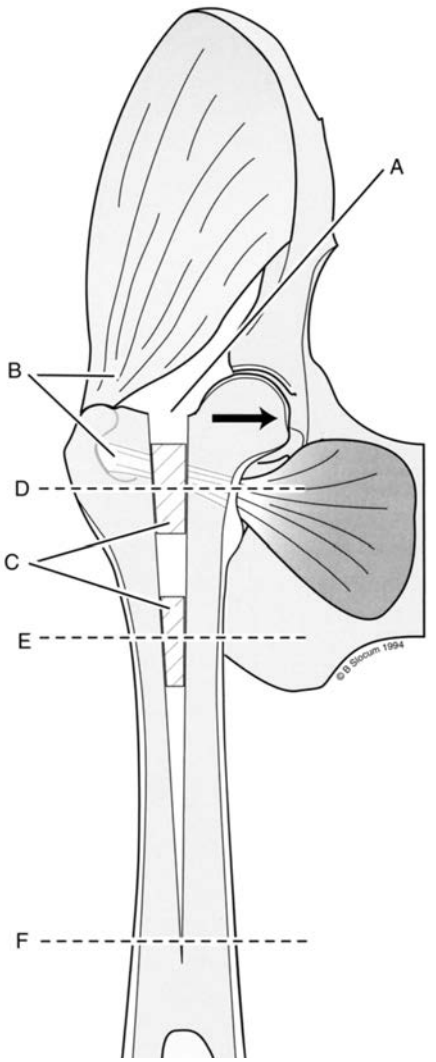

Figure 60-64. The proximal portion of the femoral osteotomy is spread apart *(A)*, which moves the femoral head into the reduced position *(arrow)*. This tightens the hip rotators *(B)*. Femoral Neck Lengthening Wedges are placed into the osteotomy *(C)* to maintain the femoral neck length. Internal fixation is first placed at the level of the third trochanter *(D)*, followed by additional fixation (*E* and *F*).

anticipated, and compensation by fusing the capital physis and adding the anticipated femoral neck deficit may be undertaken at the initial surgical procedure.

A lateral approach to the proximal half of the femur is achieved by unwrapping the origin of the vastus lateralis muscle from the femur as previously described, while leaving the femoral insertion of the deep gluteal intact. A 7.5-cm (3-inch) osteotomy of the greater trochanter in the craniocaudal direction from the web between the greater trochanter and the femoral head to the lateral cortex is made (Figure 60-65). The internal hip rotators (superficial, middle, and deep gluteal muscles) and the external hip rotators (gemelli, internal and external obturator, and quadratus femoris muscles) remain attached to the greater trochanter. The distal end of the trochanteric section is reflected dorsally to expose the hip joint capsule (Figure 60-66).

Subperiosteal elevation of the vastus lateralis from the cranial femoral neck to the joint capsule exposes the femoral side of the capital physis or the capital epiphysis if it is displaced cranially. The joint capsule is minimally opened cranially, to observe the articular surface of the femoral head. The capital epiphysis is anatomically reduced, if possible. If anatomic reduction is not possible because of trauma, then the capital epiphysis is positioned over the femoral neck to be functional for weight-bearing. A lag screw is placed up the femoral neck or remnant of the femoral neck from the surface of the osteotomy to secure the relationship between the head and the neck. The screw head is countersunk only enough to avoid protrusion into the osteotomy kerf; overtightening the screw causes the end of the screw to protrude from the surface of the femoral head (See Figure 60-66). The cranial joint capsule is closed by cranial capsulorrhaphy.

Femoral neck lengthening is performed to establish the adult femoral neck length (Figure 60-67). This length is determined by measuring the neck length in the parent of the same sex (if the patient resembles that parent) or by measuring neck length in another dog of the same breed and body type. A Femoral Neck Lengthening Wedge of the appropriate thickness is placed at the level of the third trochanter. A lag screw is placed in the distal end of the trochanteric segment. The glide hole should be large enough to accommodate lateralization of the greater

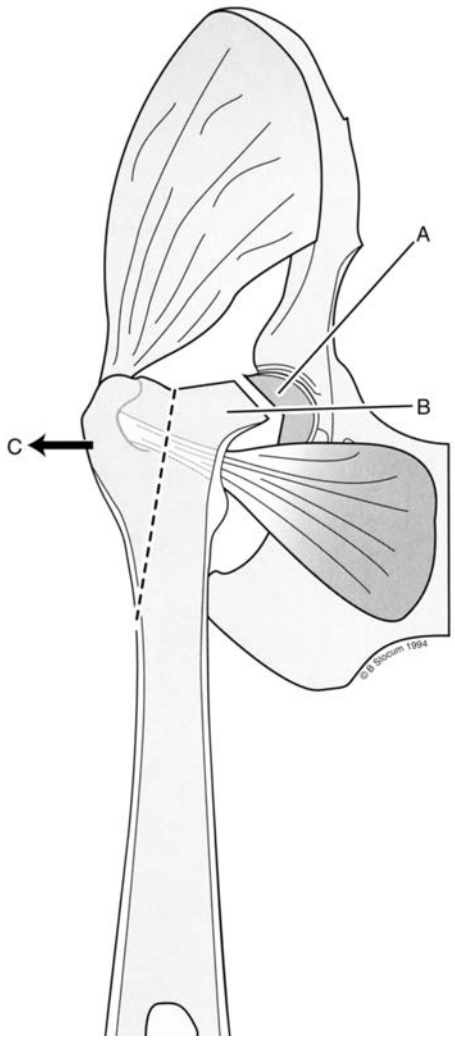

Figure 60-65. Fracture of the capital femoral physis and displacement of the epiphysis *(A)* and the femoral neck *(B)* are often accompanied by lateral movement of the proximal femur *(arrow)* and visual prominence of the greater trochanter *(C)*. A long trochanteric osteotomy *(dashed line)* provides good access for surgical repair.

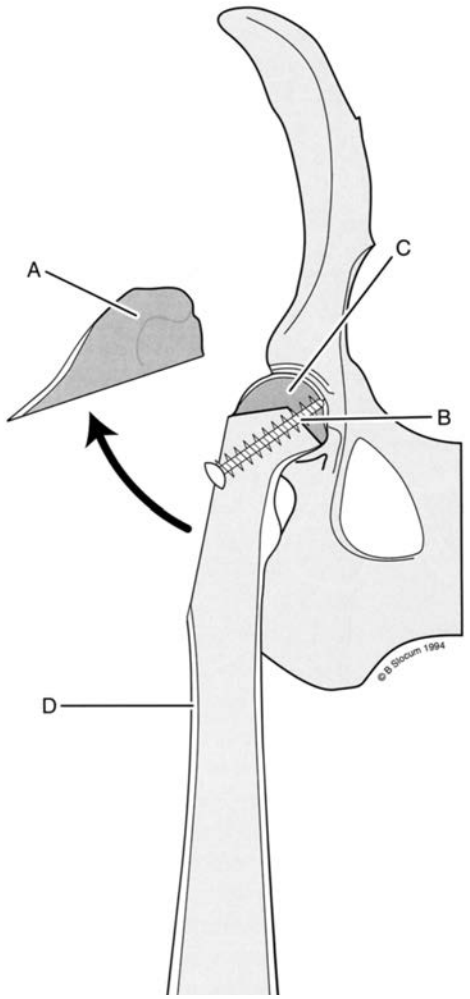

Figure 60-66. After osteotomy, the greater trochanter *(A)*, with the internal and external rotators attached, is retracted dorsally (arrow). A small opening in the cranial joint capsule gives access for assessment of the reduction and placement of the screw. Respecting the blood supply to the epiphysis, which enters dorsally, a lag screw *(B)* is used to fix the epiphysis *(C)* to the femur *(D)*.

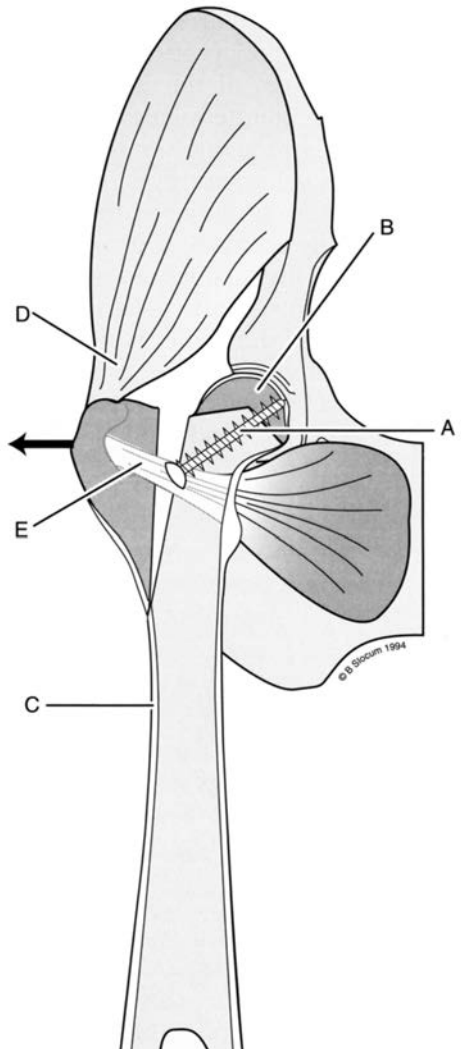

Figure 60-67. The screw *(A)* that holds the capital femoral epiphysis *(B)* to the femur *(C)* is hidden by the replacement of the greater trochanter. Femoral neck lengthening moves the trochanter laterally *(arrow)* to establish the adult femoral neck length in anticipation of the capital femoral physeal fusion because of the trauma and screw fixation. The internal *(D)* and external *(E)* rotators of the hip are placed under tension. Trochanteric fixation is not shown.

trochanter. The lag screw is tightened while taking care not to split the cortex of the trochanteric fragment. The Femoral Neck Lengthening Wedge can be fixed by a screw through the lateral cortex, wedge and medial cortex, but a pin and cerclage wire, as previously described, are more secure. Closure is similar to that described for classic femoral neck lengthening.

Modified Technique

A lateral approach to the proximal half of the femur is achieved by unwrapping the origin of the vastus lateralis muscle from the femur as previously described while leaving the femoral insertion of the deep gluteal intact. An osteotomy of the femur is made in the sagittal plane from the depression in the web between the greater trochanter and the femoral head to a point 6.5-cm (2.5-inch) distal. A small biradial or cylindric saw blade is used to complete the osteotomy between the kerf generated and the lateral cortex. The internal hip rotators (superficial, middle, and deep gluteal muscles) and the external hip rotators (gemelli, internal, and external obturator, and quadratus femoris muscles) remain attached to the greater trochanteric segment (Figure 60-68).

A 3.5-mm hole is drilled through the distal end of the trochanteric segment and also through the medial cortex. The depth of the hole is measured with a depth gauge, and a screw 2 to 4 mm longer is selected. The lateral cortex is overdrilled using a 4.5-mm drill bit and is countersunk. The medial cortex is tapped with a 3.5-mm tap. A 3.5-mm cortical lag screw is placed through the lateral cortex and loosely engaged in the medial cortex. A second hole is drilled through the lateral cortex at the level of the third trochanter, is countersunk, and is tapped. The depth of the hole is measured to the medial cortex. The screw selected is equal to the depth of the hole plus the displacement of the femoral head obtained by comparing the compression and distraction radiographic views. When the screw is placed in the second hole, the greater trochanter is lateralized the appropriate amount. Third and fourth screws are placed proximal and distal to the second

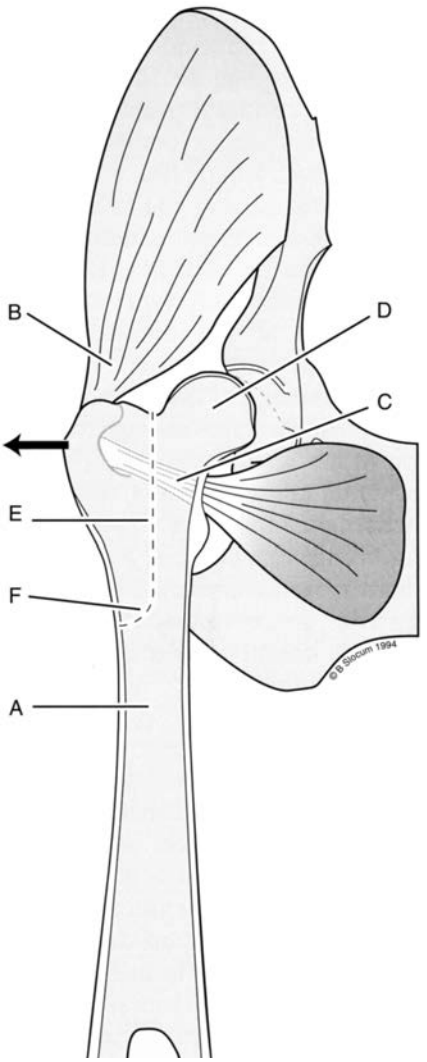

Figure 60-68. The femur *(A)* is moved laterally *(arrow)* to tension the internal hip rotator group *(B)* and external hip rotator group *(C)*. The femoral head *(D)* is in the luxated position. A linear portion *(E)* and a cylindric portion *(F)* of the modified femoral neck lengthening osteotomy are shown by the dashed line.

screw, engaging both the lateral and medial cortices (Figure 60-69). The first screw is then firmly tightened. Closure is routine.

A more stable configuration is the application of an appropriately sized wedge placed at the second screw hole. The wedge size is determined from the displacement of the femoral head obtained by comparing the compression and distraction radiographic views. This configuration prevents the femoral neck lengthening from relying on the threads of the screws alone.

Although the primary indication for femoral neck lengthening is hip dysplasia, this technique can also be used with a pelvic osteotomy in patients with an excessively stretched joint capsule. The excessive slope of the dorsal acetabular rim is corrected before the femoral neck lengthening. A dorsal acetabular rim slope greater than 7.5° is addressed by a pelvic osteotomy because that surgical procedure deals with the axial compressive forces of the femur; the femoral neck lengthening technique increases the medial directed forces created by the rotators. Bone graft has not been necessary for augmenting bone healing, because bone marrow elements promote extraordinarily rapid bone healing, usually within 5 to 6 weeks.

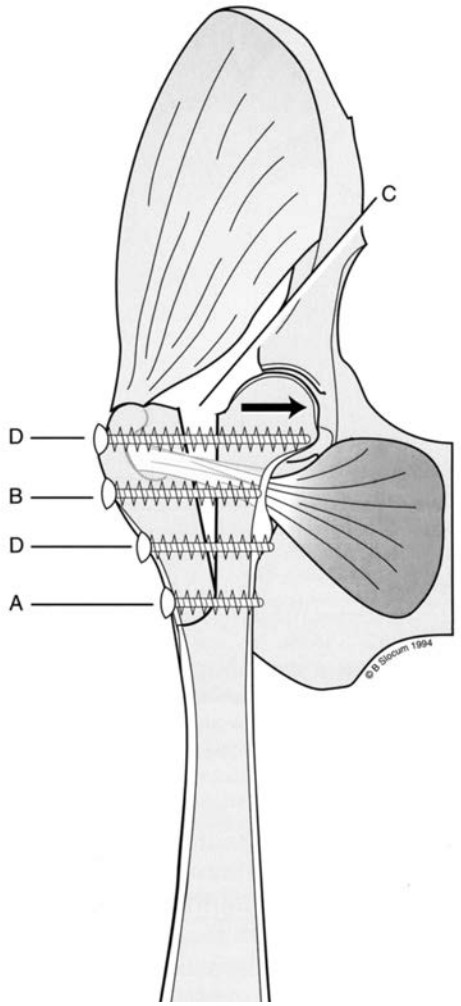

Figure 60-69. The modified femoral neck lengthening osteotomy is fixed by four screws. The distal screw *(A)* is a lag screw, which is initially loosely applied. Only the lateral cortex is drilled and tapped for femoral neck lengthening screw *(B)*, which is equal in length to the depth plus displacement measured from the compression and distraction radiographs. The first screw *(A)* is firmly tightened to complete the creation of the femoral neck lengthening gap *(C)*. Both the lateral and medial cortices are drilled and tapped for neutral screws *(D)* used to maintain fixation.

The postoperative instructions are strict for femoral neck lengthening surgery. The patient must be kept under direct control of the owner while in the house, on good footing, with no playing, and with no other dogs or other excitable activities. The patient is allowed outside only to perform bodily functions on a leash with a bellyband. The patient is kept in a traveling kennel when the owner is not present, to prevent the patient from injuring itself. Tranquilizers may be necessary to maintain this confinement until the femoral neck lengthening is healed.

Femoral neck anteversion can also be corrected using the femoral neck lengthening procedure. In addition to lateralizing the greater trochanter, the lateral cortex is moved cranially to detorse the femur and to provide the appropriate relationship between the greater trochanter and the femoral head. The Femoral Neck Lengthening Wedge and internal fixation are applied with routine closure.

The femoral neck lengthening technique is powerful when used according to the proper indications. Overlengthening the femoral neck can cause the femoral head to move ventral to the acetabulum, particularly if performed concurrently with a pelvic osteotomy technique. The advantage of the femoral neck lengthening technique is that it provides an increase in the medially resultant force holding the hip in the acetabulum. This reestablishes stable hip biomechanics without the necessity for overrotating the acetabular segment in patients with excessive joint capsule laxity. In addition, this procedure is gentle on the patient, the owner, and the surgeon.

Acknowledgments

Kenneth Sinibaldi, DVM, Steven Stoll, DVM, and Gary Brown, DVM, have made contributions to the modification of the femoral neck lengthening technique.

Pelvic Osteotomy

Barclay Slocum and Theresa Devine Slocum

The first principle in treating acetabular hip dysplasia is to neutralize any luxating force created by a slope of the dorsal acetabular rim (DAR) or adduction of the femur. This requires an axial rotation of the acetabular segment by pelvic osteotomy. The second principle is the establishment of a greater trochanteric muscle force moment for creating dynamic stability of the femoral head by femoral neck lengthening, when the femoral neck is short or the joint capsule is excessively lax. The third principle is to reduce the redundancy of the joint capsule by capsulorrhaphy, which adds static stability to the hip when the femoral neck is normal and excessive laxity of the joint capsule is greater than 6 mm. This discussion addresses the first principle, the surgical technique of pelvic osteotomy.

Pelvic osteotomy is a triple osteotomy of the pelvis that frees the acetabular segment for axial rotation to reduce the DAR angle to 0° (Figure 60-70). The primary indication for pelvic osteotomy is excessive slope to the DAR. By far the most common circumstance for this condition is acetabular hip dysplasia, which is an excessive slope of the DAR by definition. Occasionally, pelvic torsion, secondary to a transitional vertebra of the sacrum, causes a unilateral excessive slope of the DAR that is also treated by pelvic osteotomy. Dislocation of a dysplastic hip is an immediate indication for pelvic osteotomy, as long as the articular surfaces can be replaced with congruity. Reduction of a dislocated dysplastic hip fails unless pelvic osteotomy is performed. Reduction of a dislocated hip without treating the underlying hip dysplasia is unacceptable. A short femoral neck as in an akita, chow, or Tibetan mastiff, or secondary to premature closure of the capital femoral physis, requires femoral neck lengthening if found primarily, but damage to the DAR by the head of the femur with the shortened neck reduces the coverage of the DAR and requires a pelvic osteotomy to stabilize the hip.

The degree of correction for rotation of the pelvic osteotomy is determined by looking at the abnormalities in specific structures. Joint capsule laxity can be calibrated by the angle of reduction, stress radiography, and the Bardens palpation. Damage to the articular cartilage can be assessed by palpation, with the patient under anesthesia, to distinguish joint capsule distraction from tearing. The characteristics of the articular cartilage can also be distinguished by hip palpation as normal, fibrillated, or eburnated. The DAR radiographic view and linear tomography create a visual representation of articular cartilage thickness and damage to the weightbearing portion of the acetabulum. Acetabular depth can be evaluated radiographi-cally using the frog view at 45° of abduction, the compression view in the ventrodorsal position, and the DAR view. Acetabular depth can also be assessed by the angle of subluxation and the combined interpretation of actual DAR slope and ligament of femoral head redundancy.

The slope of the DAR is measured directly from the D AR radiograph. The subchondral surface of the dorsal acetabulum is linear unless distorted by acetabular filling or chronic luxation of the femoral head. The angle of subluxation provides a good assessment of the functional slope of the DAR.

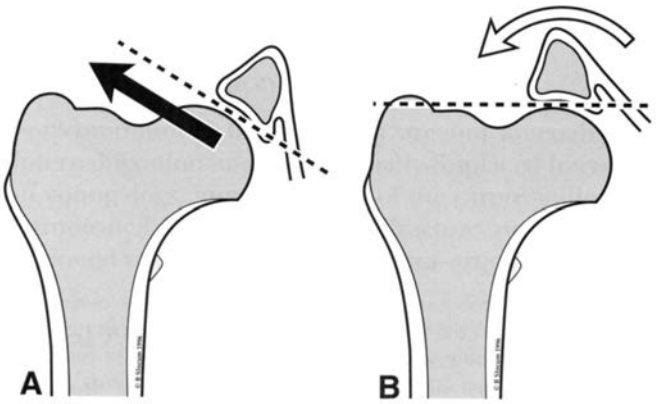

Figure 60-70. A. The excessive slope *(dotted line)* of the *Dorsal Acetabular Rim* (DAR) causes the femur under axial load to luxate *(solid arrow)*. **B.** After pelvic osteotomy *(white arrow)*, the DAR slope is 0°, and the hip is functionally stable.

Surgical Procedures

The acetabular segment of the pelvis is freed for axial rotation by osteotomies of the pubis, ischium, and ilium and is fixed with just enough rotation by a Canine Pelvic Osteotomy Plate (Slocum Enterprises, Eugene, OR) to stabilize the femoral head in the acetabulum (Figure 60-71). The patient is anesthetized, the limb is prepared for surgery with the dog in lateral recumbency, and the limb is hung by a foot wrap. The entire hindquarter is draped free to allow for access to the pubis, tuber ischiadicum, and ilium.

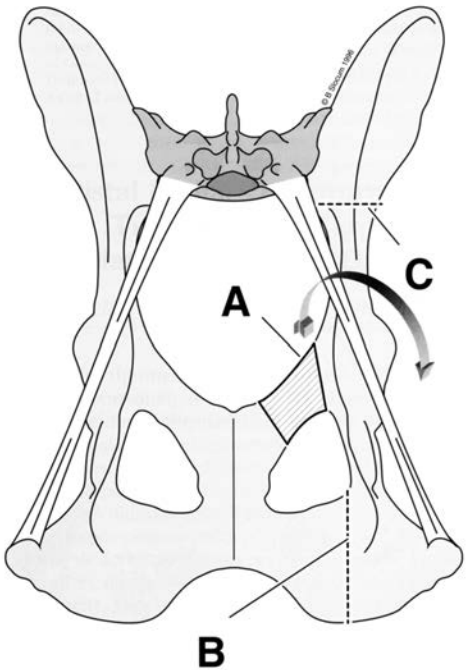

Figure 60-71. Three osteotomies of the pelvis are necessary to free the pelvis for axial rotation of the acetabular segment *(arrow)*. The pubic osteotomy *(A)* is performed first and includes removal of the pubic ramus (shaded area). The ischial osteotomy *(B)* is performed in the sagittal plane through the table of the ischium at the lateral margin of the obturator foramen. The ilial osteotomy *(C)* is performed perpendicular to a line in the sagittal plane that is tangent to the portion of the acetabulum to be rotated.

Pubic Osteotomy

The skin is incised over the proximal one-fourth of the pectineus muscle and inguinal crease. The gracilis and adductor muscles are elevated from the ventral pubis. The prepubic tendon and pectineus are elevated from the cranial pubis (Figure 60-72). The obturator nerve is retracted caudomedially. An osteotomy is made in the sagittal plane at both the medial and lateral limits of the pubis. The entire pubis along the cranial margin of the obturator foramen is removed and is saved for an ilial osteotomy bone graft. The gracilis muscle is closed to the prepubic tendon to prevent an inguinal hernia. Subdermal sutures are used to preclude difficult suture removal.

Ischial Osteotomy

A sagittal incision is made over the midtuber ischiadicum and is carried to bone of the dorsal ischial plateau. The internal obturator muscle is elevated from the dorsal table of the tuber ischiadicum. The sacrotuberous ligament is elevated from the lateral prominence of the tuber ischiadicum medially to laterally. An osteotomy of the tuber ischiadicum at the lateral limit of the obturator foramen (Figure 60-73) is performed in the sagittal plane. A 20-gauge fixation wire is preplaced through two holes on either side of the osteotomy site. Closure is delayed until after the ilial osteotomy and plate application is completed. Once the ilial osteotomy is plated, then the ischial wire is tightened. The perineal fascia is closed using a cruciate suture pattern. The skin of the ischial incision is closed with a simple interrupted pattern.

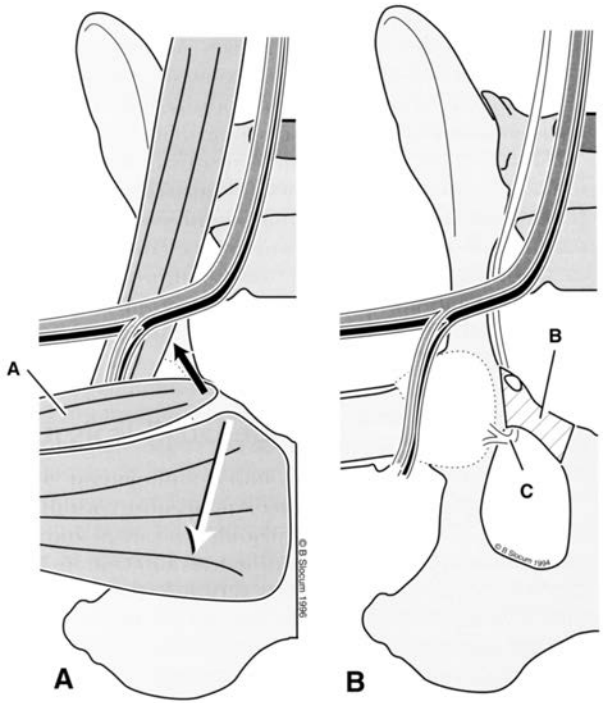

Figure 60-72. A. The pubic osteotomy is performed through a 3-cm incision centered on the inguinal crease and just caudal to the pectineus muscle *(A)*. The gracilis and adductor magnus are elevated and retracted caudally *(white arrow)*. The pectineus is elevated from the pubis and retracted cranially *(black arrow)*. **B.** With the elevation of the musculature, the pubis is exposed completely *(B)*. The obturator nerve *(C)* is retracted from the pubis. The pubic ramus *(striped area)* is cut medially and laterally and removed. It is reduced to 3-mm fragments and used as bone graft for the ilial osteotomy.

Ilial Osteotomy

A skin incision is made from the midcranial wing of the ilium to the base of the cranial aspect of the greater trochanter (Figure 60-74). The gluteal fascia is incised parallel to the skin incision. The separation between the middle gluteal muscle and the tensor fasciae latae is made. En masse, the deep and middle gluteal muscles are elevated from the body and wing of the ilium cranially, but they are left intact dorsally on the tuber sacrale (Figure 60-75). The cranial circumflex iliac artery is cauterized, but the cranial gluteal nerve to the tensor fasciae latae is preserved. A Langenbeck periosteal elevator is placed dorsal to the body of the ilium in the greater ischiatic notch and is moved cranially until contact is made between both the ilium and the sacrum. A relaxing incision in the tensor fasciae latae tendon provides the extra exposure to the greater ischiatic notch. A guide pin is placed dorsal to the lateral prominence of the tuber ischiadicum, beneath the internal obturator muscle. The pin is pushed cranially to the junction between the ventral and middle third of the cranial margin of the wing of the ilium (Figure 60-76). The ilial osteotomy is made perpendicular to the axis of the guide pin, just cranial to the Langenbeck elevator. The free acetabular segment is moved cranially into the operative field.

The caudal half of the Canine Pelvic Osteotomy Plate is applied to the body of the ilium (Figure 60-77) 3 mm dorsal to the ventral margin of the ilium using a spheric drill guide and 4.0-mm fixation screws. A 1.25-mm hemicerclage wire is placed through the wire hole in the caudal half of the plate, encircling the ilial body ventrally. The spike of ilial bone dorsal to the plate is removed.

The ilial osteotomy is reduced, and a 4.0-mm screw is placed in the ventral compression hole of the cranial portion of the Canine Pelvic Osteotomy Plate using a 1.0-mm compressive drill guide. The hip is tested for stability by axial compression of the femur in the sagittal plane (Figure 60-78). If the hip is unstable (the femoral head luxates), then the next larger angle of plate needs to be used. The screw holes of all Canine Pelvic Osteotomy Plates are in the same relative position. When applying the remaining two screws, care should be taken to place the screws perpendicular to the plate.

On small patients, these screws may have to be directed caudally to drill into the body of the sacrum. A bone graft of the pubis, fragmented to 3 mm or less, is placed caudal to the wing portion of the ilium between the sacrum and the acetabular segment. Closure of ilial approach is routine.

The objective of the pelvic osteotomy technique is to provide acetabular support and stability for the femoral head by increasing the acetabular coverage. Reducing the acetabular slope to 0° is optimal. The preoperative examination of the patient determines the angle for the Canine Pelvic Osteotomy Plate to be used. Although the angle of subluxation is theoretically the ideal angle for pelvic osteotomy, it is usually insufficient to provide hip stability unless the DAR is undamaged. The angle of reduction, which indicates joint capsule stretching, is the absolute maximum angle for pelvic osteotomy and is excessive, especially if a great difference exists between the angles of reduction and subluxation. The slope of the rim as determined

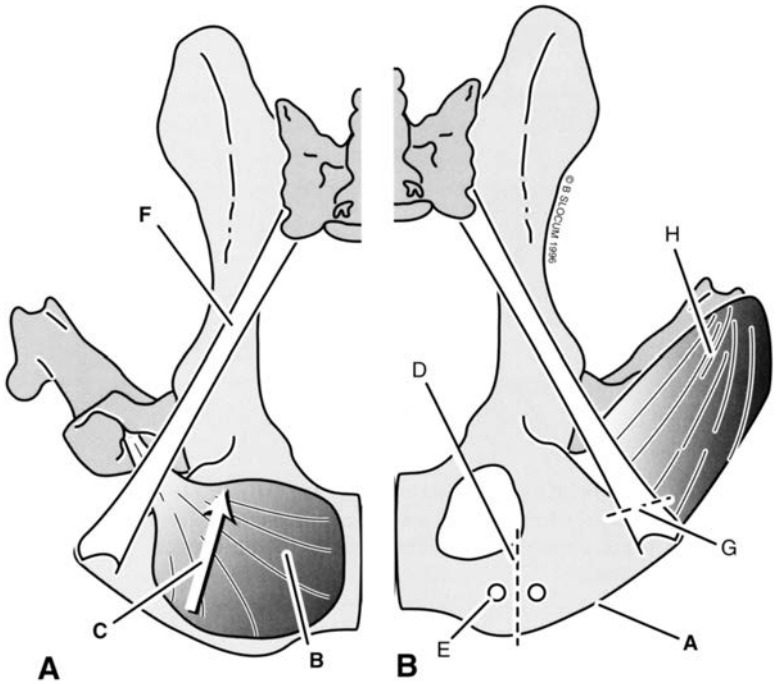

Figure 60-73. A. The ischial osteotomy is made through a 3-cm incision in the sagittal plane over the midtuber ischiadicum. The internal obturator muscle *(B)* is elevated from the ischial table, parallel and medial to the body of the ischium *(C)*. The sacrotuberous ligament *(F)* extends between the sacrum and the lateral prominence of the tuber ischiadicum. **B.** With the table of the ischium freed from muscle *(A)*, a reciprocating saw is used to make a sagittal plane osteotomy in the tuber ischiadicum, as far laterally in the obturator foramen as possible *(D)*. A wire hole is placed on either side of the osteotomy *(E)*. The sacrotuberous ligament is incised just proximal to the lateral prominence *(G)*. The ligament is held loosely in relative position by the biceps femoris muscle *(H)*.

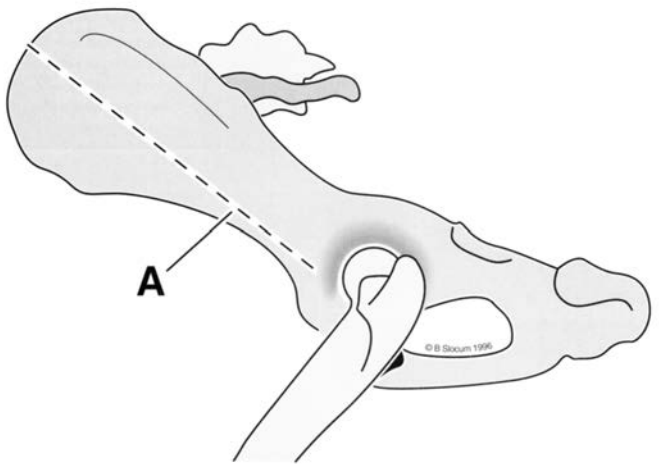

Figure 60-74. For the ilial osteotomy, a linear skin incision *(A)* is made from the cranial border of the wing of the ilium, halfway between the tuber sacrale and the tuber coxae, to the cervical tubercle of the femur.

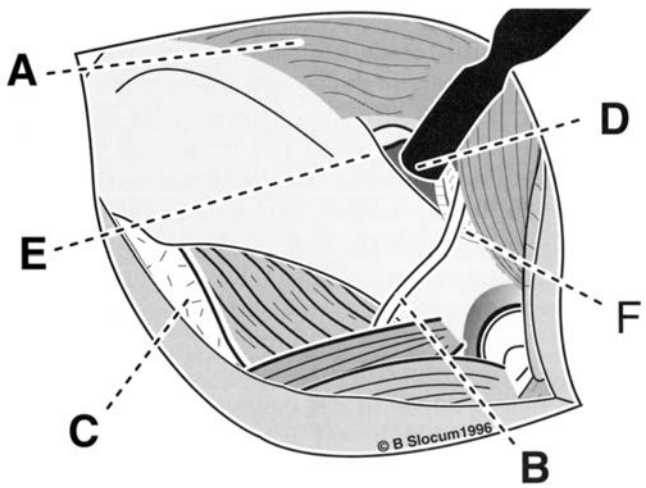

Figure 60-75. The ilial approach is made by rolling up the middle and deep gluteal muscles *(A)*. The cranial gluteal nerve to the tensor fasciae latae muscle *(B)* can be preserved by a relaxing incision in the tensor fascia origin *(C)*. A Langenbeck retractor *(D)* is placed dorsal to the body of the ilium and is moved cranially to contact the sacrum *(E)*. This protects the cranial gluteal neurovascular bundle to the gluteals *(F)*, and the cranial margin of the retractor is a guide for the osteotomy.

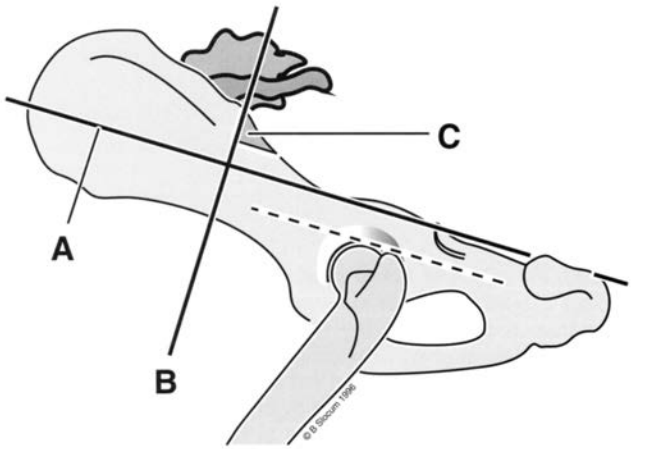

Figure 60-76. The tangent to the acetabulum *(broken line)* contacts the acetabulum at the singular point at which the femoral head leaves during subluxation. The guide pin *(A)* is placed parallel to the tangent to the acetabulum. The ilial osteotomy *(B)* is made perpendicular to the guide pin at the junction of the sacrum and the pelvis. The pointed piece of bone *(C)* is removed.

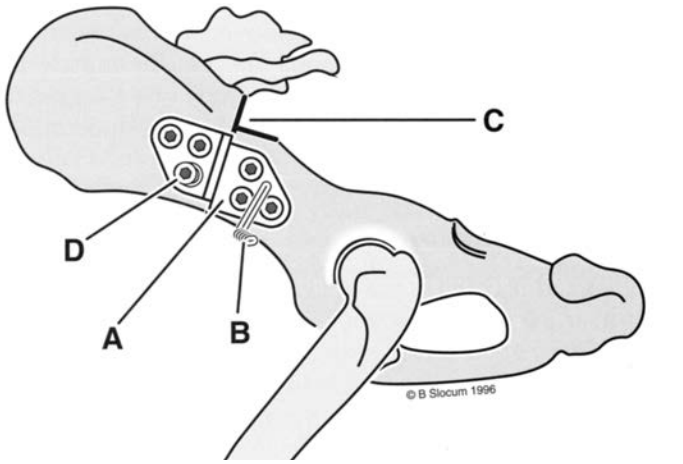

Figure 60-77. The Canine Pelvic Osteotomy Plate *(A)* is applied to the acetabular segment, and a hemicerclage wire *(B)* is added. The point *(C)* is removed. The compression screw *(D)* is applied, and the hip is checked for stability by the femoral axial compression test. If the hip is unstable, a capsulorrhaphy, femoral neck lengthening or the next larger angle of osteotomy plate should be considered.

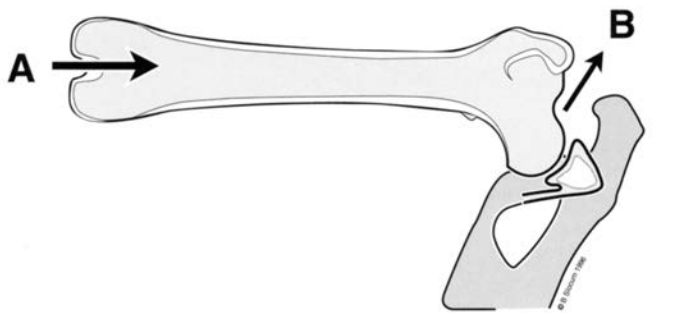

Figure 60-78. The axial compression test of the femur is performed by applying a force *(A)* to the distal femur in the sagittal plane and witnessing the response of the femoral head *(B)*. A positive test is when the femoral head leaves the acetabulum and represents hip instability. A negative test is when the hip remains within the acetabulum.

from the DAR radiograph is an accurate reference for the amount of axial rotation for the acetabular segment.

If joint capsule laxity is excessive, femoral neck lengthening or capsulorrhaphy should be used to achieve hip stability while maintaining an optimum range of motion rather than overrotation of the acetabular segment. Overrotation causes impingement of the femoral neck, the advancement of degenerative joint disease, and pain.

Several aspects of the pelvic osteotomy need to be observed to ensure consistently good results from the procedure. Most important, only enough axial rotation of the acetabular segment to provide hip stability should be performed. The slope of the DAR should be brought to 0° and not beyond, for the benefit of the function of the patient. When the ilial osteotomy is placed as described, the ilial osteotomy overlies the sacrum about 3 mm cranial to its caudal margin. This prevents the saw from penetrating the ilium, to damage the pelvic plexus and cause dysuria, as may occur when the osteotomy is made caudal to the sacrum. Using the guide pin properly orients the osteotomy and prevents excessive angulation of the caudal portion of the acetabular segment, as occurs when the osteotomy is made perpendicular to the long axis of the ilium, rather than the long axis of the pelvis. Rotation of the acetabular segment and internal fixation are much more difficult when the cut is incorrect. A Hohmann retractor should not be used dorsal to the body of the ilium. The sciatic nerve, which lies medial to the body of the ilium, is easily crushed between the tip of the retractor and the bone during retraction. The well-intentioned assistant often replaces a displaced Hohmann retractor into a position of danger.

If the SI nerve root is encountered when drilling the dorsal holes in the cranial portion of the plate, then the screw applied to that hole should be short enough to avoid contact with the nerve or the hole should be redirected to avoid the nerve root.

The Canine Pelvic Osteotomy Plate has two characteristics which makes it superior to twisted linear plates. The width of this plate and the placement of screws more efficiently resist the torsional moments of the acetabular segment than the linear plates, which tend to pry the screws from the bone (Figure 60-79).

The sacrotuberous ligament release prevents elevation of the caudal acetabular segment during axial rotation that would otherwise malalign the ilial osteotomy and place static tension on the sacrotuberous ligament, leading to a gradual release of tension in the elongating ligament and subsequent loss of compression at the ilial osteotomy as the sacrotuberous ligament lengthens (Figure 60-80). The loss of compression by yielding of the sacrotuberous ligament causes cyclic forces on the screws with premature loss of fixation. This same effect is noted when the angle of the osteotomy is not perpendicular to the axis of the pelvis. The greater the angle of the osteotomy from the perpendicular to the guide pin, the greater is the ventralization of the tuber ischiadicum (Figure 60-81). With the release of the sacrotuberous ligament at surgery, the fixation relies on compression of the bone that statically loads the screws only in one direction and prevents cycling.

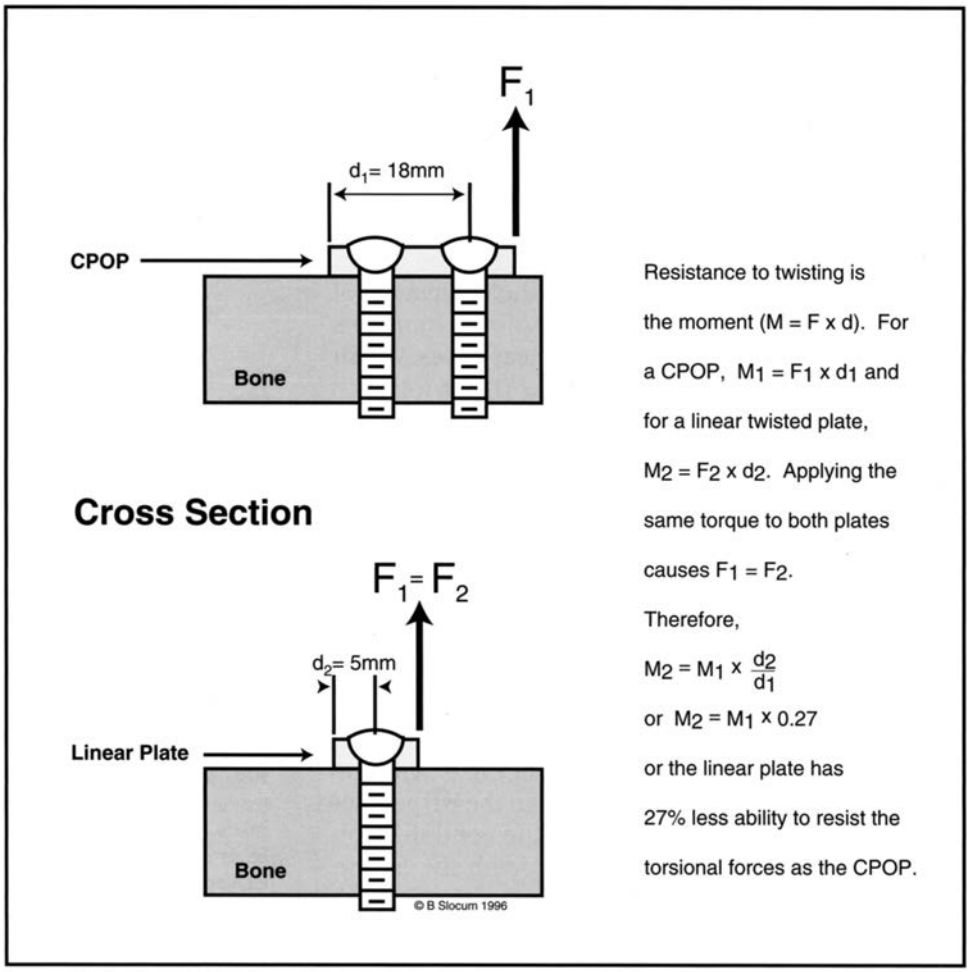

Figure 60-79. Diagram comparing the resistance of a torsional load of a Canine Pelvic Osteotomy Plate (CPOP) with that of a standard 10-mm wide linear plate.

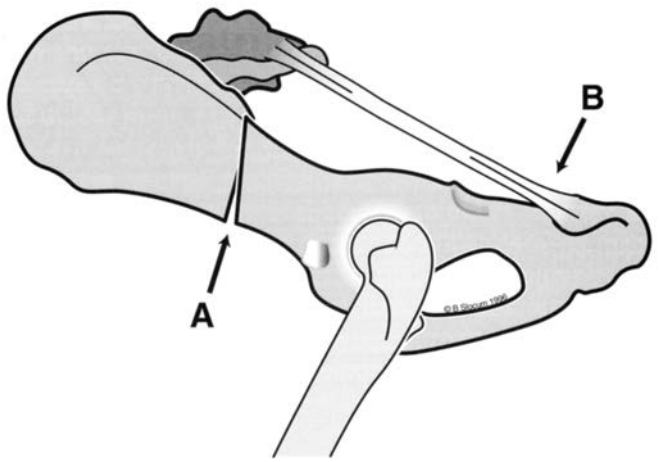

Figure 60-80. The sacrotuberous ligament maintains a fixed length between the sacrum and the lateral prominence of the tuber ischiadicum. Unrestricted rotation of the acetabular segment around the guide pin axis lengthens the distance between the sacrum and the tuber ischiadicum. As a result, a gap will occur *(A)* unless the ligament is released *(B)*.

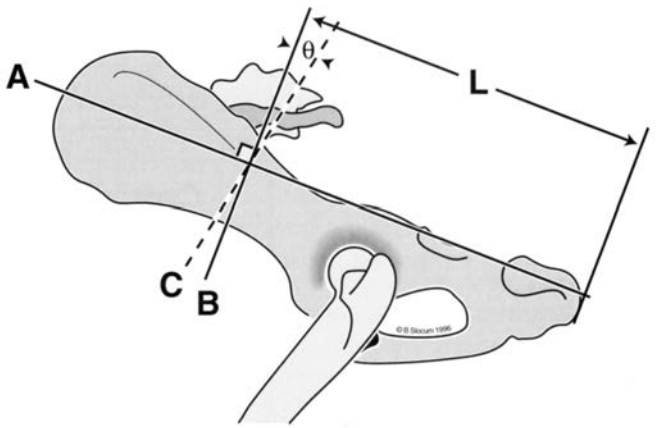

Figure 60-81. The direction of the ilial osteotomy *(B)* is ideally made perpendicular to the guide pin *(A)*. If the osteotomy were made parallel to the guide pin, then the tuber ischiadicum would be lateralized by the distance from the osteotomy to the tuber ischiadicum, *L*, times the sine of the angle, θ, of the plate used. If the osteotomy *(C)* is made at angle θ to the perpendicular to the guide pin, then lateralization of the tuber ischiadicum, *T*, can be expressed as: $T = L \times \sin Ø \times \sin \theta$.

The results of pelvic osteotomy are predictably good if meticulous attention is paid to case selection, surgical technique, and aftercare. The technique provides for the return of normal function and activity for dogs with hip dysplasia and prevents the progression of degenerative osteoarthritis. The ideal candidate for this procedure has minimal filling of the acetabulum, an intact DAR, and an increased slope of the DAR of 10 to 20° on the dysplastic hip. The amount of joint capsule laxity (angle of reduction or distraction index) is smaller after healing of the pelvic osteotomy because the joint capsule tightens when the capsule-stretching forces created by the increased slope of the DAR are treated by the pelvic osteotomy. The most advanced stage of acetabular hip dysplasia that has a good functional result for the patient depends on the amount of acetabular filling and trauma to the DAR.

Three Plane Intertrochanteric Osteotomy

Terry D. Braden and W. Dieter Prieur

Introduction

Early stage canine hip dysplasia is manifested by coxofemoral joint laxity, lameness, pain and characteristic radiographic changes.[1] The first radiographic change is femoral head subluxation (Figure 60-82).[2] Subluxation results from the following causes, singly or in combination: increased femoral neck inclination angle; increased femoral neck anteversion; or loose supporting structures (muscles, joint capsule, ligaments).[3] Subluxation decreases the contact area between the acetabulum and femoral head. Because the contact area is decreased in dysplastic dogs, the load per area of articular cartilage is increased. This continued biomechanical overloading of the joint surface results in cartilage necrosis, which leads to progressive worsening of the radiographic and clinical signs of Canine Hip Dysplasia (CHD).[4]

The first report[5] of successful use of the intertrochanteric osteotomy treatment of coxofemoral osteoarthritis in human beings appeared over 60 years ago, although the procedure itself was first described by Kirmission in 1894.[6] The purpose of the intertrochanteric osteotomy is to reestablish or improve the contact area of the acetabular and femoral head surfaces and thus improved the biomechanical function of the hip joint.[7,8] This is accomplished using the intertrochanteric osteotomy by changing the femur's position relative to the acetabulum in three planes. The first plane, the inclination of the femoral neck, is changed from a valgus to a varus position.[9] The second plane, the anteversion of the femoral neck, is rotated toward normoversion.[10,11] The third plane is medialization of the femoral head, neck and trochanteric region in relation to the shaft of the femur (See Figures 60-82 and 60-83).

Figure 60-82. Ventrodorsal radiograph of the pelvis and femurs of a 9-month-old St. Bernard with early-stage hip dysplasia. Note the subluxation of the coxofemoral joints but relatively normal acetabulum and femoral head and neck, bilaterally.

Figure 60-83. Ventrodorsal radiograph of the pelvis and femurs of the same dog as in Figure 60-82 immediately after a three-plane intertrochanteric osteotomy of the left hip. Note the improvement in the contact area between the femoral head and acetabulum.

Indications for Intertrochanteric Osteotomy

Intertrochanteric osteotomy is indicated when both the radiographic and clinical signs of early stage CHD are present. The typical clinical signs are stiffness on rising, rising using the front legs only, bunny hopping, pain, and lameness. Any or all of these signs may be present. The radiographic signs of early stage CHD are subluxation of the head of the femur from the acetabulum, with minimal or no deformity of the acetabulum or femoral head, and minimal or no arthritis of the joint (See Figure 60-82). In the early manifestation of this disease, the most common radiographic sign is subluxation of the hip. Subluxation of the coxofemoral joint also may be present in dogs without CHD.[12] Therefore, subluxation of the coxofemoral joint alone is not diagnostic of early stage CHD. Subluxation of the femoral head with the appropriate clinical signs is necessary for the initial diagnosis of early-stage CHD. If the subluxation advances to luxation, or if the deformity to the femoral head or acetabulum (shallowness) is significant, or if there is moderate to severe arthritis, this procedure is not indicated. In those situations, a total hip replacement would be indicated.

Greater than 95% of dogs that have CHD are affected bilaterally. The radiographic pathology is not generally symmetric; that is, one side usually is worse than the other, but most of the time both sides have some pathology (See Figure 60-82). The indications for surgical intervention on the first side, as mentioned previously, are radiographic subluxation of the coxofemoral joint and clinical signs of CHD. The indication for surgery for the second side (4 to 6 weeks later) are radiographic subluxation with or without the clinical signs. Surgery on the second side generally is prophylactic, whereas the first side is therapeutic. Because of the dog's ability to shift weight, if the surgery is performed on the second side only after clinical signs are noticed, there are too many secondary changes to the acetabulum and femur, and an intertrochanteric osteotomy is no longer indicated. Subluxation of the second hip must be seen at least once (either on the initial examination radiograph, the postoperative radiograph of the first hip, or the 4 to 6 week postoperative follow-up radiograph). Greater than 95% of the time, subluxation can be seen at one or all of these times on the second hip, and the second surgery is indicated (Figures 60-84 and 60-85). If all three of these radiographic examinations are negative for subluxation, the surgery is not recommended on the second side.

Figure 60-84. Ventrodorsal radiograph of the pelvis and femurs of the same dog as in Figure 60-82, shown 6 weeks postoperatively. Note the healing and remodeling at the osteotomy site.

Figure 60-85. Ventrodorsal radiograph of the pelvis and femurs of the same dog as in Figure 60-82. The left hip is shown 6 weeks postoperatively, and the right hip is shown immediately postoperatively. Note the biomechanical improvement of the coxofemoral joints bilaterally.

Preoperative Planning

The first step in the preoperative planning for an intertrochanteric osteotomy is determination of the angle of inclination of the femoral neck. This is the angle between the axis of the femoral shaft and the axis of the femoral neck. Properly positioned ventrodorsal hip (pelvis and femurs) radiographs are absolutely essential in establishing these axes. The femurs must not be rotated; therefore, the patellas must be centered on the intercondylar sulci and the outline of the intertrochanteric fossa must be well-visualized. The pelvis must not be rotated; therefore, the obturator foramen must be equal in size on both sides of the pelvis (See Figure 60-82).

A transparent paper is placed over the ventrodorsal (V-D) radiograph, and the femur is traced. The axis of the shaft of the femur is established by drawing two lines perpendicular to the long axis from the medial to the lateral cortices (Figure 60-86). One is drawn at the junction of the proximal and middle third of the shaft (line A), and the second is drawn at the junction of the middle and distal third of the shaft (line B). These two lines are then bisected (points A and B), and these points are connected by a straight line extended to the top of the femur (See Figure 60-86). This is the axis of the femur.

To determine the axis of the femoral neck, a line is drawn perpendicular to the femoral axis line, connecting the most distal point of the intertrochanteric fossa to the medial cortex of the femoral neck (line C). The bisect of this line is point D (See Figure 60-86).

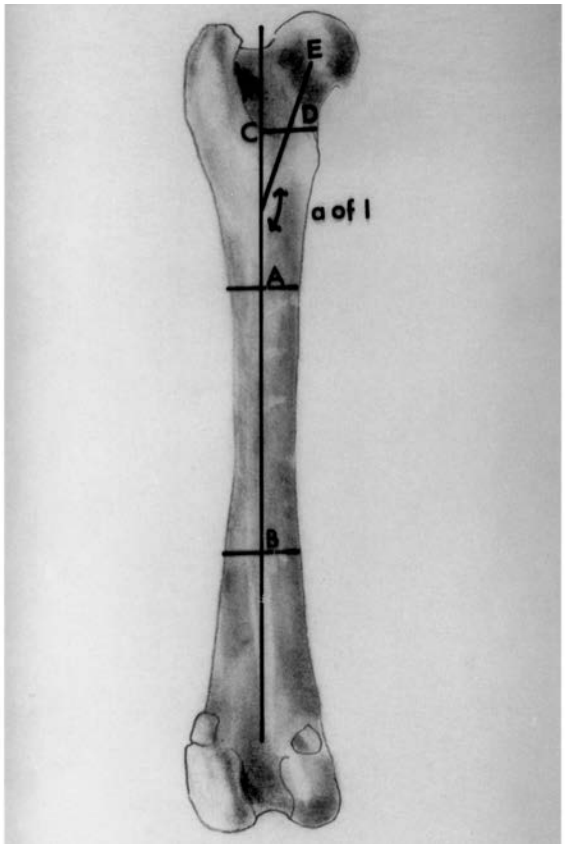

Figure 60-86. Drawing of posterior view of the femur illustrating a method of determining the angle of inclination (a of I) of the femoral neck. Line A-B is the axis of the femoral shaft, and line E-D is the axis of the femoral neck.

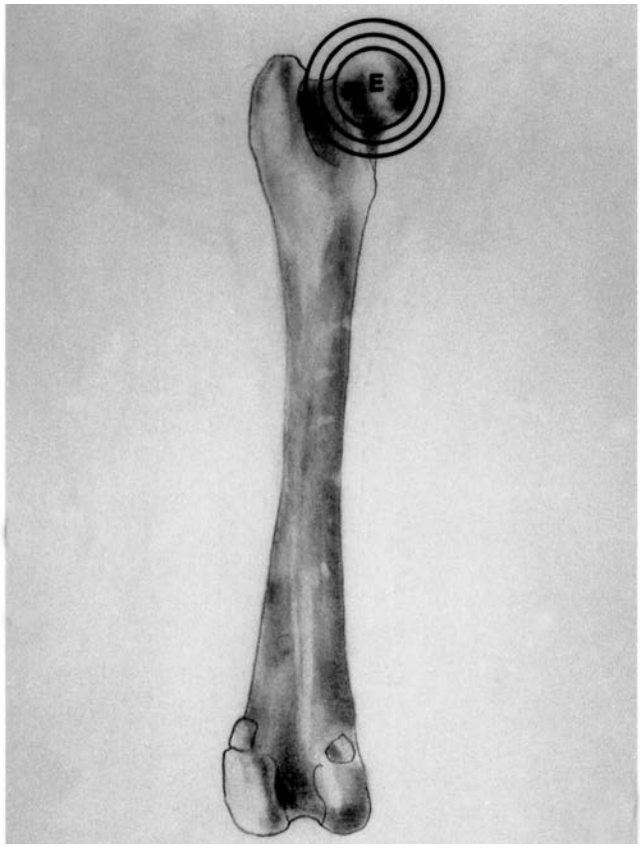

Figure 60-87. Posterior view of the femur illustrating the determination of the center (point E) of the femoral head using concentric rings of a standard goniometer.

The center of rotation of the femoral head (point E) is determined, using the concentric circles of a standard goniometer (Roentgen Ischiometer MEM, Protek AG, Berne, Switzerland), which has a number of concentric rings with a known central point. By matching the identically sized ring with the femoral head, the center of the head is easily determined (Figure 60-87).[13] Points E and D are connected, and this line is continued until it crosses line AB. The obtuse angle formed by these two lines is the angle of inclination (a of I) of the femoral neck (See Figure 60-86).

The average angle of inclination of the femoral head in the dog is 149 degrees with a range of 141 to 157 degrees. The desired angle of inclination resulting from an intertrochanteric osteotomy is 135 degrees. The degree of overcorrection is thought to decrease stress on the joint cartilage by increasing the loaded surface area of both the femoral head and acetabulum. The difference between 135 degrees and the measured angle in the dog with early stage CHD is the size of the wedge removed in the intertrochanteric osteotomy. The typical wedge removed is approximately 25 degrees. On severe cases of valgus inclination of the femoral neck, a 35 degree wedge is removed.

On a second transparent paper overlying the V-D radiograph of the hip, a line perpendicular to the line of axis of the femoral shaft is drawn connecting the lateral cortex (point F) and the point of the lesser trochanteric (point G). This represents the first osteotomy site (Figure 60-88). Using a goniometer or a protractor to measure the degrees of the wedge to be removed, a mark (point H) is made on the medial cortex of the femoral neck, above the lesser trochanter. Points F and H are connected. This line is the second osteotomy (See Figure 60-88). The triangular wedge of bone, HFG, is removed.

Care must be taken that the line F-H, the second osteotomy, does not enter the ventral medial aspect of the femoral head. In dogs with a short area between the femoral head and the lesser trochanter, the calculated edge may be too large to remove without taking part of the ventral femoral head. In those cases, the second osteotomy is directed to the junction of the femoral neck and femoral head.

The transparency paper is cut in half from point F to point G. Then, the wedge (point F to Point H) is cut out of the paper. The paper femur is reduced, and the plate (Double Hook Plate, Synthes, Paoli, PA) is contoured to the lateral aspect of the paper femur. The center of the solid portion of the plate, between the first and second proximal holes (Figure 60-89), should be aligned over point F. Additional bending of the plate may be necessary during surgery.

The second step in the preoperative planning for an intertrochanteric osteotomy is measuring the anteversion. The anteversion of the femoral neck and head can be measured from an axial radiograph of the femur. With the dog on its back on the radiographic table, the long axis of the femur is positioned at a right angle to the table and the x-ray beam is aimed down the shaft of the femur

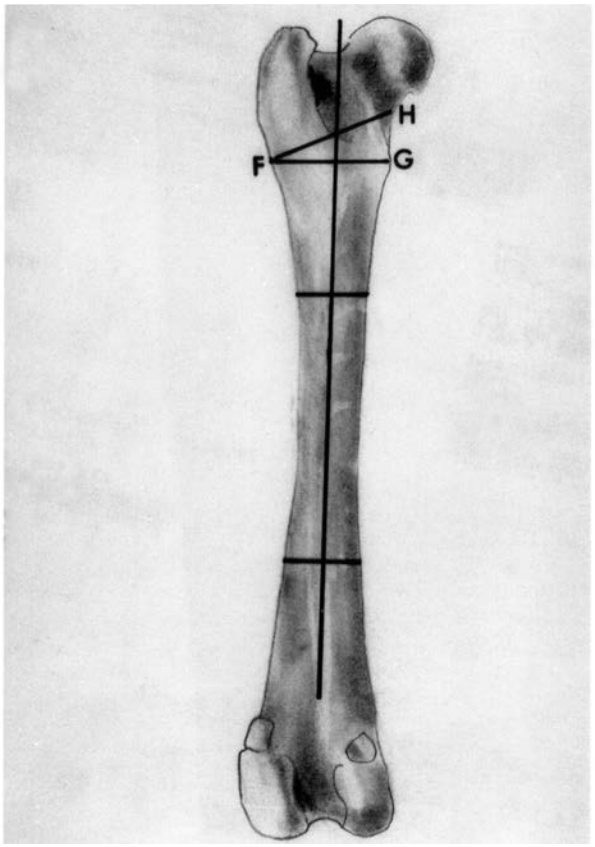

Figure 60-88. Posterior view of the femur illustrating the determination of the first osteotomy (line F-G) and the second osteotomy (line F-H) of the intertrochanteric osteotomy surgery.

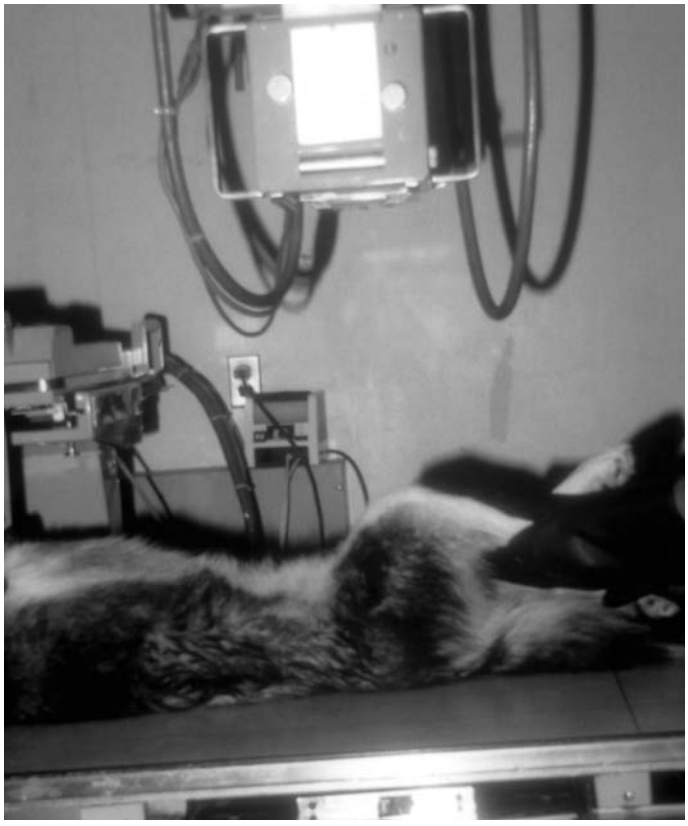

Figure 60-90. Dog in dorsal recumbency on the radiographic table with the femur positioned at the right angle to the table. The x-ray beam is directed down the long axis of the femoral shaft to obtain an axial radiograph of the femur.

Figure 60-89. Five-hole double hook plate used for fixation after three-plane intertrochanteric osteotomy of the femur.

from the stifle to the coxofemoral joint (Figure 60-90). Femoral head and neck anteversion is defined as the angle formed by the plane containing the axis of the shaft and the plane containing the axis of the femoral neck.[13] In other words, with the medial condyle being medial, the lateral condyle being lateral, and the patella being anterior, the shaft of the femur is in anatomic position. With the femur in anatomic position, the direction the femoral neck takes as it leaves the shaft of the femur is either normoverted (straight medial), anteverted (anterior towards the ilium), or retroverted (posterior towards the ischium). An excellent radiographic sign of anteversion is the outline of the lesser trochanter. With the femur in a normal anteversion (10 to 20 degrees), only the tip of the lesser trochanter will be seen on the standard ventrodorsal (V-D) radiograph of the pelvis and femurs. With increased anteversion, more or the entire lesser trochanter will be seen on the standard (V-D) radiograph (See Figure 60-82).

To measure the angle of anteversion, a piece of transparent paper is placed over the axial radiograph of the femur (Figures 60-91 and 60-92). A straight line is drawn from the most posterior point of the medial condyle (point M) to the most posterior point of the lateral (point L) condyle (Figure 60-93). Next, a straight line is drawn from the point where the femoral head meets the femoral neck dorsally (point J) to the ventral femoral head-neck junction (point I). Also, a straight line is drawn between the points where the femoral neck meets the femoral shaft dorsally (point K) and ventrally (point N). A line is drawn connecting the bisect of these two lines. This line is the axis of the femoral neck. This axis line is extended to the condylar line (Figure 60-93). The angle between the two lines is the angle of anteversion of the femoral neck.

Preoperative Planning – Shortcut

The above radiographic measuring and preoperative planning should be carried out on each surgeon's first half a dozen cases, or until the surgeon has a really good feel for the three dimensional geometry of the coxofemoral joint. During those first surgeries you will notice that the size of the wedge you surgically remove is almost always the same even though your measurements were different. The reason for this is twofold. One, there

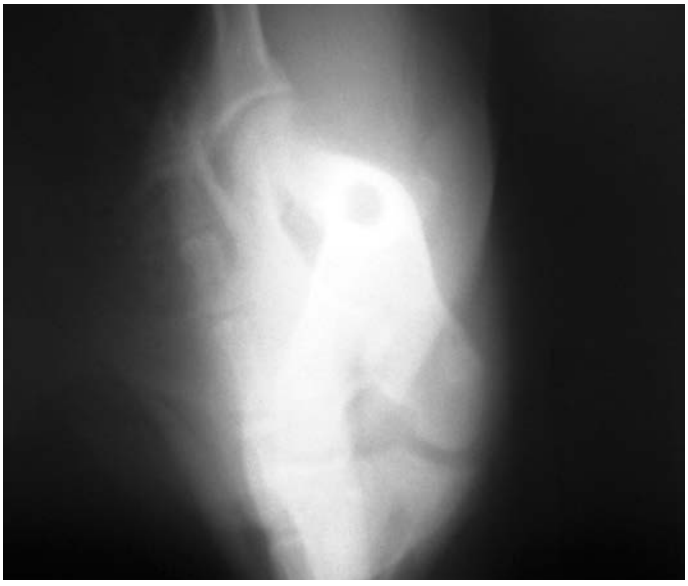

Figure 60-91. Axial radiograph of the femur. Note the angle of the femoral neck in relation to the shaft of the femur. This angle is the anteversion of the femur.

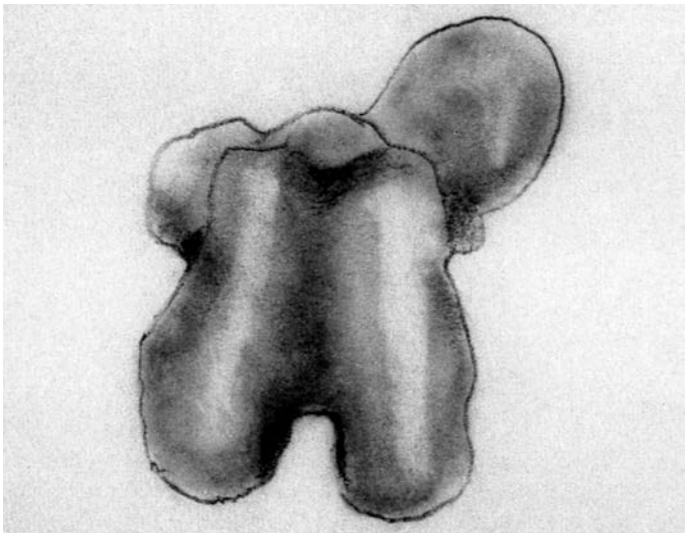

Figure 60-92. Axial view of the femur. Compare this drawing to the axial radiograph of the femur in Figure 60-91.

is 5 to 10% error in everyone's measuring, i.e., if you come back a day later and remeasured your angles, you would vary 5 to 10%. The second reason is there is a 2 to 5 degree variation in the surgery itself, even with the instrumentation available. This all adds up to a 2 to 10 degree variation between what you measured and what you accomplished surgically.

Therefore, the philosophy that can be practiced (after you have a firm three dimensional mental vision of the geometry of the coxofemoral joint) is to improve the relationship of the femoral head to the acetabulum, you should not think you are returning the angles of the femoral neck to normal. Mainly because most people do not agree what normal is, it varies with different breeds, your measurements are not exact and your surgery is not exact (within 1 or 2 degrees).

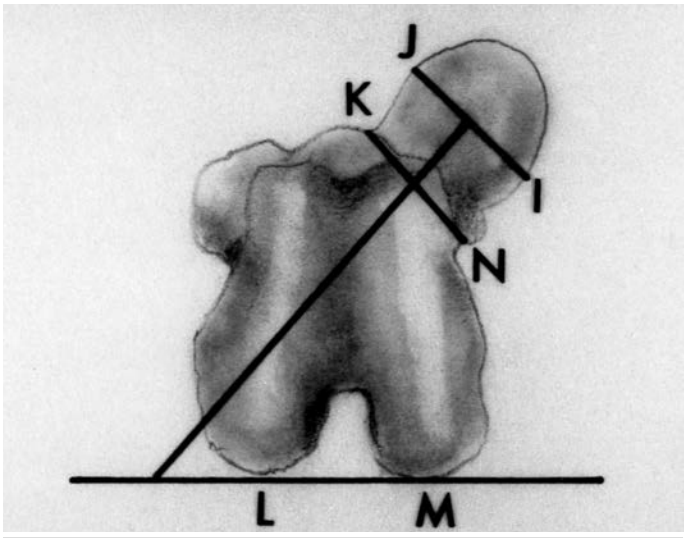

Figure 60-93. Axial view of the femur illustrating one method of determining the angle of anteversion of the femoral neck. *M* = posterior point of medial condyle; *L* = posterior point of lateral condyle; *J* = dorsal junction of femoral head and neck; *I* = ventral junction of femoral head and neck; *K* = dorsal junction of femoral neck and shaft; *N* = ventral junction of femoral neck and shaft.

Therefore with the philosophy of improving the subluxated coxofemoral joint, you can skip the measuring and proceed directly to removing a wedge from the intertrochanteric region that has a base 1/4" (6 mm). The base of the wedge is H-G (See Figure 60-88). This is accomplished by making a mark on the lateral surface of the femur directly opposite the lesser trochanter. This mark and the point of the lesser trochanter is the line of your first osteotomy (point F on Figure 60-88). After the first osteotomy, the proximal part of the femur is steadied with a bone clamp on the greater trochanter and the muscles elevated off the medial femoral neck with a periosteal elevator. The second osteotomy is started at the same point the first osteotomy was started and directed so the wedge of bone has a base of 1/4 inch (6 mm). You can stop as often as necessary and check to see that your saw blade is directed correctly. Please realize that this generalization or shortcut is only possible because most of the dogs are large breed young dogs, very similar in size. If you decide to do this procedure on a medium size dog or a giant breed dog, you can adjust the base of your wedge +/- 1 or 2 mm.

After removing the wedge of bone, the proximal metaphysis of the femur is reduced to the diaphysis of the femur. This reduction (making sure you have bone on bone and no gap) will improve the angle of inclination 15 to 25 degrees.

The other two planes of correction (antiversion and medialization) of the proximal femur are accomplished as directed in the surgical procedure, and without the need of presurgical measurements.

In conclusion, this shortcut was presented not to save time or because of laziness. It was presented to inspire in each surgeon the surgical goal of improving the biomechanical potential of the coxofemoral joint, not returning the joint to normal (or so-called normal) angles.

Surgical Procedure

The dog is prepared for aseptic surgery of the intended rear leg from the dorsal midline to the hock and placed in lateral recumbency. The proximal half of the femur is exposed by routine incision of the skin, subcutaneous tissues, and fascia lata. The biceps femoris muscle is retracted posteriorly. The superficial gluteal muscle is elevated from its insertion and retracted dorsally.

The posterior half of the origin of the vastus lateralis muscle (on the lateral aspect of the femur) is incised and retracted cranially (Figure 60-94). The lesser trochanter is palpated with the forefinger on the posterior-medial aspect of the femur, and a mark is made in the bone with a bone saw on the lateral aspect of the femur exactly opposite the lesser trochanter (See Figure 60-94). The special drill guide (No. 380.01, Synthes, Paoli, PA) is laid on the lateral aspect of the femur so that the line on the drill guide is exactly above the mark scored on the bone (Figure 60-95). Using the leveling screw, the long axis of the drill guide is set parallel to the shaft of the femur (Figure 60-95). If the long axis of the drill guide is not parallel, there will be the possibility that the first osteotomy may not be perpendicular to the long axis of the femur. The proximal-caudal hole is drilled with a 3.2 mm drill bit (Drill bit with stop, No. 380.03, Synthes, Paoli, PA) into the greater trochanter to the stop on the drill bit. The 3.2-mm locking pin from the drill guide is placed through the guide into the hole in the greater trochanter. The most distal hole of the three proximal holes in the guide is drilled with a 2.0 mm drill bit into the greater trochanter. The 2.0 mm locking pin is placed through the drill guide into the bone. The remaining hole (proximal-cranial) is now drilled in the greater trochanter with the 3.2 mm drill bit down to the stop. Using this specially designed drill guide ensures that holes in the greater trochanter are exactly placed to accept the hooks on the plate (See Figure 60-89). Next, a 2mm hole is drilled through the center of the distal hole in the tail of the drill guide through one cortex only (Figure 60-95). This hole will be used later for anteversion correction.

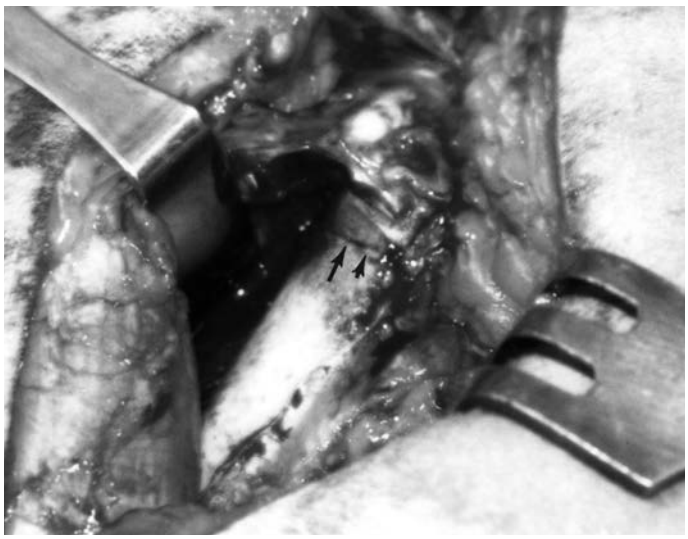

Figure 60-94. Lateral aspect of the femur with the vastus lateralis retracted cranial and the biceps femoris muscle retracted caudal. A mark is made on the bone of the lateral cortex *(arrows)* exactly apposite the lesser trochanter.

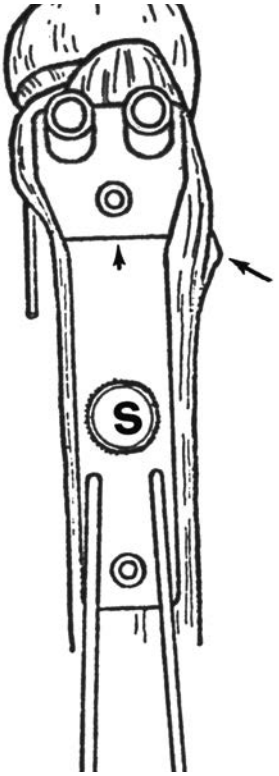

Figure 60-95. Drawing of the lateral aspect of the femur with the special intertrochanteric drill guide in place on the lateral femur. The line on the drill guide *(small arrow)* is placed exactly on top of the mark made on the lateral cortex of the femur, which indicates the level of the lesser trochanter *(large arrow)*. The leveling screw *(S)* is used to set the long axis of the drill guide parallel to the shaft of the femur.

The first osteotomy is now performed, cutting the femur from the mark scored on the lateral aspect of the shaft to the point of the lesser trochanter. There is a saw guide (No. 380.07, Synthes, Paoli, PA) available that hooks into the two 3.2 mm holes in the greater trochanter (Figure 60-96). After the hooks of the saw guide are in place, the blade of the saw guide is adjusted and directed so it is lined up on the score in the bone on the lateral aspect of the femur and the tip of the lesser trochanter on the medial side of the femur. After the first osteotomy is performed, the goniometer (No. 380.05, Synthes, Paoli, PA) is placed in the osteotomy and the femur reduced with two bone clamps. The goniometer is held stable by the pressure of the reduced femur. The blade of the saw guide is now changed to the degree as calculated from the radiograph during the planning stage or to give you a 1/4 inch (6 mm) base to your wedge (Figure 60-97). The saw guide blade is tightened. Using the saw guide, the second osteotomy is made and the wedge of bone removed (Figure 60-98). The femur is now reduced taking extreme care that there is 100% bone contact at the osteotomy site. To have the varus correction of the angle of inclination of the femoral neck, there must be bone-to-bone contact with no gap where the wedge was removed. While maintaining this reduction at the osteotomy site, an aluminum template is laid on the lateral aspect of the femur and contoured to match the femur. The template slides into the saw guide allowing coordinated bending of the proximal plate and the three predrilled holes in the proximal femur. The final bending of the plate is performed to match the template. The hooks are then inserted into the greater trochanter.

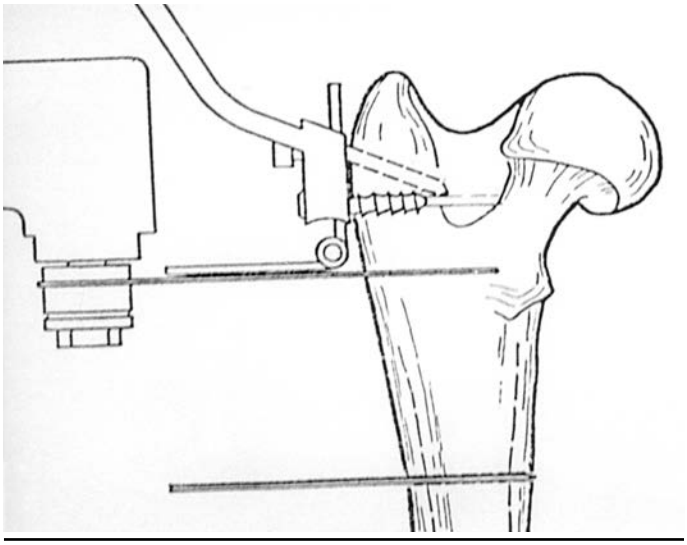

Figure 60-96. Posterior view of the proximal femur with the intertrochanteric saw guide in place. The two hooks of the saw guide fit into the proximal two holes that were drilled in the greater trochanter for the hooks of the intertrochanteric plate.

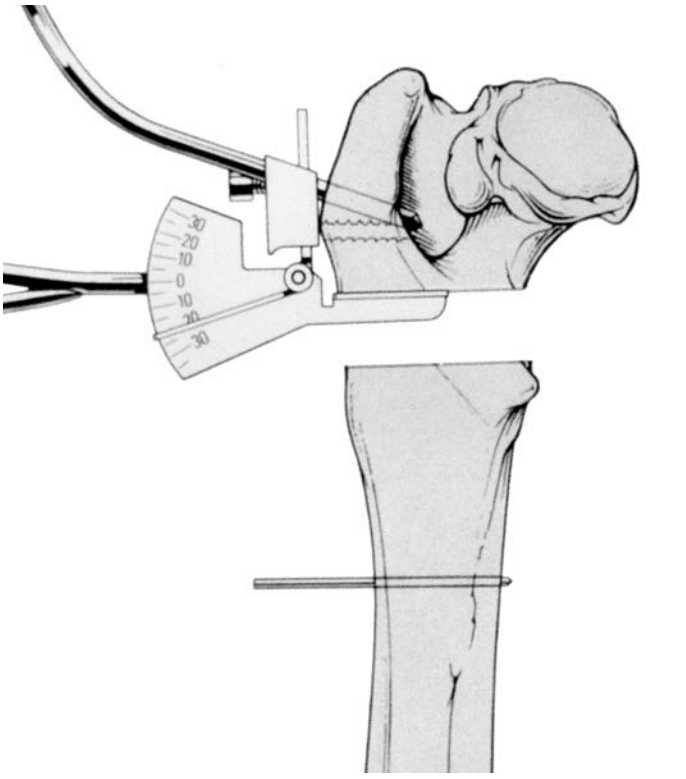

Figure 60-97. Posterior view of the proximal femur with the first osteotomy made (See Figure 60-88) and the saw guide in the greater trochanter and the goniometer in the first osteotomy.

The femur is now reduced again, making sure there is no gap at the osteotomy site. The hole just distal to the two hooks in the proximal segment is now redrilled with a 2.5 mm drill bit. This hole is tapped with a 3.5 mm cortical tap. The plate is loosened approximately 4 mm and two washers (No. 219.99, Synthes, Paoli, PA) are placed between the hook plate and the bone, in line with the hole in the plate and bone (Figure 60-99). The screw is then placed and tightened. The washers placed under the plate will medialize the proximal femur 3 mm compared to the shaft of the femur, and this pushes the head of the femur deeper into the acetabulum. If the placement of these washers interferes with reduction at the osteotomy site, the screw and the plate should be removed. The plate is recontoured as needed to conform to the perfectly reduced femur. The plate is then reapplied. This step is repeated as necessary until the reduction at the osteotomy site is perfect, with no gap between the proximal and distal femur.

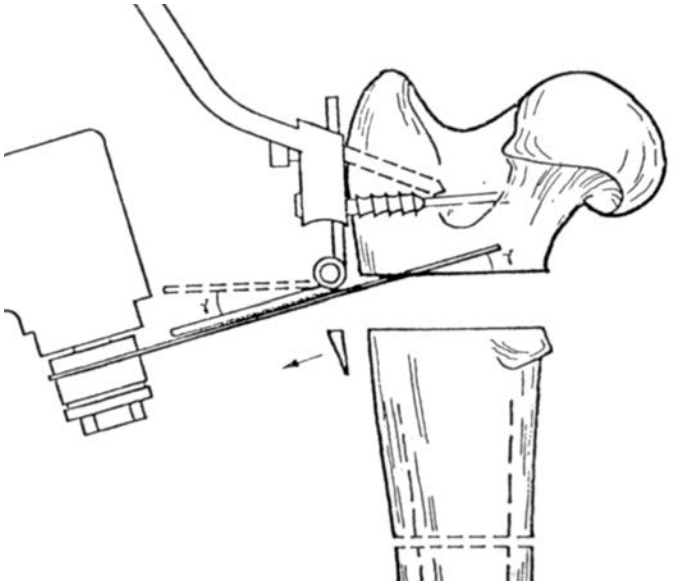

Figure 60-98. Posterior view of the proximal femur with the saw guide in the greater trochanter. The second osteotomy is performed with the help of the blade of the saw guide in the new position (compared to Figure 60-96) to remove the calculated wedge of bone.

Figure 60-99. Ventrodorsal radiograph of the pelvis and femurs of a 7-month-old Golden Retriever immediately following a three-plane intertrochanteric osteotomy of the right hip. Note that the femoral head, neck, and trochanteric region are medialized compared to the shaft. This is accomplished by placing two washers between the plate and the bone at the most proximal screw.

With the femur reduced at the osteotomy site, the shaft of the femur is rotated outwardly so that the stifle rotates outward until the 2 mm hole that was drilled in the distal lateral cortex is just visible at the caudal edge of the plate. This degree of rotation will cause a 15 degree reduction in anteversion of the femoral head toward normoversion (Figures 60-100 and 60-101). The hole just distal to the osteotomy site is now drilled with a 2.5 mm drill bit through a compression (loaded) drill guide, tapped, and a 3.5 mm cortical bone screw is placed. After each screw placement, the reduction must be checked at the osteotomy site and at the rotation guide hole. The remainder of the holes in the plate are now filled with 3.5 mm screws placed in a neutral position.

The vastus lateralis muscle is pulled over the plate and sutured to its incised origin. The superficial gluteal muscle is pulled over the greater trochanter and proximal plate and sutured to the lateral fascia of the vastus lateralis muscle. The biceps femoris muscle is sutured to the fascial lata. The subcutaneous tissue and skin are sutured closed.

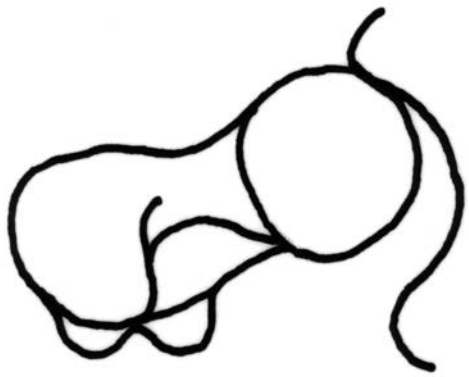

Figure 60-100. Axial view of the femur and acetabulum. This femur has 50 degrees of anteversion.

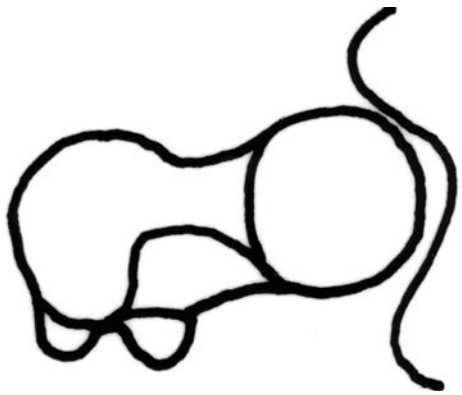

Figure 60-101. Axial view of the femur and acetabulum. This femur has been derotated (retroversion correction) to 15 degrees of anteversion.

Postoperative Care

After surgery, a wound bandage is applied and left in place until suture removal 12 to 14 days later. If the dog removes the bandage, it usually is not replaced. Candidates for an intertrochanteric osteotomy are usually young, healthy animals with no preoperative traumatized tissue; therefore, prophylactic antibiotics are not needed. The dogs are allowed to use the leg immediately. When the procedure is properly performed, there is little concern about fixation loosening before clinical union. Dogs usually are dismissed from the hospital 1 or 2 days after surgery to be confined to the house or kennel and walked restrained by a leash. Running and jumping are not permitted for 4 weeks, and no yard freedom is allowed.

The second side is reconstructed 4 to 6 weeks later, if necessary. Postoperative care for the second side is the same as the first. Owners are requested to give a progress report 6 weeks later. The plates are not removed unless a problem, such as loose screw(s), cause clinical signs of pain or lameness.

Results

There have been two retrospective studies on this procedure.[11,14] The first study[11] was performed on 210 dogs that underwent intertrochanteric osteotomies. Clinical evaluation from 1 to 7 years after surgery on 183 of the dogs revealed an 89.6% excellent or good return to motor activity. The results relating to motor activity at a minimum of 1 year were rated as follows: excellent, walking and running normally without pain for long distances; good, was defined as walking or running normally without pain but with a slight limp appearing after exercise. Postoperative physical examinations on 90 dogs from 6 months to 1 year after surgery demonstrated an increase in circumferential thigh muscle mass over the operated leg in the dogs that showed good to excellent results.[11]

Dogs operated on before the appearance of radiographic signs of degenerative joint disease had better results than those operated on after degenerative joint disease was established.

Only 12.1% of the dogs with severe osteoarthritis had excellent results, whereas a 51.4% of the dogs without preoperative osteoarthritis changes and 45.8% of those rated as having moderate osteoarthritis were considered to have excellent results.

The second study involved a clinical evaluation after 7 years of using this surgery on dogs with early stage CHD.[14] The retrospective study was performed on 37 dogs that had 43 hips reconstructed. The clinical evaluation consisted of a questionnaire, and/or an orthopedic examination; and/or a report from the owner(s) via telephone. At least one form of evaluation was conducted for 42 of 43 hips (98%). Before surgery, on 11 of 37 hips (30%) had been evaluated as functionally good or excellent. In this study, excellent function was defined as normal function. Good function was defined as normal weight bearing with joint stiffness after strenuous exercise or long rest. On the basis of the owner's telephone report, 19 of 28 hips (68%) were functionally good or excellent at postoperative month 11 (on average). On the basis of the questionnaire data, 17 of 24 hips (70%) were functionally good or excellent at postoperative year 1. On the basis of the orthopedic examination findings, 27 of 33 hips (84%) were functionally good or excellent at postoperative month 15 (on average). Of 36 owners, 33 (91.6%) reported they would have the procedure performed again if the circumstances were the same.

Results of statistical analysis indicated that the procedure was helpful for up to 3 years after surgery.[14] This observation was true regardless of who examined the dog after surgery, surgeon

or owner. Because there were not enough data after postoperative year 3, no statement could be made concerning whether the benefit of surgery would still be detected after that point.

After performing the intertrochanteric osteotomy for the treatment of early-stage hip dysplasia for twenty-five years, we have found a 92% success rate for the surgery, if performed on dogs without moderate or severe degenerative joint disease, i.e., with no or only mild degenerative joint disease and subluxation. The remaining 8% of the dogs have advanced their osteoarthritis from mild to severe, and have been treated with a total hip replacement or with pain medication if the owner did not wish the replacement.

Discussion

Because the potential for remodeling is greatest early in life, corrective orthopedic procedures such as the three-plane intertrochanteric osteotomy ideally should be performed while the bones and joints have the greatest remodeling potential.[1,14,15,16] Therefore, as soon as clinical signs of CHD and subluxation of the coxofemoral joint are detected, surgery should be recommended.

In early stage CHD, the femoral head is movable in and out of the acetabulum; therefore, subluxation may not always be demonstrable on each radiographic exam. This may be due in part to the inward rotation that the holder puts on the limbs; this will torque the joint capsule and may move the head into the acetabulum. Others feel this same torque is developed by overextending the hind limbs to obtain the standard V-D view of the pelvis. It also may be influenced by muscle tension; therefore, some have recommended all radiographic exams of the canine pelvis be performed under anesthesia or at least heavy tranquilization.

Because there is a direct correlation between increasing age and severity of osteoarthrosis[11] and because there is an inverse relationship between severity of osteoarthrosis and improvement after surgery, intertrochanteric osteotomy is best performed in young dogs prior to the development of osteoarthrosis. Once degenerative changes occur, the prognosis for return to normal function diminishes.

In early stage CHD, relief of pain owing to the three-plane intertrochanteric osteotomy may be explained by biomechanical principles involving 1) improved congruity of the head and acetabulum with wider surfaces of contact, 2) a medial shifting of the line of weight bearing, and 3) relief of pressure by release of muscle contracture.[17]

The results of the two studies are remarkably similar. In the first study, 89.6% of the dogs were evaluated as excellent or good in return to motor activity. In the second study, 91.6% of the owners indicated they were pleased with the results and would have the procedure performed again if the circumstances were the same.

The intertrochanteric osteotomy is a conservative procedure because the option of a conversion to a total hip replacement in unsuccessful situations remains.[17] In fact, when this procedure was adopted 25 years ago, it was performed with the goal eliminating pain and improving function in young dogs until they were old enough for total hip replacement. Of the first 240 hips in which an intertrochanteric osteotomy was performed, 9 have subsequently required a total hip replacement to relieve the pain of osteoarthritis secondary to CHD.

Intertrochanteric osteotomy provides relief of pain in humans for an average 5 to 6 years.[18] Although each dog varied as to duration of benefit, most remained comfortable and had normal function for their entire lives.

In conclusion, the goal of the three-plane intertrochanteric osteotomy is to decrease stress in the coxofemoral joint, thereby relieving pain associated with early stage CHD. Although radiographically detectable degenerative changes within the coxofemoral joint continue, the degenerative changes proceed at a slower pace than if the surgery was not performed and the clinical signs of hip pain do not manifest for the greater majority of the dogs having this procedure (Figure 60-102).

DARthroplasty: Another Treatment for Hip Dysplasia

Dean R. Gahring and Theresa Devine Slocum

Introduction

In hip dysplasia, laxity and incongruity of the hip joint lead to progressive degenerative changes, inflammatory responses, and pain. The consequences of these responses are gait abnormality, lameness, and limb weakness.

Treatment for hip dysplasia has historically included four options: 1) long-term medications, 2) femoral head and neck excision arthroplasty (FHE), 3) triple pelvic osteotomy (TPO), and 4) total hip replacement (THR). Each of these approaches has its benefits and drawbacks. The ultimate objective is to return the patient to the most comfortable and functional status possible. FHE will often leave the patient with gait abnormalities and limb weakness (especially larger patients weighing over 25 pounds). Results with TPO are best when done in young patients with minimal degenerative changes, reasonably good joint congruity, and minimal to no acetabular filling. Cases with more advanced degenerative changes, acetabular filling, and laxity usually continue to show progressive degenerative changes. Consequently, we choose to perform TPO's on patients with the restricted criteria of minimal degenerative changes and incongruity of the hip joints, no appreciable acetabular filling, and the presenting complaint is essentially pain and lameness with joint laxity. THR is not recommended in young patients less than a year old. It is primarily recommended as a salvage procedure for hips with extensive loss of cartilage. Consequently, a "gap" in surgical treatment options has developed between the candidate for TPO and the candidate for THR.

A fifth option is DARthroplasty.[1] This procedure was designed to create additional dorsal bone support of the femoral head and prevent the pain associated with joint capsule tears from the dorsal acetabular rim by creating a bony extension of the dorsal acetabular rim (DAR) of the acetabulum. The new DAR shelf should dramatically reduce dorsal subluxation and often significantly reduces the tendency for lateral translation. The additional dorsal bone support should provide the patient more joint stability and thus allow the patient to gain more strength in the limb.

The Surgical Procedure

The DARthroplasty technique is a two-part process which involves harvesting cortical and cancellous bone graft from the wing of the ilium and applying that bone graft to the dorsal acetabulum. One, two, or even three corticocancellous strips can be used, which are tied together and then anchored to the dorsal hip joint capsule with strong absorbable sutures that are passed through drill holes in the bone strips, and the strips are placed next to or overlapping the original dorsal acetabular rim. Holes are drilled into the original DAR and the new shelf is overlaid with cancellous bone graft.

The dog is placed in lateral recumbency to prepare for surgery. The hair is shaved over the affected hip dorsally to the midline of the spine, to 5 cm cranial to the wing of the ilium, ventrally 10cm distal to the greater trochanter, and caudally to the level of the tuber ischium. Appropriate sterile surgical preparation and draping of the surgical site is done. A 5 cm incision is made half way between the tuber sacrale and the tuber coxae from the cranial limit of the ilium toward the greater trochanter. A standard gluteal muscle roll-up approach is used. A Gelpi retractor is placed just under the gluteal fascia.

A Langenbach elevator is used to elevate the middle and deep gluteal muscles by placing it on the wing of the ilium at the sartorius muscle and sliding along the ilium toward the greater trochanter. Elevate only to the level of the deep gluteal nerve. Three to five corticocancellous bone strips are harvested from the lateral aspect of the wing of the ilium using a bone gouge to obtain appropriate sized graft curls. Cut parallel to the long axis of the ilium with the bone gouge, being careful not to perforate the medial cortex of the ilium. Note the order of the corticocancellous strips for easy assembly later. Cancellous bone graft is then harvested with a curette from the same site. Closure of this incision is routine.

A dorsal approach is made to the acetabular rim, either via a second incision or an extension of the first one. The skin incision is made parallel to the cranial margin of the biceps femoris muscle, from the level of the third trochanter to the level of the sacrotuberous ligament. The fascia along the cranial margin of the biceps femoris is incised and the biceps femoris is retracted caudally. The sacrotuberous ligament is isolated from the sciatic nerve and caudal gluteal vessels. In cases where two or three

strips are used, the sacrotuberous ligament may need to be transected to minimize the risk of sciatic nerve impingement. The superficial and middle gluteal muscles are retracted cranially. The joint capsule can be palpated between the deep gluteal muscle and the cranial margin of the gemellis muscles. A small vessel can usually be identified at this landmark between these muscles. Handheld retractors are used to gently retract the gemellis caudally and the deep gluteal muscle cranially and these muscles are freed from the joint capsule cranially, caudally and dorsally to the bone of the acetabulum with a periosteal elevator. *Always be aware of the sciatic nerve and be very careful not to be too aggressive in retracting the gemellis.* Pushing the femoral head distally, withdraw any excessive joint fluid. We also inject bupivacaine into the joint to provide postoperative pain relief.

A protected 1/8 inch (3.2 mm) Steinman pin or a drill bit is used to drill 6-10 holes in the lateral cortex around the acetabulum (Figure 60-103), being careful to avoid perforation of the acetabulum. The dorsal apex of the femoral head is palpated through the joint capsule. The leg can be manipulated to help identify the point of maximal subluxation of the femoral head. The number of corticocancellous strips anchored to the joint capsule depends upon how many are needed to cover the joint capsule from the high point of femoral head luxation to the edge of or to slightly overlap the acetabular rim. If 2 or 3 strips are needed, they are sutured together with absorbable sutures at the ends and in the middle to create an appropriate bone "cap" over the femoral head. The corticocancellous bone strips are contoured to create an appropriate bone cap using Kelly forceps to put a curve in the strips. The corticocancellous bone cap is laid over the joint capsule, *cortical side to the joint capsule and cancellous side toward the dorsal rim drill holes,* placed beneath the external rotators and the deep gluteal muscles, then anchored to the joint capsule with 1 or 2 heavy absorbable sutures, passed through the joint capsule from medial to lateral, then through drill holes in the middle of the most lateral bone strip and tied snugly in place. Place a strip of graft on its edge dorsally to prevent medial migration of graft. Cancellous bone graft is placed over the drill holes and between the strips. The cancellous bone graft should be in contact with the drill holes so blood supply and the conditions for healing directly between the graft and acetabulum are established. Any additional corticocancellous strips are packed over the new graft to provide a cortical shell.

The deep gluteal muscle is pulled over the new graft and sutured to the internal obturator tendon and muscle. This helps stabilize the graft and minimizes its tendency for movement and/or migration. The superficial gluteal muscle is reattached to its incised fascia, the biceps femoris muscle is reapposed to the gluteal fascia, and the remainder of the closure is routine. Post-operatively, 3 radiographic views are taken: hip-extended, lateral, and DAR views.

Results

We have been performing this procedure for several years. Our criteria for performing a DARthroplasty are simple. As long as there is joint cartilage present in cases of hip dysplasia, then a DARthroplasty can be done (Figures 60-104 and 60-105). If joint cartilage is completely worn away and the joint palpates with notable crepitus, then that hip is *not* a candidate for DARthroplasty. We have performed DARthroplasties on cases where one hip had a TPO done and the other hip was a DARthroplasty. Thigh circumference is usually slightly greater on the TPO side, which would be anticipated since TPO requires a hip with no acetabular filling, whereas the indications for DARthroplasty include both acetabular filling and distortion of the DAR. What was surprising was that, in most cases, the DARthroplasty hip was deemed as strong and as functional as the TPO hip by the owners, even

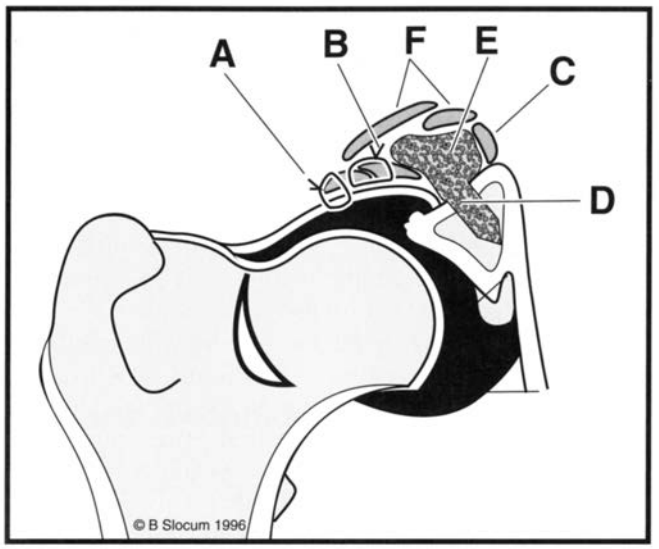

Figure 60-103. The DARthroplasty is formed from a bone graft. A corticocancellous strip is contoured to the joint capsule at the dorsal apex of the femoral head, and it is held in place by one or two capsular sutures *(A)*. A second strip may be contoured to the joint capsule and sutured to the first *(B)*. Barrier strips are placed dorsally, cranially, and caudally *(C)*. The lateral cortex of the pelvis is perforated with multiple holes *(D)*, which are packed with cancellous bone *(E)* and are covered with additional corticocancellous strips *(F)*.

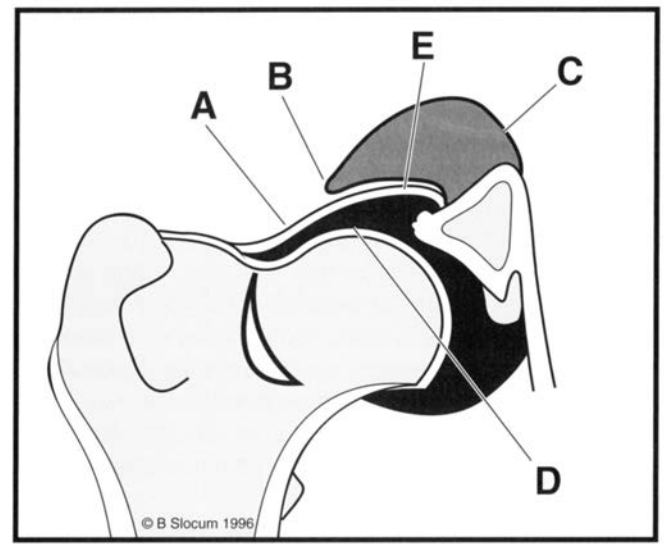

Figure 60-104. Four months after bone grafting, the joint capsule *(A)* is covered by the new dorsal acetabular rim (DAR) *(B)*. The DARthroplasty *(C)* is maturing into a solid bone continuous with the pelvis. The dorsal apex of the femoral head *(D)* lies beneath the new DAR *(B)*. Usually, one sees a concavity for the joint capsule *(E)*, and the femoral head does not subluxate.

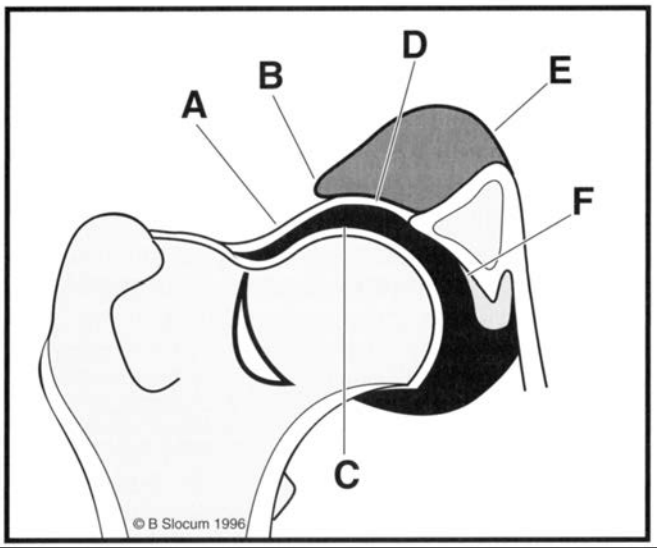

Figure 60-105. One year after bone grafting, the joint capsule *(A)* is covered by the new dorsal acetabular rim (DAR) *(B)*. The dorsal apex of the femoral head *(C)* lies beneath the new DAR *(B)*. The concavity for the head beneath the DARthroplasty *(D)* is often continuous with the old DAR. The DARthroplasty *(E)* is mature bone that is continuous with the pelvis. Acetabular osteophytes *(F)* continue slow and progressive filling of the acetabulum until the femoral head is stable in the "new acetabulum".

though the DARthroplasty was performed on the "poorer" hip. We have also performed DARthroplasties on hips that were *markedly* arthritic, but had intact cartilage, that also did very well clinically.

Weight bearing is surprisingly rapid after surgery and most patients are sent home with their owners the day after surgery. Exercise and activity are restricted to leash walking for the first month after surgery, and then allowed to increase once the graft is radiographically fused to the pelvis (usually 8 to 16 weeks after surgery). Pain free, normal activity can be noted as early as 2 weeks after surgery and the hip joint palpates stable, with no evidence of subluxation noted. All patients experience a decrease in abduction due to the extended DAR. By 4 months post-operatively, most patients are running, jumping, and playing normally, without pain. Radiographs 2 to 4 months after surgery may show that the femoral head has migrated medially, back into the acetabulum.

Long-term follow-ups have also been rewarding. We have found that patients continue to be active, athletic, and pain free and a very high percentage do not require any anti-inflammatory medications. As the shelf arthroplasty matures, it provides a stable bony support for the femoral head and the joint capsule becomes an extension of the joint cartilage weightbearing surface. The joint capsule loses its collagenous appearance, which is presumed to undergo metaplasia to a fibrocartilage. Because pain free activity results, limb strength and muscle mass increase. As noted, abduction remains minimally to moderately limited, but all other ranges of motion usually remain at or near normal.

Complications with the procedure primarily involve temporary sciatic dysfunction. The sciatic nerve may be injured during retraction or drilling and may, in cases requiring very large grafts, become trapped between the bone graft and the sacrotuberous ligament. This can be prevented by severing the sacrotuberous ligament at the time of surgery. These complications should be minimized as the surgeon and assistants gain experience. Infections are almost nonexistent. Although the criteria are very broad for performing DARthroplasties, one limitation, besides lack of cartilage, may be patients with completely luxated hips.

Conclusion

DARthroplasty has been a very effective procedure that fills the gap between the cases with narrow indication criteria for TPO and the end-stage salvage criteria for total hip replacement. DARthroplasty was originally developed by Dr. Barclay Slocum with the idea that additional bone could be produced that would enhance future THR. Although previous DARthroplasty does not preclude THR, none of our patients that have undergone DARthroplasty have developed signs that would even suggest *considering* total hip replacement. As stated before, we have been pleasantly surprised at how small a percentage of cases that have undergone DARthroplasty even require anti-inflammatory medications to remain comfortable.

Total Hip Arthroplasty

Marvin L. Olmstead

Surgical Description: Total Hip Arthroplasty

Total hip arthroplasty is also known as total hip replacement. It is the most effective way to provide a canine patient with a mechanically sound, pain free, ball and socket hip joint, once osteoarthritis is present. Both cemented and cementless prosthesis have been successfully used to treat non-infectious, non-neoplastic disabling conditions of the canine coxo-femoral joint. The cementless hip is commercially available. Most dogs can be successfully treated with either a cemented or a cementless total hip arthroplasty. However, some small boned dogs can have a cemented prosthesis implanted but not a cementless one. Also large boned dogs with a straight or "stove pipe" femur are not good candidates for implantation of a cementless stem, as the risk of subsidence is high. In the event of a failure of a cementless prosthesis, a cemented prosthesis is often used to successfully preserve the total hip arthroplasty. The cementless hip prosthesis is also less forgiving during implantation than the cemented prosthesis. For these reasons, a surgeon should be very comfortable with the technique for cemented hip arthroplasty before learning the technique for implanting a cementless prosthesis. Thus, this chapter will concentrate primarily on cemented techniques.

The most commonly implanted prosthesis is a cemented modular prosthesis made by BioMedtrix Inc. (Boonton, NJ), which also manufacture cementless implants that use the same head as

the cemented prosthesis. This allows the surgeon to implant a cemented component in one portion of the hip (either the acetabulum or the femur) and a cementless component in the hip's other portion. This creates a hybrid total hip arthroplasty.

Dogs with clinical signs related to hip dysplasia or other disabling hip conditions are candidates for surgery once their physis have closed at 9 to 10 months of age and they have a skeletal size that will accommodate the available prosthesis, which generally starts at 14 kg. They are candidates if they are not responsive to medical management or if medical management is no longer relieving clinical signs. When the dog's function is used as an indicator of the need for total hip arthroplasty and not just radiographic evaluation, 80% of dogs will only need one total hip arthroplasty.

Special care must be taken to insure that the surgery is done under strict aseptic conditions. The dog's hind limb is clipped the day prior to surgery. The skin is evaluated for bacterial dermatitis, which, if present, will delay the procedure until the condition is resolved. If the skin is dirty, the dog is bathed. Intravenous antibiotics are administered immediately prior to surgery. Draping of the patient with sterile paper and self-adhering plastic drapes provides a barrier at the surgical site that is impermeable to bacteria. Special instrumentation has been developed to facilitate the implantation of the modular prosthesis (BioMedtrix Inc., Boonton, NJ). Radiographic templates are used prior to surgery to estimate the size of acetabular cup and femoral stem that will be implanted.

The coxo-femoral joint is exposed via a cranial lateral approach. The skin incision starts dorsal and caudal to the greater trochanter and curves along the front edge of the femur. The tensor fascia lata is reflected cranially. Retracting the middle and superficial muscles dorsally with an Army-Navy retractor exposes the deep gluteal muscle. The deep gluteal muscle is incised at its origin and split into 2 segments. The joint capsule is incised along with the vastus medialis and lateralis muscles (Figure 60-106).

At various points in the surgical procedure the femur will be rotated in position. All references in the following text to the lateral, medial, cranial or caudal surface of the femur refer to that surface when the femur is in normal position. To properly perform the femoral osteotomy, the femur is externally rotated so the patella is oriented 90% lateral to its normal position. The medial edge of the greater trochanter is identified. The femoral osteotomy originates at this point. A template of the femoral prosthesis is aligned parallel to the long axis of the femur and the axis of the femoral neck (Figure 60-107). The template acts as a guide for performing the osteotomy. The diseased femoral head is removed. Instrumentation developed specifically for the modular prosthesis allows power reaming of the femur and acetabulum. Although the reaming can be done by hand it is easier and more accurately done with power.

The acetabular bed is prepared first using the acetabular reamer (Figure 60-108). No flush is used during the acetabular reaming so that the cancellous bone shavings can be collected and saved for possible use later. The shavings can be packed into areas of

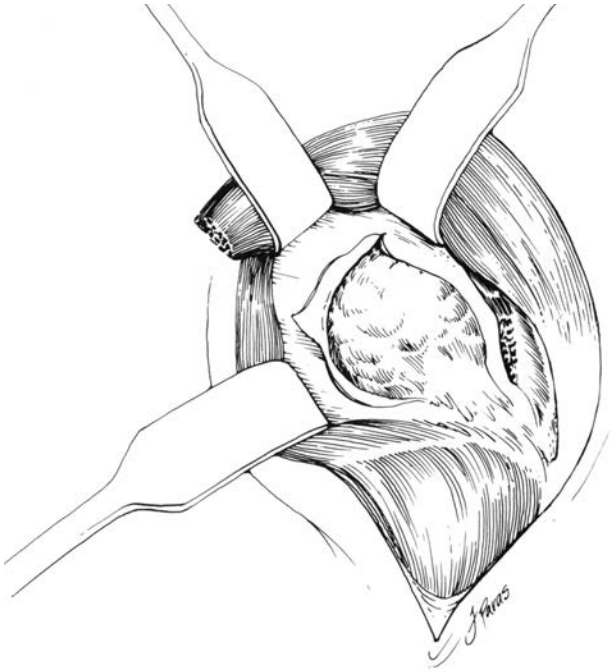

Figure 60-106. The hip joint is exposed through a cranial lateral approach. The deep gluteal muscle is partially incised at its origin, divided longitudinally and retracted cranially. The joint capsule is incised parallel with the axis of the femoral neck and along its insertion on the femur. (Used with permission from BioMedtrix Inc.)

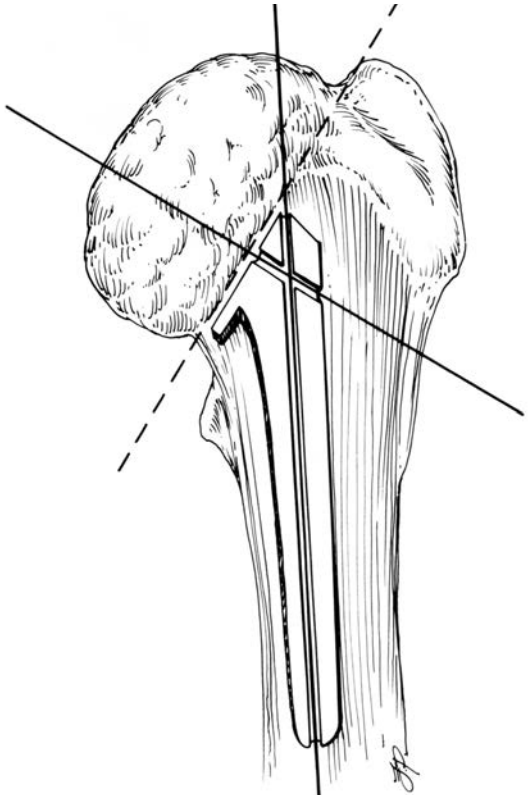

Figure 60-107. A template is used to insure that the osteotomy of the femur is properly positioned. The line running the long axis of the template should parallel the long axis of the femur and the short line on the template is aligned parallel with the axis of the femoral neck. The medial edge of the trochanter is the landmark for the origin of osteotomy. The cut should parallel the collar of the prosthesis. (Used with permission from BioMedtrix Inc.)

deficit in the acetabulum or along fissures in the femoral neck, should either of these be present. The acetabulum is reamed until the medial cortical wall is exposed. Remnants of ligament of the head of the femur may need to be removed to fully expose the medial wall. Three or more holes are drilled around the rim of the acetabulum using a drill bit from the modular system and the tissue guard, which protects soft tissues (Figure 60-109). The holes are connected with a curette. This undercut provides anchor sites for the bone cement or polymethyl methacrylate (PMMA).

The femoral shaft is rotated laterally 90%. A wide tipped Hohmann retractor is used to elevate its proximal end lateral to the tissues that lie dorsal to it. The femoral shaft is first drilled with a drill bit that matches the size of the femoral stem that has been selected for insertion (Figure 60-110). It may be necessary to start drilling with the bit oriented perpendicular to the osteotomy line. As soon as the proximal cancellous bone is penetrated the drill bit should be reoriented so it is parallel with the long axis of the femur. The fluted reamer, that is the same number as the drill bit used, widens the hole in the femoral shaft (Figure 60-111). The final preparation of the femoral shaft is done by hand with a finishing file and sometimes a broach (Figure 60-112). It is important to ream the femoral shaft along the medial edge of the trochanter to insure complete access to the femoral canal. In some cases the wall of the trochanteric fossa must be removed with a rongeur after the drill bit has created an opening to insure that the femoral canal is adequately opened. Reaming along the endosteal surface of the femoral neck accommodates for the curved portion of the femoral prosthesis. A trial prosthesis the same size as the one to be implanted is inserted to ensure the prosthesis will fit properly and that there will be an adequate cement mantel around the prosthesis. The trial prosthesis should move freely in all directions after it is inserted. This motion indicates that there is adequate room for cement around the stem.

Thoroughly cleaning the acetabular bed and the femoral shaft is necessary before the cement is injected. The PMMA should be mixed according to the manufacture's specifications. Only PMMA with a liquid phase of 3 to 7 minutes can be injected. PMMA is injected through a catheter tip syringe into the acetabular bed first. Specific landmarks and the acetabular cup positioner are used to achieve proper position of the acetabular cup (Figure 60-113). All excess PMMA is removed. A second batch of PMMA is mixed for the femoral shaft injection. The shaft is cleared of blood and debris and PMMA is injected into the femoral canal

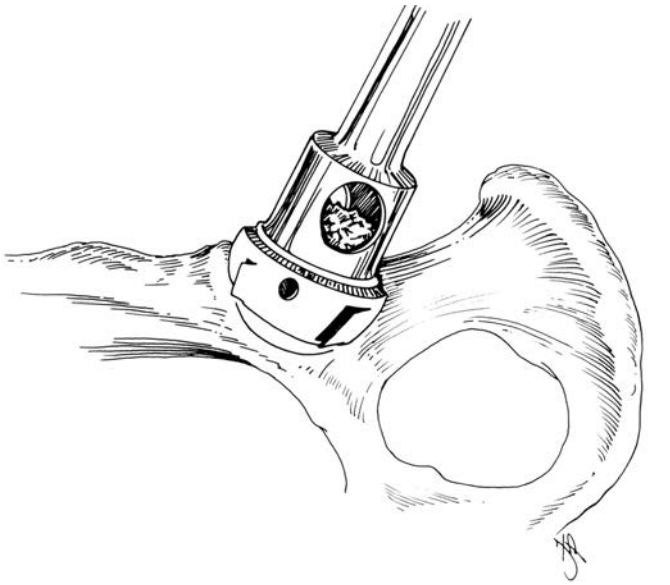

Figure 60-108. An acetabular reamer is used to remove degenerative bone and cartilage to the level of the medial cortical wall of the acetabulum. (Used with permission from BioMedtrix Inc.)

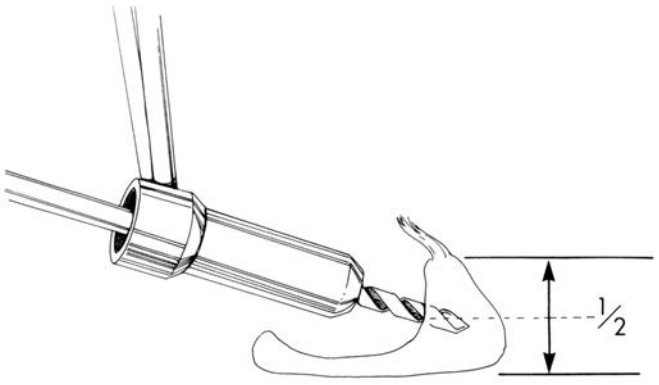

Figure 60-109. Multiple holes in the acetabular bed are made into a trough by connecting the holes. The trough provides anchor points for the polymethyl methacrylate (PMMA) or "bone cement". A tissue guard is used with the drill bit. The holes should be located in the cancellous bone 1/2 between the medial cortical wall and the lateral most edge of the acetabular rim. (Used with permission from BioMedtrix Inc.)

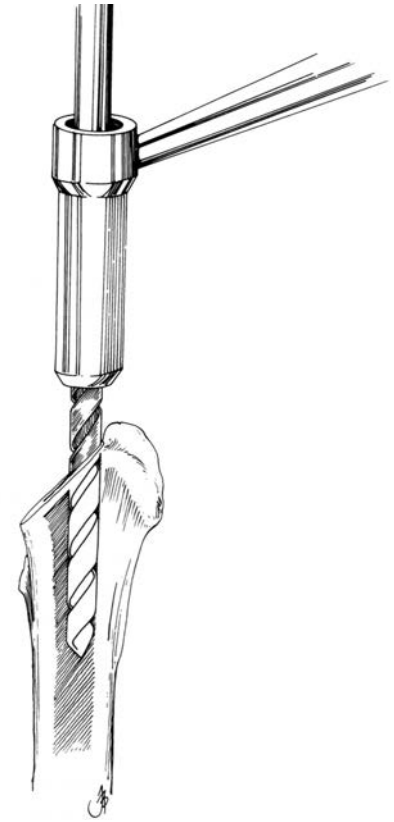

Figure 60-110. The opening into the femoral canal is started with a drill bit the same size as the femoral stem selected for implantation. (Used with permission from BioMedtrix Inc.)

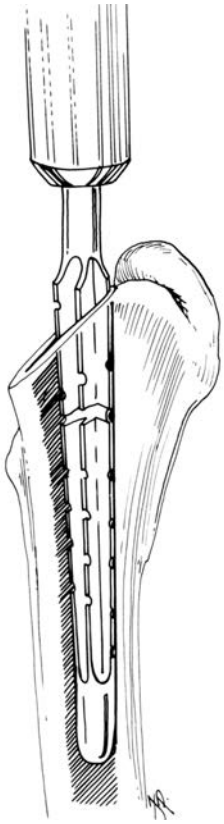

Figure 60-111. The femoral canal is opened further with a power driven fluted reamer. (Used with permission from BioMedtrix Inc.)

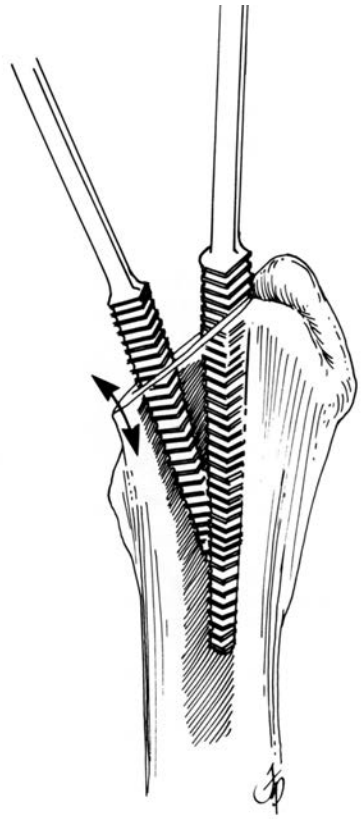

Figure 60-112. After power reamers are used to make holes in the femoral shaft, a finishing file and sometimes a broach (not shown) are used to make the hole in the shaft of an adequate size to accept the femoral stem. (Used with permission from BioMedtrix Inc.)

using a 60 cc catheter tip syringe. The cobalt chrome femoral stem is aligned with the long axis of the femur and inserted down the shaft until the prosthesis collar rest is flush with the osteotomy line. The stem is held solidly in place with the stem impactor. Excess PMMA is removed while the cement in the femoral canal hardens.

A trial plastic head is placed on the femoral stem so that neck length can be assessed (Figure 60-114). The prosthesis with the trial head is reduced and the tightness of fit tested. Once the proper neck length has been determined the cobalt chrome head is placed on the stem and tapped securely into position. The head is reduced into the acetabular cup. Cultures are taken and the joint capsule is tightly closed. The surgical site is closed in layers.

Lateral and ventro-dorsal pelvic radiographs are taken immediately post operatively so the position of the acetabular and femoral components and the fill of the PMMA can be assessed. Antibiotic therapy is continued until the culture results are known. If the results are negative, which is almost always the case, antibiotics are discontinued. On the rare occasion when results are positive, antibiotics based on sensitivity patterns should be continued for at least 4 weeks. The dogs are maintained on limited activity for 2 months following the surgery. No activity more strenuous than a walk is allowed and the dog

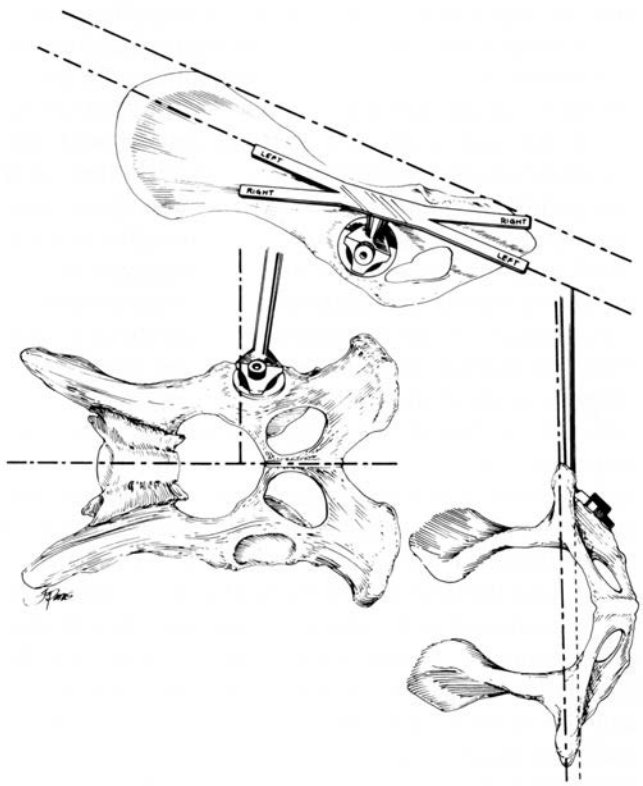

Figure 60-113. To position the acetabular cup correctly the positioner must be aligned in 3 planes relative to specific anatomic landmarks. In the top drawing the bar of the positioner is aligned parallel with the top of the ilium and the ischium. In middle left drawing the bar of the positioner is tilted caudally, positioning the cup in retroversion. In the bottom right drawing the shaft of the positioner is aligned parallel with the tuber ischia. (Used with permission from BioMedtrix Inc.)

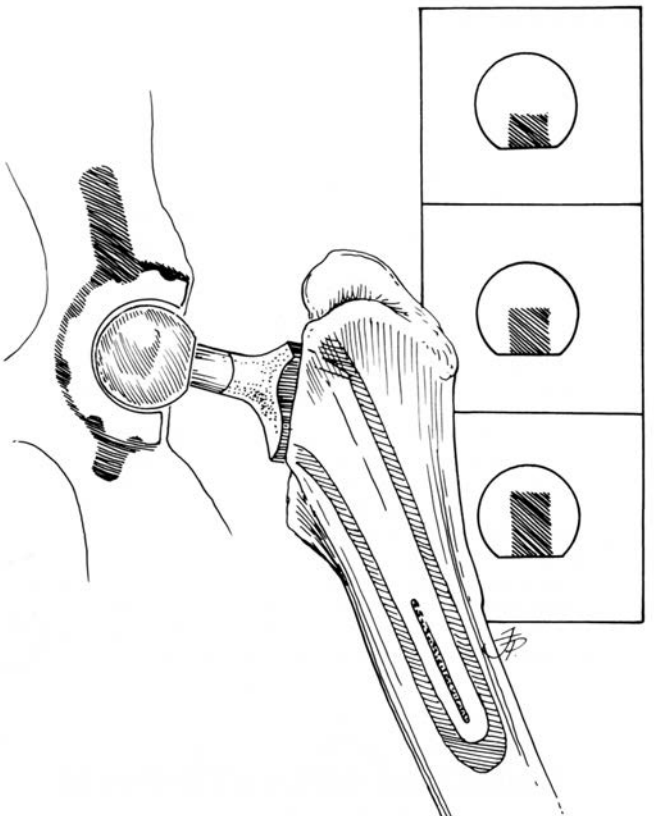

Figure 60-114. Cross-sectional cuts of the femoral head show the 3 different depths of holes that are found in the femoral head. Placing a head with the shallow hole on the stem will result in long femoral neck, while placing a head with the deep hole on the stem will give a short femoral neck. Neck length is determined with trial heads after the femoral stem and acetabular cup are cemented. (Used with permission from BioMedtrix Inc.)

is to be outside only on a leash. After that period the dog can gradually return to normal activity.

Discussion

The modular system has improved the technique of total hip arthroplasty in the dog over the previously used fixed head prosthesis. It gives the surgeon state of the art instrumentation, a wider choice of neck lengths and increased implant sizes. Thus it is possible for the veterinary surgeon to offer better care for the dog with disabling hip conditions. Smaller dogs can be treated because a wider range of prosthesis sizes is available. The size of the femoral canal and acetabulum are limiting factors in prosthesis implantation. The modular system allows the proper size of prosthesis to be chosen for each dog's femoral canal and acetabular cup. The clinical results achieved with the modular system are better than those of the fixed head system. Experience obtained with the fixed head system has shortened the learning curve for the modular system.

Dogs with THAs have achieved normal or near normal hind limb function 95% or more of the time. Pain free function, a full range hip motion, increased exercise tolerance, increased muscle mass and an improved quality of life are standard findings. Working dogs returned to field or police work and pets were exercised more without pain. It has been found that 80% of the dogs will not need the other un-operated hip replaced. They get enough relief from 1 THR that operating on the other side is not necessary. Often on reevaluation it was found that neither hip was painful when both had been hurt before surgery. The thigh circumference of the side with the THR is routinely 1 to 4 cm larger than the un-operated side. Because the prosthesis provides the normal ball and socket arrangement of the hip joint, the femur maintains its normal position relative to the pelvis and the hind limb is able to generate maximal propulsion forces during locomotion. This is not the case if the ball and socket joint configuration is not present.

Total hip arthroplasty in the dog is a very effective way of treating disabling conditions of the dog's hip joint. To be proficient at this procedure a surgeon must be well trained in the technique and do it routinely. Not every veterinarian should be doing THAs. However, every veterinarian should know enough about the procedure to be able to discuss it as a treatment option when indicated.

Total hip arthroplasty is well known by the general public as a treatment for people with hip problems. Because of this more owners are demanding it for their pets and more referral centers are offering it as part of their service. The future of THAs in veterinary medicine is bright and will continue to be so as long as the latest information and technical developments are incorporated into the total hip arthroplasty protocol.

Excision Arthroplasty of the Femoral Head and Neck

Joseph M. Prostredny

Introduction

Numerous pathologic conditions exist that interfere with the normal function of the canine coxofemoral joint. Regardless of the inciting cause, dogs with coxofemoral joint pathology usually experience pain during motion of the joint. Surgery of the coxofemoral joint is usually performed to improve comfort and function.

Femoral head and neck excision is one of the most common surgeries performed on the coxofemoral joint. A more common name for the procedure is femoral head ostectomy (FHO). However, the term FHO is misleading because it is necessary to remove both the femoral head and neck to consistently achieve satisfactory results.

Removal of the femoral head and neck allows formation of a pseudoarthrosis (false joint) between the femur and the acetabulum. This procedure is considered a salvage operation to improve the quality of life in patients with severe coxofemoral joint disease. Pain is relieved and function is improved by eliminating the articulation of the femur and the acetabulum.

Indications

Femoral head and neck excision is suitable for most conditions that compromise the integrity of the coxofemoral joint. Common indications in dogs and cats include aseptic necrosis of the femoral head (Legg- Perthes disease), severe fractures of the coxofemoral joint, chronic or recurrent coxofemoral luxations, coxofemoral joint instability, or severe osteoarthritis. Femoral head and neck excision is most commonly used as a lower cost alternative to total hip replacement, or in animals that are too small for hip replacement. There is a tendency for some veterinarians to overuse femoral head and neck excision for conditions that can be managed by primary repair.

Results of femoral head and neck excision depend on a number of factors, including body size, body condition, animal temperament, surgical technique and postoperative physical therapy. There is a general consensus that success varies with the size of the patient. Cats and small breed dogs can, in general, be expected to do well. With adequate postoperative care, satisfactory results can be consistently achieved in non-overweight dogs up to 50 kg or more. However, dogs over 25 kg will usually perform better with primary repair or total hip replacement if appropriate or affordable to the owners. Results in giant breed dogs are, at best, inconsistent, and a femoral head and neck excision should only be considered as a last resort in these breeds.

Surgical Technique

Several approaches to the coxofemoral joint have been described. The currently accepted standard technique for femoral head and neck excision is the craniolateral approach. Some surgeons prefer the ventral approach because it is more cosmetic and allows for bilateral excision without repositioning the patient. However, the exposure with the ventral approach is more limited and should only be used in small patients.

Craniolateral Approach

The patient is positioned in lateral recumbency. A straight or slightly curved incision is centered at the level of the greater trochanter along the cranial border of the femur. The incision should extend distally approximately one-fourth to one-third of the length of the femur and proximally two-thirds the distance to the dorsal midline. After dissecting through the subcutaneous tissue, the incision is continued through both layers of the fascia lata along the cranial border of the biceps femoris muscle, extending proximally along the cranial border of the superficial gluteal muscle. The incision through this layer should include the insertion of the tensor fascia lata muscle in the deep layer of the fascia lata. The fascia lata and tensor fascia lata muscle are retracted cranially and the biceps femoris and superficial gluteal muscles are retracted caudally to expose the underlying vastus lateralis, middle gluteal and deep gluteal muscles. The middle gluteal muscle is then retracted caudodorsally to expose the insertion of the deep gluteal muscle on the greater trochanter (Fig. 62-115). To improve exposure of the hip joint, a partial tenotomy of the ventral two-thirds of the deep gluteal insertion can be performed prior to dorsal retraction to expose the underlying joint capsule of the coxofemoral joint.

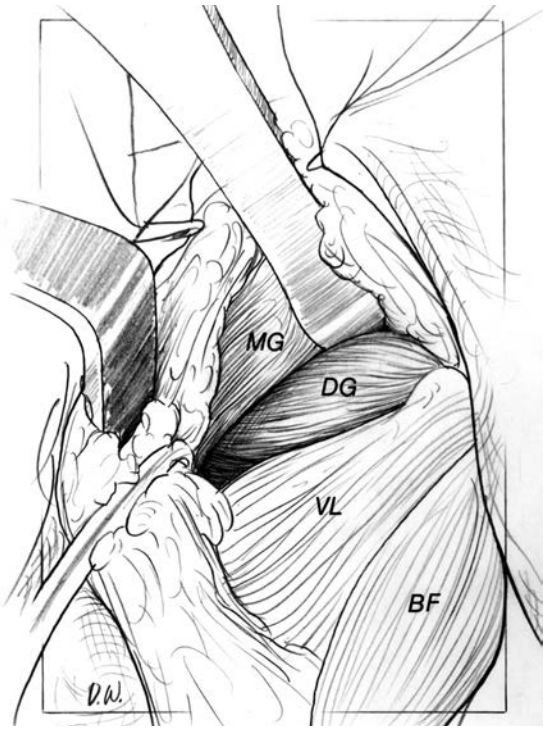

Figure 60-115. Craniolateral approach to the coxofemoral joint. The middle gluteal muscle *(MG)* has been retracted craniodorsally to expose the deep gluteal muscle *(DG)*. The vastus lateralis muscle *(VL)* and biceps femoris muscle *(BF)* are also shown. (From Prostredny, J.M., Toombs, J.P., Van Sickle, D.C. Effect of two muscle techniques on early morbidity after femoral head and neck excision in dogs. Vet Surg Blackwell Publishing 1991; 20:298-305.)

A transverse incision is made in the joint capsule to expose the femoral head. A second longitudinal incision should be made through the joint capsule, along the femoral neck through the origin of the vastus lateralis muscle for adequate exposure of the femoral neck. The femoral head should be luxated prior to the osteotomy. It is necessary to cut the ligament of the head of the femur if it is still intact. The femur should then be externally rotated ninety degrees so the cranial aspect of the femoral head and neck are facing up. The osteotomy to excise the femoral neck can be made with an oscillating saw or an osteotome. An oscillating saw will provide the smoothest and most accurate cut. An osteotome also works well as long as it is sharp. Use of a dull osteotome can result in a subtrochanteric fracture of the femur. A proper osteotomy should remove all of the femoral head and neck without damaging the greater or lesser trochanter. With the femur held in ninety degrees of external rotation, the oscillating saw or osteotome should be placed on the upward facing cranial surface of the femoral neck at an angle demonstrated in Fig. 62-116. The cut should be directed caudally and medially. If the cut is directed perpendicular to the surgery table, a portion of the caudal femoral neck will remain because of anteversion of the femoral neck. The cut should extend from the base of the greater trochanter across the neck, in a line that will completely remove the neck without removing the lesser trochanter. The osteotomy must be smooth, without bony projections or irregularities. If present, they may be removed with a bone rasp or rongeurs. Incomplete removal of the femoral neck may result in increased contact between the femur and acetabulum, resulting in long-term discomfort.

After completing the osteotomy, the femoral head is grasped and any remaining attachments of the joint capsule are divided to allow removal of the femoral head and neck. Closure is achieved by placing one or two mattress sutures in the deep gluteal tendon. The incised edge of the vastus lateralis muscle is sutured to the cranioventral edge of the deep gluteal muscle. The fascia lata and tensor fascia lata muscle are sutured to the cranial edge of the biceps muscle. The remainder of the closure is routine.

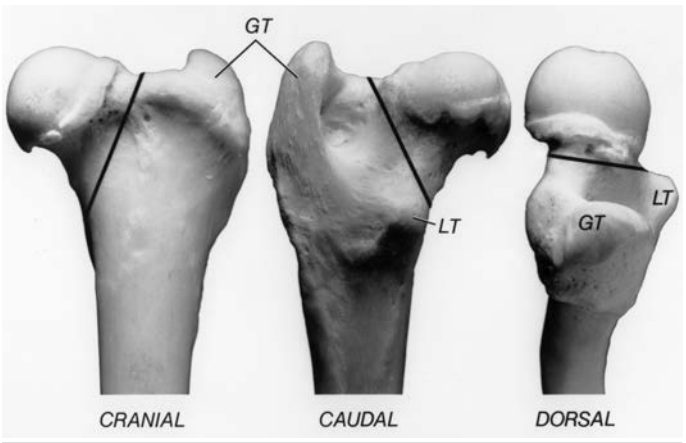

Figure 60-116. Correct angles for femoral head and neck excision. *GT:* greater trochanter, *LT:* lesser trochanter.

Ventral Approach

This approach provides a much more limited exposure than the previously described craniolateral approach. The patient is placed in dorsal recumbency with the hind legs abducted. The skin incision is made over the pectineus muscle, which is easily palpable. The underlying fascia is divided and the pectineus muscle is isolated, taking care to avoid the femoral artery, vein, and saphenous nerve cranial to the muscle belly. The pectineus muscle is transected at its origin on the pubis. The pectineus is then reflected distally. The iliopsoas muscle is retracted cranially and the adductor muscle is retracted caudally to expose the ventral joint capsule. Care must be taken to avoid the deep femoral artery and vein, as well as the obturator nerve, which lie ventral and medial to the joint. The joint capsule is then incised to reveal the ventral femoral head and neck. The osteotome or oscillating saw is then positioned on the ventral-most aspect of the femoral neck and directed to the trochanteric fossa to the allow complete removal of the femoral head and neck as described previously. The pectineus muscle can be re-attached to its origin or the prepubic tendon with mattress sutures. The remainder of the closure is routine.

Muscle Transposition

Early postoperative lameness following femoral had and neck excision is thought to be at least partly due to bone on bone contact between the femur and the pelvis. This contact may be more pronounced in larger dogs because their greater body mass tends to drive the bones together. Pain in the early postoperative period can significantly slow the return to function and result in a more restrictive pseudoarthrosis. Techniques that interpose a muscular pad between the osteotomy site and the acetabulum have been developed in an effort to decrease early postoperative pain and lameness. These flaps can be used at the surgeon's discretion.

There are two commonly used muscle pad techniques; the deep gluteal flap and the biceps sling. Biceps slings provide more coverage of the femoral osteotomy site then deep gluteal flaps. The biceps sling can be either a full or partial thickness flap. In a controlled experimental setting, the use of full thickness bicep slings was associated with high postoperative morbidity. This morbidity was not seen in a similar study using partial thickness slings.

Both deep gluteal flaps and biceps slings are performed through the previously described craniolateral approach. To create a deep gluteal flap, a tenotomy of the ventral two-thirds of the deep gluteal tendon is performed at its insertion on the greater trochanter. The muscle is then incised longitudinally from the tenotomy to its origin on the ilium. This creates a muscular flap that can be rotated distally (Fig. 62-117). After the femoral head and neck excison is performed, the femur is rotated externally to expose the insertion of the iliopsoas muscle on the lesser trochanter. The distal end of the deep gluteal flap is then sutured to the insertion of the iliopsoas muscle (Fig. 62-118). When the femur is returned to its normal position, the deep gluteal flap is drawn across the osteotomy site to form a pad between the osteotomy site and the acetabular rim (Fig. 62-119).

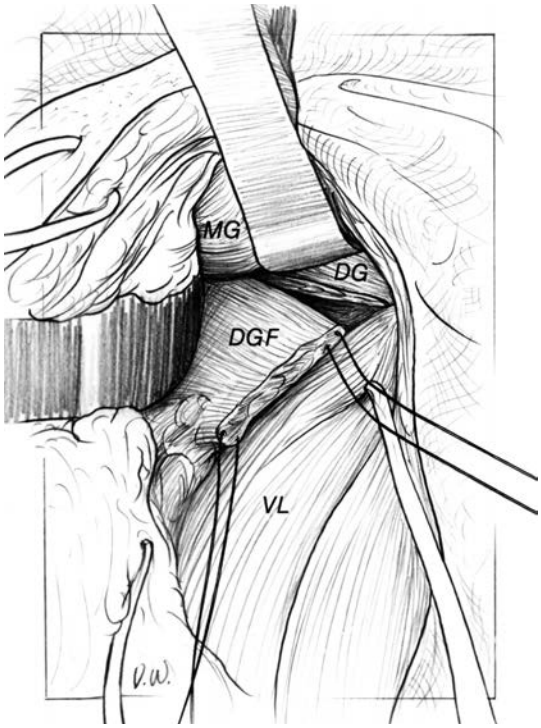

Figure 60-117. A partial tenotomy is made in the tendon of insertion of the deep gluteal flap *(DG)*. The muscle is split longitudinally from the tenotomy proximally to mobilize a deep gluteal flap *(DGF)*. The middle gluteal muscle *(MG)* and vastus lateralis muscle *(VL)* are also shown. (From Prostredny, J.M., Toombs, J.P., Van Sickle, D.C. Effect of two muscle techniques on early morbidity after femoral head and neck excision in dogs. Vet Surg Blackwell Publishing 1991; 20:298-305.)

Figure 60-118. With the femur *(F)* held in external rotation so the osteotomy site is positioned cranially, sutures are placed between the distal portion of the deep gluteal flap *(DGF)* and the underlying iliopsoas muscle *(I)*. The acetabulum *(A)* is medial to the femur. *VL:* vastus lateralis muscle. (From Prostredny, J.M., Toombs, J.P., Van Sickle, D.C. Effect of two muscle techniques on early morbidity after femoral head and neck excision in dogs. Vet Surg Blackwell Publishing 1991; 20:298-305.)

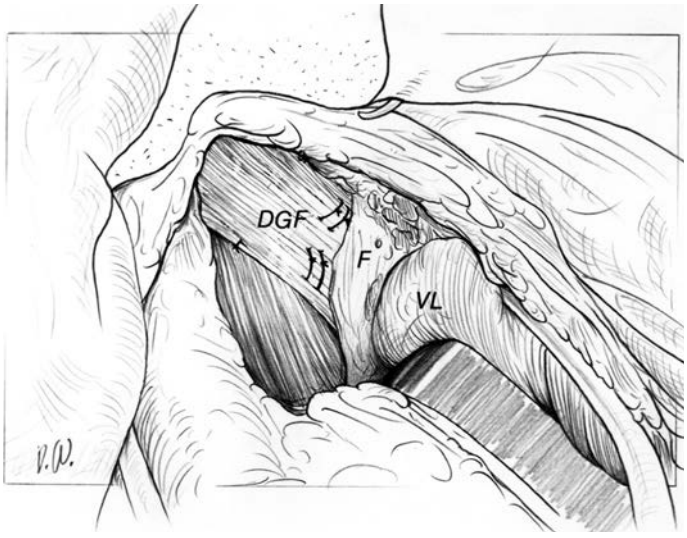

Figure 60-119. Final placement of the deep gluteal flap *(DGF). F:* femur, *VL:* vastus lateralis muscle. (From Prostredny, J.M., Toombs, J.P., Van Sickle, D.C. Effect of two muscle techniques on early morbidity after femoral head and neck excision in dogs. Vet Surg Blackwell Publishing 1991; 20:298-305.)

To create a biceps sling, the previously described skin and fascial incision for the craniolateral approach must be extended to the stifle. Creation of a partial thickness sling is recommended to avoid excessive postoperative morbidity. The muscle flap is created from the craniolateral portion of the biceps femoris muscle. The free end of the flap should be widest at the base (approximately 1.5 times the width of the osteotomy site) and should taper distally (Fig. 62-120). The sling is elevated by sharp dissection with the cut angled to produce a flap 0.5 to 1 cm thick, depending on the size of the patient. A wide fenestration is made in the caudal aspect of the coxofemoral joint capsule to allow easy passage of the sling through the joint in a caudal to cranial direction. Use of a suture snare to pull the muscle flap through the joint, minimizes muscular trauma (Fig. 62-121). The sling is then positioned to cover the osteotomy site and the distal portion of the sling is sutured to the vastus lateralis muscle (Fig. 62-122). To prevent movement of the sling across the osteotomy site, the sling can also be sutured to the deep gluteal muscle dorsally and the iliopsoas muscle ventrally. The fascia lata is then sutured to the remaining biceps muscle.

Postoperative Management

An early return to function is necessary for the development of a functional pseudoarthrosis. Motion of the coxofemoral joint in the early postoperative period will aid in the formation of a fibrous joint with a good range of motion. If postoperative motion is restricted, the pseudoarthrosis that forms will have a limited range of motion and the long-term function will be less desirable.

Appropriate doses of analgesics for at least one to two weeks (longer if necessary) are essential to encourage early use. The owners should perform passive range of motion exercises at least two to three times a day. Exercise should be encouraged in the form of walking or swimming. Swimming is one of the best forms of postoperative physical therapy, and owners should be encouraged to pursue this option if it is available.

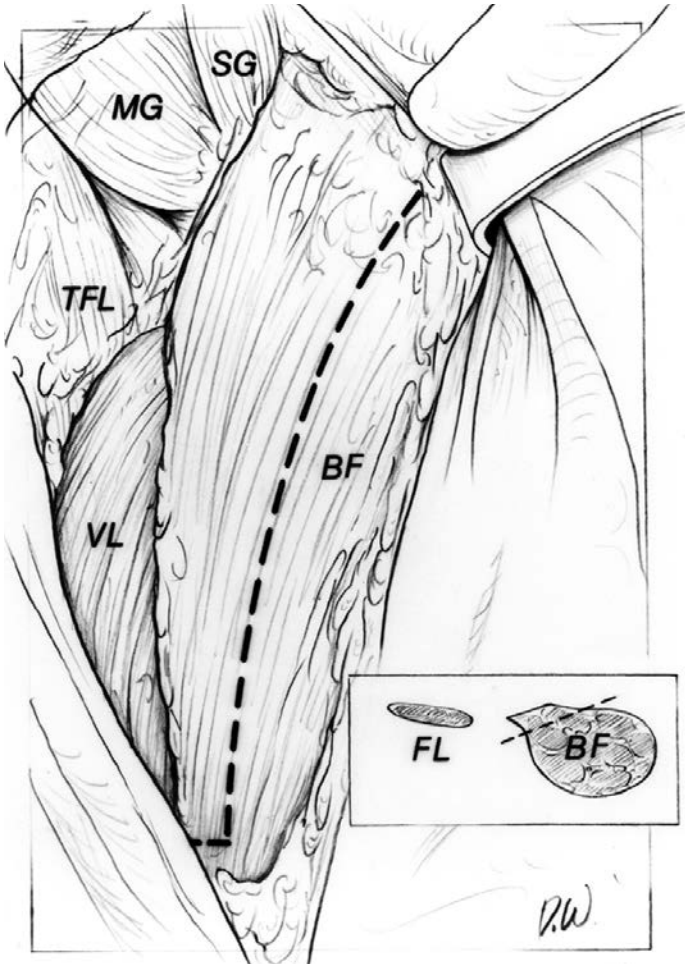

Figure 60-120. Dimensions of the partial thickness biceps sling are indicated by the broken line on the lateral surface of the biceps femoris muscle *(BF)*. The superficial gluteal muscle *(SG)*, middle gluteal muscle *(MG)*, tensor fascia lata muscle *(TFL)*, and vastus lateralis muscle *(VL)* are shown. The cut is angled as shown by the broken line in the inset drawing; a cross-sectioned view of the biceps femoris muscle and fascia lata *(FL)*. (From Prostredny, J.M., Toombs, J.P., Van Sickle, D.C. Effect of two muscle techniques on early morbidity after femoral head and neck excision in dogs. Vet Surg Blackwell Publishing 1991; 20:298-305.)

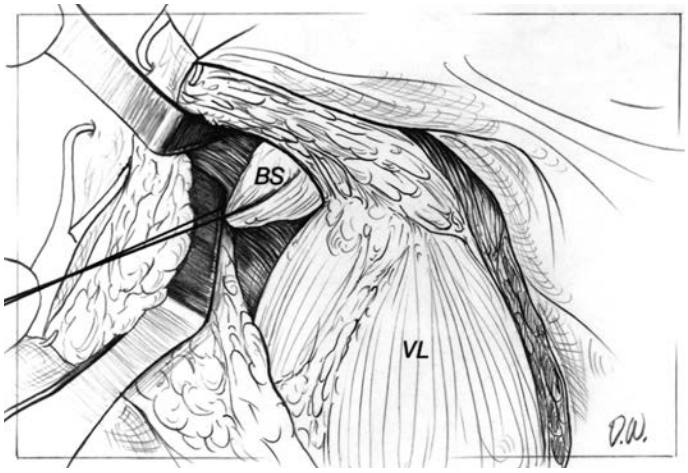

Figure 60-121. After a large fenestration is made in the caudal aspect of the joint capsule, a loop of suture is passed through the joint from cranial to caudal. The loop is placed around the distal portion of the sling ("Suture Snare") and the biceps sling *(BS)* is pulled across the osteotomy site from the caudal to cranial. *VL:* vastus lateralis muscle. (From Prostredny, J.M., Toombs, J.P., Van Sickle, D.C. Effect of two muscle techniques on early morbidity after femoral head and neck excision in dogs. Vet Surg Blackwell Publishing 1991; 20:298-305.)

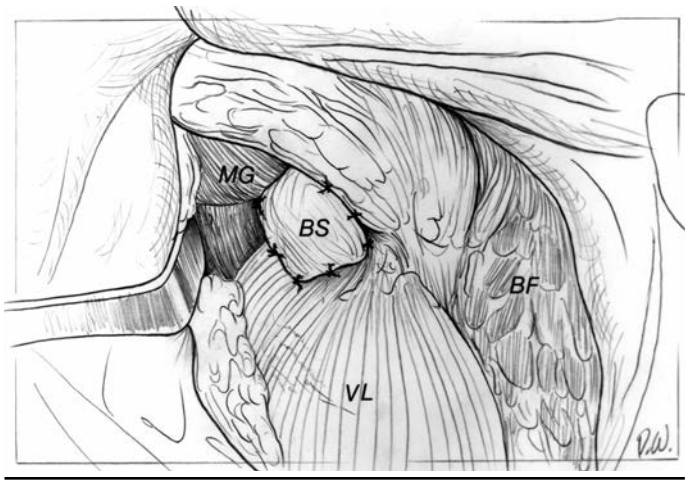

Figure 60-122. The sling *(BS)* is positioned to cover the osteotomy site and sutured to the vastus lateralis muscle *(VL)* and the underlying deep gluteal and iliopsoas muscles. *MG:* middle gluteal muscle. (From Prostredny, J.M., Toombs, J.P., Van Sickle, D.C. Effect of two muscle techniques on early morbidity after femoral head and neck excision in dogs. Vet Surg Blackwell Publishing 1991; 20:298-305.)

Proper surgical technique and proper postoperative physical therapy can produce consistent satisfactory results in non-overweight dogs of most breeds. Results may still be inconsistent in overweight dogs and giant breeds.

Chapter 61

Femur and Stifle Joint

Internal Fixation of Femoral Fractures

Dougald R. Gilmore

Editor's Note – The reader is encouraged to review other sections of this text regarding more recent options for the repair of femoral fractures: Chapter 50 – Interlocking Nailing; Chapter 51 – SOP Locking Plates; Chapter 52 – Plate-Rod Fixation; and Chapter 53 – Hybrid External Skeletal Fixation.

Fractures of the Femoral Head and Neck

Pelvic limb lameness with vehicular trauma often is caused by a fracture of the acetabulum or proximal femur. In the immature animal, fracture through the physis of the femoral head is encountered most commonly. This fracture is due to the weak area at the zone of hypertrophy at the growth plate. Other, less common fractures involve the base of the neck or the trochanteric region (Figure 61-1).

When examination of a dog less than 12 months of age reveals pain on manipulation of the hip joint, one should suspect either a fracture of the proximal femur or acetabulum or a coxofemoral luxation. The exact diagnosis requires radiographic evaluation including ventrodorsal (normal hip dysplasia position) and lateral views. Occasionally, a "frog leg" view assists in the diagnosis. This view requires the animal to be in dorsal recumbency with the pelvic limbs held in a flexed and slightly abducted position. An awake animal is more likely to cooperate for this view than for the normal ventrodorsal view.

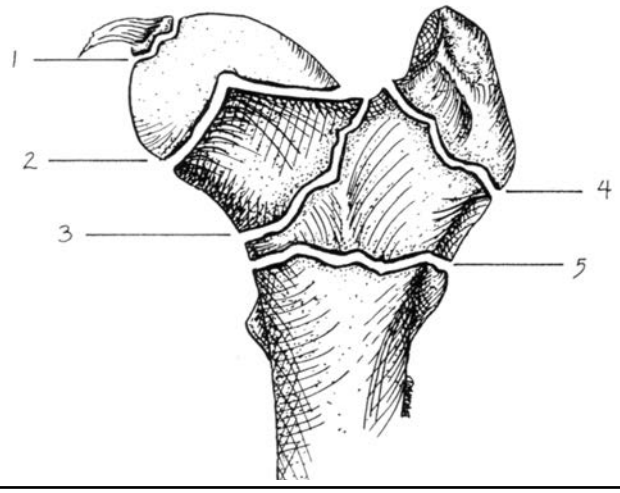

Figure 61-1. Sites of common fractures of the femoral head and neck and of the proximal femur: 1, capital epiphysis (avulsion fractures); 2, capital (proximal) physis; 3, femoral neck; 4, greater trochanteric physis; and 5, intertrochanteric region.

Anatomic Considerations

In the extremely young animal, the proximal growth plate extends from the greater trochanter to the femoral head. As the animal matures, separation into a capital femoral growth plate and a greater trochanteric growth plate occurs. Investigators have estimated that the capital physeal growth plate contributes up to 25% of the femoral length, whereas the greater trochanteric physis contributes little to the length. The ligament of the femoral head, which extends from the femoral fovea to the acetabular fossa, provides significant support to the hip joint.

The vascular supply to the femoral head continues to be of concern to most veterinary surgeons. If precise, delicate surgical intervention with appropriate stabilization is practiced, few complications should be encountered. Important aspects of the vascular supply include the lateral and medial circumflex femoral arteries, which are branches of the femoral and deep femoral arteries. The lateral branch provides most of the supply to the femoral head and the dorsal aspect of the femoral neck. The medial branch supplies the ventral aspect of the joint capsule, and a branch of the caudal gluteal artery supplies a small portion of the dorsal aspect. Dorsal and ventral ascending branches from the lateral and medial circumflex femoral arteries anastomose and form a rich interosseous arch within the epiphysis. Metaphyseal branches of the lateral and medial circumflex vessels do not communicate with the epiphyseal branches in the immature animal. No evidence suggests that a blood supply enters the epiphysis from the ligament of the femoral head.

Presurgical Considerations

Avascular necrosis of the femoral head secondary to a fracture is not a significant problem if appropriate surgical treatment is followed. Most reports of repair list few cases of avascular necrosis. Although the femoral head completely loses its vascular supply at the time of the initial trauma, revascularization is rapid after stabilization. The time interval to surgery is important because more damage is sustained if the repair is delayed. Attempts by the animal to walk on the affected limb may damage the soft metaphyseal bone of the neck as it rubs on the acetabular rim. Loss of bone results in the inability to reduce and stabilize the fracture components correctly. The degree of damage is most often ascertained at the time of surgery. Occasionally, radiographic evaluation reveals the damage.

Surgical Approach

The craniolateral approach is most often recommended for femoral head and neck fractures because of the preservation of vascular supply. The dorsal approach, including greater trochanteric osteotomy, may be used if increased exposure is required, but it damages the branches of the lateral circumflex femoral artery. In addition, damage to the physis of the greater trochanter may lead to a valgus deformity in a young animal. Successful use of the dorsal approach has been reported, but research also shows that the vascular damage may not be significant.

In the craniolateral approach, the skin incision is curved in a cranial direction starting 3 to 4 cm proximal to the greater trochanter and extending distally to include the proximal one-quarter of the femoral shaft. An incision is made into the fascia lata just cranial to the greater trochanter and is extended to allow retraction of the biceps femoris muscle caudally and the fascia cranially. The muscular tensor fasciae latae is then dissected from the fascia of the vastus lateralis and the middle gluteal muscles. The gluteal muscles are retracted dorsally and the tensor fasciae latae cranially to allow visualization of the cranial aspect of the joint capsule. The joint capsule is incised perpendicular to the acetabular rim, extending to the origin of the vastus intermedius and lateralis. The exposure can be increased by performing a partial tenotomy of the deep gluteal muscle. If difficulty is encountered in visualization and reduction of the fracture, trochanteric osteotomy may be performed. With either approach, the location of the sciatic nerve should be noted.

Fixation Techniques

Capital Physeal Fractures

Reduction of a capital physeal fracture may be difficult. Handling of the femoral head with a retractor or bone-holding forceps should be minimized to lessen damage to the articular cartilage. One or several Kirschner wires are placed to stabilize the fracture after reduction. These pins are placed in retrograde fashion from the fracture site laterally or in a normograde manner from the lateral surface of the proximal femur (Figure 61-2A). After fracture reduction, the pins are seated in the femoral head.

If a lag screw is to be used, the gliding hole through the proximal femur may be drilled before reduction to ensure placement into the center of the neck. A small threaded hole is drilled into the femoral head before measuring and tapping the hole (Figure 61-2B). As the head is encountered, tapping becomes more difficult. Care is taken to ensure that the articular surface is not penetrated. A screw that is 2 to 4 mm shorter than the measured length should be used because of the shortening obtained during lag screw fixation (Figure 61-2C).

Use of measurements taken from the radiographs can help to ensure that implants of appropriate size are used. The articular surface should be inspected after implant placement to check for implant penetration. Areas not visualized may be inspected using a curved instrument to check for any irregularities. Any articular damage fills with fibrocartilage, which permits satisfactory recovery of most animals.

Interfragmentary compression alone should be adequate for most animals. Kirschner wires may be left in place to increase rotational stability if necessary. After the joint is flushed, the joint capsule is closed with a nonreactive suture material before anatomic closure of the other layers.

Other Articular Fractures

Occasionally, an avulsion fracture of the ligament of the femoral head occurs in association with a coxofem-oral luxation. Removal of this fragment and the ligament is recommended if surgical intervention is necessary for stabilization of the hip joint. Closed reduction of this type of coxofemoral luxation may result in degenerative joint disease because the interposed avulsed fragment produces cartilaginous damage.

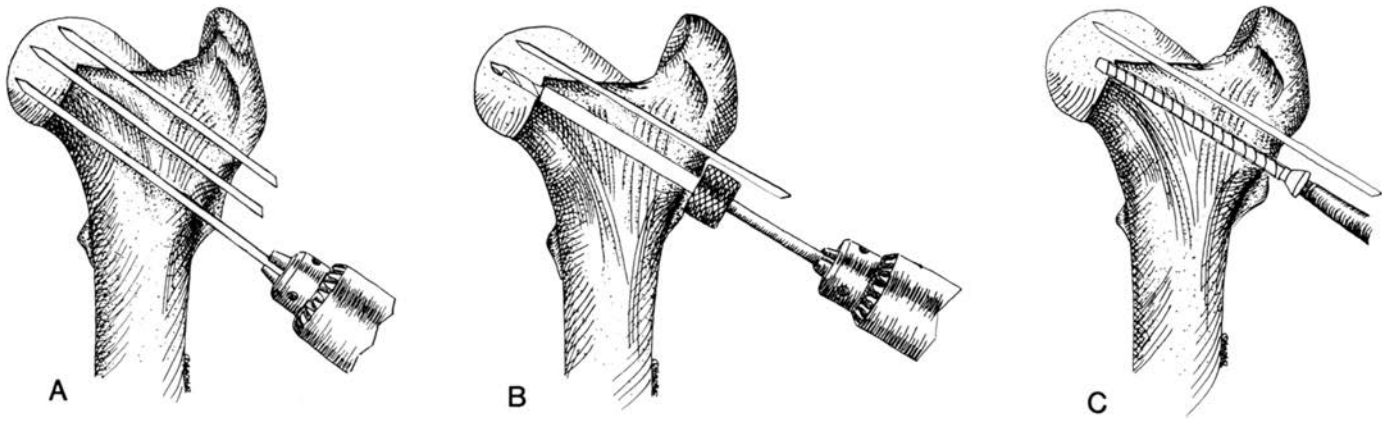

Figure 61-2. A capital physeal fracture can be stabilized by multiple Kirschner wires placed from the lateral surface into the subchondral bone **A.**, or by lag screw fixation. In the latter method, after normograde or retrograde drilling of the glide hole, a drill guide is inserted and a thread hole drilled **B.**; a screw is then inserted to compress the fracture **C.** The Kirschner wire can be left in place to provide further stabilization.

Fractures involving the dorsal articular surface require stabilization to lessen degenerative joint disease. Femoral head and neck excision is an alternative if the articular cartilage is severely damaged or if reduction is too difficult. Fracture fragments involving the non-articular surfaces may be removed.

Extracapsular Fractures

Fractures through the base of the femoral neck are most often encountered in mature animals. Repair is performed as described previously for femoral head fractures (See Figure 61-2). Osteonecrosis is not a problem because of the extracapsular nature of the fracture. Fractures through the apophysis of the greater trochanter sometimes occur in association with a capital physis fracture. Careful evaluation of the radiographs may be necessary because of the superimposition of the greater trochanter on the femoral shaft. Stabilization is performed through a craniolateral approach with retraction of the greater trochanter. After stabilization of the femoral head with a Kirschner wire and lag screw, the greater trochanter is reattached by tension band fixation (Figure 61-3). Care is necessary to ensure complete reduction and realignment before stabilization.

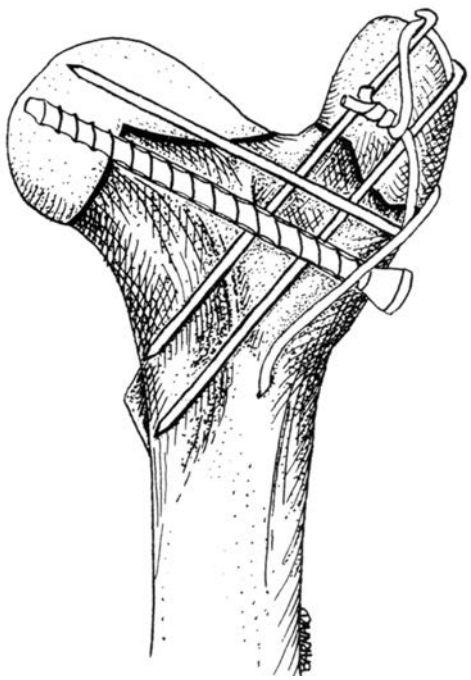

Figure 61-3. Fractures involving both the greater trochanteric and capital physis are stabilized by a lag screw, Kirschner wire, and tension band fixation. This type of fixation also is used when a trochanteric osteotomy is performed to approach the coxofemoral joint.

Proximal Femoral Fractures

Greater Trochanteric Fractures

Fractures of the greater trochanter are commonly associated with fractures involving the femoral head in young animals and with comminuted proximal femoral fractures in mature animals. The traction physis associated with the greater trochanter is believed to provide no significant contribution to longitudinal bone growth.

Repair of a greater trochanteric fracture is necessary because the distraction forces applied by the gluteal muscles do not allow for normal union. Approach is made just cranial to the greater trochanter, allowing separation of the fascia lata from the biceps femoris muscle. Incision into the origin of the vastus lateralis may be necessary to allow visualization of the fracture.

Of the repair methods available, tension band fixation is probably the easiest and most satisfactory. This method converts distracting forces into compressive forces at the fracture site. Two Kirschner wires are inserted at right angles to the fracture line (See Figure 61-3). Care is taken to gain maximum purchase prox-imally in the greater trochanter and to ensure purchase into the medial cortex at or below the lesser trochanter. Orthopedic wire (18 to 20 gauge) is placed through a hole drilled in a craniocaudal direction 3 to 4 cm distal to the fracture line. This wire is placed around the proximal ends of the Kirschner wires in a figure-of-eight configuration and then is tightened to counteract the distracting forces of the gluteal muscles.

Intertrochanteric and Subtrochanteric Fractures

Either stack-pinning or plate fixation can be used to neutralize both bending and rotational forces acting on the intertrochanteric and subtrochanteric fractures. Approach to the area requires transection of the origins of both the vastus lateralis

and intermedius muscles. Pin placement should originate from the proximal point of the greater trochanter and should extend distally, gaining maximal purchase in the femur. A common mistake is to exit the pins within 3 to 4 cm of the fracture line. This technique provides less than satisfactory stabilization. A figure-of-eight wire may be placed in association with the pins to provide increased rotational stability for subtrochanteric fractures (Figure 61-4).

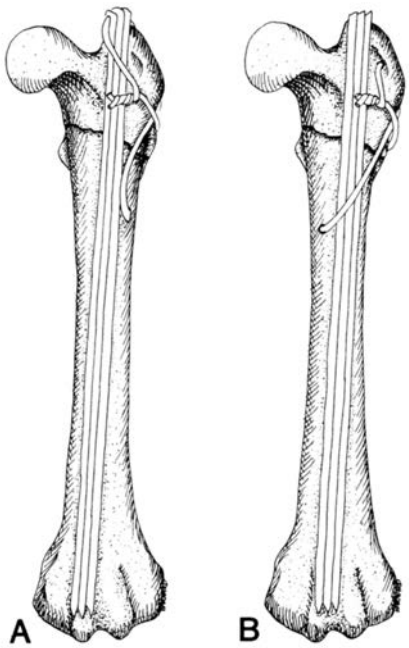

Figure 61-4. A. and **B.** An intertrochanteric fracture of the femur is repaired with multiple intramedullary pins and a figure-of-eight tension band wire. Two different methods of attaching the wire are shown.

Application of a bone plate to the lateral surface is indicated in large dog breeds for repair of these fractures. Careful contouring of the bone plate allows for the placement of at least two screws in the short proximal segment in most cases. One screw (usually cancellous) should extend into the femoral neck for increased purchase, and at least four screws should be placed in the distal segment (Figure 61-5).

Comminuted Fractures

Highly comminuted fractures of the proximal femur require aggressive fixation, usually with a bone plate and lag screws. Care must be taken to ensure adequate stabilization of the calcar region (lesser trochanter) because it is an important medial buttress. Early fixation failure can be expected if stabilization is inadequate. The fracture segments are reduced and stabilized with both lag screws and Kirschner wires. The plate is then contoured and is attached to the proximal segment with one screw placed through the second hole into the femoral neck and head. The proximal screw is placed into the greater trochanter. Use of a dynamic compression plate permits angling of the screws up to 30° from center. The plate acts as a neutralization or buttress plate for this type of fracture. The plate should be attached to the distal segment with at least three screws penetrating six cortices (Figure 61-6A). A cancellous bone graft should be placed into any areas that lack cortical bone.

Intramedullary fixation of comminuted proximal fractures is more applicable to small and medium-sized dogs than to large ones, especially if the fracture has only three or four segments. By use of hemicerclage wire and transcortical pins, a comminuted fracture can be reduced to a two-piece fracture, which then is fixed by normograde or retrograde stack-pinning (Figure 61-6B). Care must be taken to ensure that the transcortical pins do not enter to the medullary canal to allow for the introduction of a

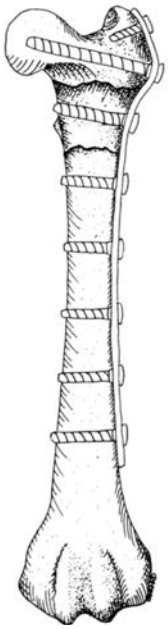

Figure 61-5. Intertrochanteric and subtrochanteric fractures can be stabilized with a bone plate applied to the lateral surface of the femur. A cortical or cancellous screw is placed through the femoral neck for increased purchase.

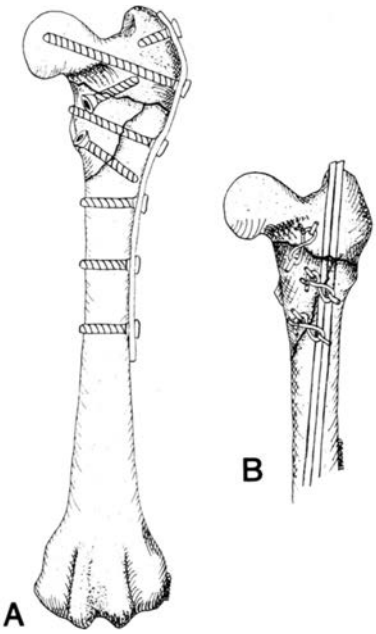

Figure 61-6. A comminuted proximal femoral fracture can be stabilized by a bone plate applied to the lateral surface and lag screw fixation of the butterfly fragment **A.** or by intramedullary pins with the butterfly fragment attached by transcortical pins and figure-of-eight wires **B.**

maximum number of stack pins. Lag screws are more difficult to incorporate into fractures stabilized with intramedullary pins.

Diaphyseal Fractures of the Femur

Transverse Fractures

Transverse diaphyseal fractures are most commonly repaired with one intramedullary pin. Although success is often reported with this method, so too is failure, mainly because of the lack of rotational stability provided by one pin. This method is most likely to succeed with immature animals in which healing is rapid and with small to medium-sized adult animals in which the single pin tends to fill a significant part of the medullary canal. Failure occurs most often in large dogs, when a small pin that does not fill a significant portion of the canal is used. Use of a Kirschner-Ehmer external fixation device (two-pin half-pin splint) in association with the intramedullary pin increases rotational stability.

Stack-pinning of transverse fracture is an easy procedure that results in few complications in most cases. The curved skin incision should be just cranial to the femoral shaft. The biceps femoris muscle belly is encountered if the incision is directly over the shaft; incision through this muscle belly is not the approach of choice. After approaching the fracture by incising the fascia lata cranial to the biceps muscle, the vastus lateralis muscle is retracted cranially, and the biceps femoris muscle is retracted caudally to allow visualization of the fracture site. Minimal stripping of the periosteum is done to check for any fissure lines

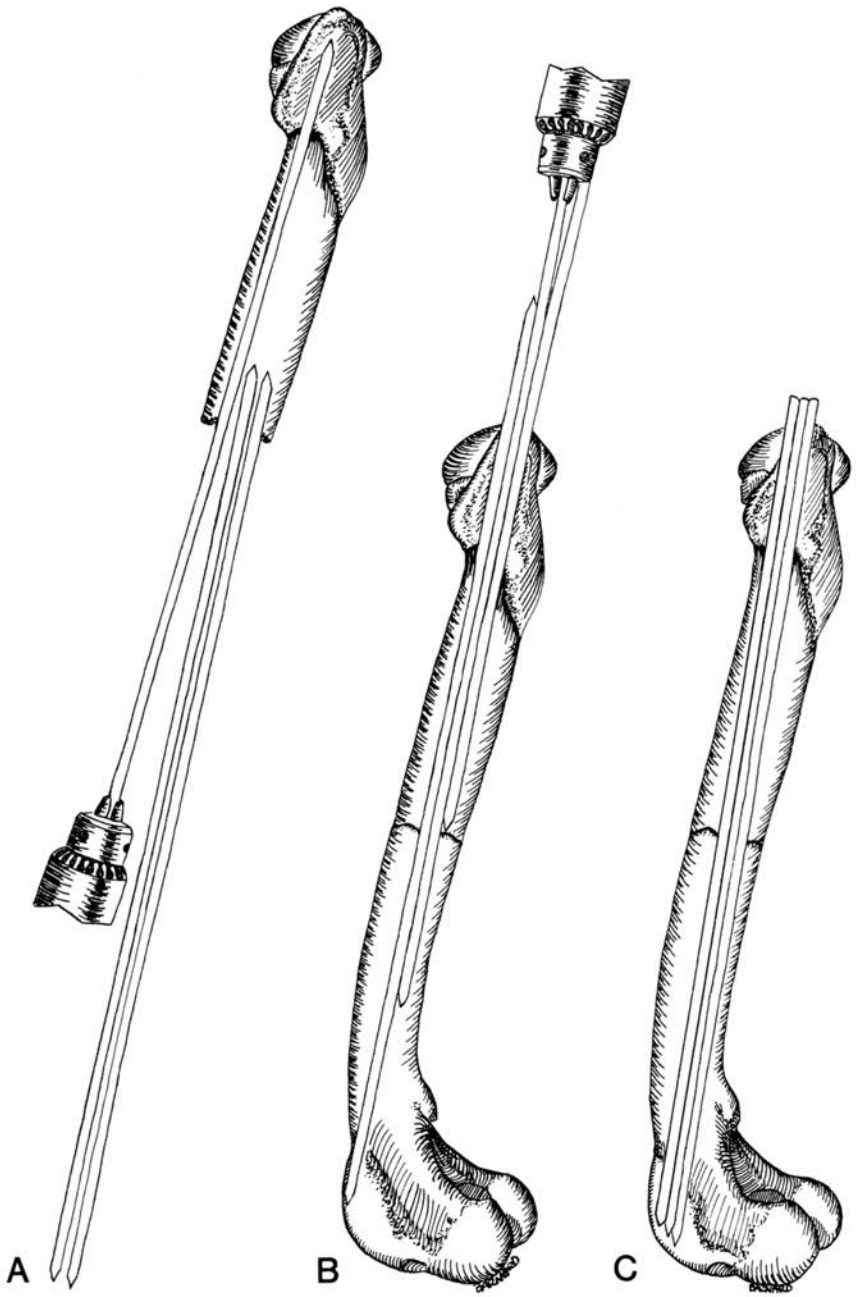

Figure 61-7. Retrograde stack-pinning of a transverse midshaft femoral fracture. **A.** The hip is extended and the femur is adducted before retrograde placement of all pins through the trochanteric fossa. **B.** The pins are driven distally to engage cortical bone. **C.** The pins are placed into but not through the distal cortex beneath the trochlear groove.

in the fracture segments. The pins are placed in retrograde fashion, exiting proximally through the trochanteric fossa (Figure 61-7A). The surgeon must extend the animal's hip joint and adduct the femur when passing the pin proximally to avoid the sciatic nerve as it passes over the greater trochanteric notch. All pins are placed proximally before reduction of the fracture segment. Enough pins are used to fill the medullary canal at its narrowest point. The pins are then driven distally into cortical bone. Because of the cranial curvature of the femoral shaft, the pins usually seat distally in the cranial metaphyseal area near the proximal end of the trochlea (Figure 61-7B). Overreduction of the distal segment allows seating of the pins further distally, but usually this leads to malalignment and instability. Because the feline femur has less curvature, the pins can be seated farther distally in the intercondylar region in cats (Figure 61-7C).

Several methods are available to add rotational support to pin fixation of transverse diaphyseal fractures. A two-pin half-pin Kirschner-Ehmer splint in association with a single intramedullary pin is one method. Use of hemicerclage or figure-of-eight orthopedic wire also can increase rotational stability. The figure-of-eight wire can be passed through holes drilled proximal and distal to the fracture line, or two can be placed around transverse Kirschner wires and tightened to form a cruciate pattern (Figure 61-8). The distance from the holes or Kirschner wires to the fracture should be at least equal to the width of the femur at the fracture site.

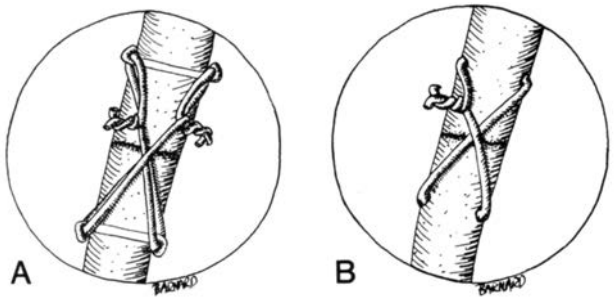

Figure 61-8. Increased rotational stability of transverse femoral fractures is achieved by use of two figure-of-eight wires placed around transversely placed Kirschner wires **A.**, or by orthopedic wire placed in a figure-of-eight fashion through two holes drilled proximal and distal to the fracture line **B**.

Application of a bone plate to the lateral or cranial surface is indicated for stabilization of transverse fractures in large breeds or in any animal requiring rigid internal fixation. Compression of the fracture line allows for rapid primary bone healing. Screw fixation in at least six cortices above and below the fracture should be obtained.

Oblique and Spiral Fractures

Oblique and spiral fractures are most successfully repaired with intramedullary pins, with additional stability provided by transcortical pins and hemicerclage wire or by full-cerclage orthopedic wire. The fracture is first stabilized with intramedullary pins, as discussed in the section on transverse fractures. Wire can be placed around transcortical pins in a figure-of-eight pattern to provide increased rotational stability (Figure 61-9A). Alternatively, full-cerclage wires can be used (Figure 61-9B).

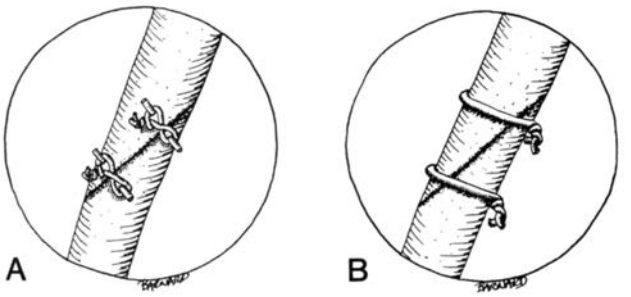

Figure 61-9. Long oblique fractures of the femur can be stabilized by transcortical pins with figure-of-eight wires **A**. or by full-cer-clage wires **B**. The transcortical pins should not enter into the medullary canal, to avoid interference with intramedullary pin placement.

Although investigators initially thought that full-cerclage wires interfered with the new periosteal blood supply needed for fracture healing, more recent studies have shown that this may not occur. Problems only arise when the wire is improperly applied. Common mistakes include inappropriate wire diameter (18 to 20 gauge is appropriate for most animals), placement too close to the fracture ends (a minimum of 5 mm is appropriate), and use of insufficient number of wires (a minimum of two wires placed 1 cm apart is appropriate). As with any technique, failure is more likely to occur when wires are applied in less than ideal fashion. Most complications occur when the wire slips into the fracture site, producing a nonunion.

Comminuted Fractures

Reduction of the fracture segments into two main segments before primary fixation with intramedullary pins provides successful stabilization of most comminuted fractures. Pin fixation is less effective with highly comminuted fractures because of the inability to neutralize compressive forces. Collapse of the fracture is more likely in these cases. Midshaft fractures with one or two butterfly fragments can be stabilized with techniques similar to those discussed in the section on oblique fractures.

Application of a bone plate to the lateral or cranial surface as a neutralization plate (no compression at the fracture site) or a buttress plate (a cortical gap is present) can stabilize most comminuted diaphyseal fractures. The large fragments are attached with Kirschner wires, orthopedic wire, or lag screws before plate attachment. Care must be taken to ensure that these implants do not interfere with placement of the plate. If possible, the plate is positioned to allow for placement of screws in all holes. Occasionally, the number of fissure lines necessitates leaving one or more holes vacant. This situation is to be avoided, especially with a buttress plate, because fatigue failure is more likely to occur at this site. Use of a leg-lengthening plate that lacks holes in the central one-third of the plate may be indicated in these cases (Figure 61-10). Contouring of the plate is made easier if a radiograph of the contralateral femur is available for comparison. By using the greater trochanter, stifle, and linea aspera (the caudal rough surface where the adductor magnus muscle attaches) as reference points, normal anatomic alignment can be obtained in these comminuted fractures.

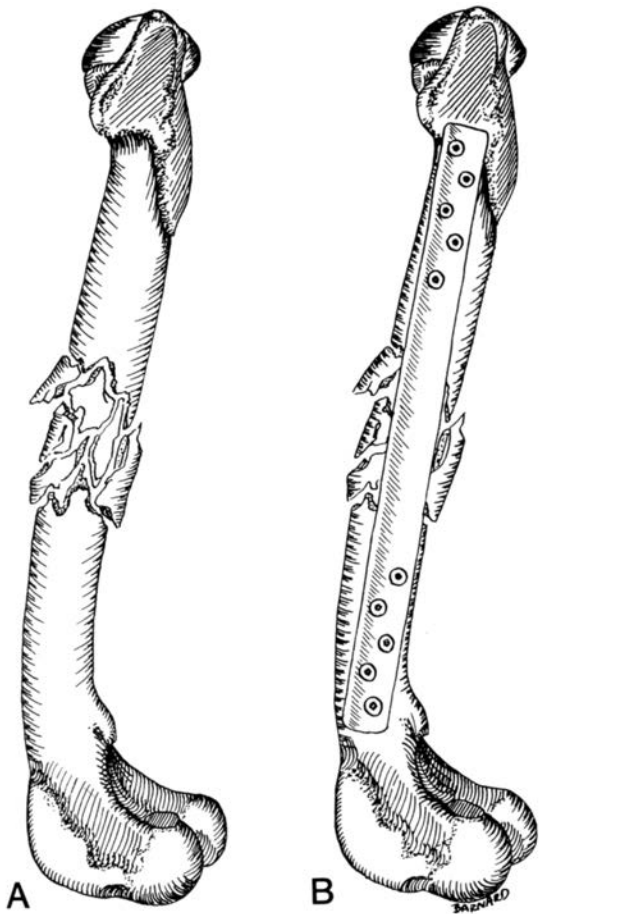

Figure 61-10. A comminuted midshaft femoral fracture **A.** can be stabilized by a buttress plate applied to the lateral surface **B**. A leg-lengthening place is used so no vacant holes are positioned over the comminuted segments.

Occasionally, highly comminuted diaphyseal fractures cannot be pieced together with pins or lag screws. Both removing these fragments and leaving them in place while spanning the gap with a bone plate have been reported. The gap is filled with autogenous cancellous bone to stimulate healing. Leg-lengthening plates are ideally suited, because they allow the closer placement of screws in the proximal and distal fragments without leaving several vacant holes over the gap. Success has been reported with the use of dynamic or standard plates with vacant holes. The plate used must be as large as possible in such cases.

Distal Femoral Fractures

Metaphyseal (Supracondylar) Fractures

Although encountered infrequently, distal metaphyseal fractures provide a challenge for repair. Fortunately, the rich blood supply to this trabecular bone promotes rapid bone healing in most cases. This type of fracture occurs most often in mature animals and is often associated with comminution.

The approach to this region is an extension of the approach used for stifle arthrotomy. The incision in the fascia lata cranial to the biceps femoris muscle is extended distally to include the lateral fascia of the stifle. Incision into the joint capsule is extended proximally, lateral to the vastus lateralis muscle to allow medial retraction of the quadriceps group and the patella. A large muscular branch of the popliteal artery must be ligated as this incision is made. Flexion of the stifle with medial retraction of the muscles allows visualization of the medial surface of the distal femur.

Bone plating of the lateral surface is recommended for stabilization of metaphyseal fractures in larger dogs, especially if comminution is present. Use of cancellous screws in the distal segment increases holding power, which is often needed because of the short length of the distal segment. Intramedullary pinning is more appropriate for stabilization in small and medium-sized animals (Figure 61-11). The techniques discussed in the following sections on physeal and epiphyseal fractures are used.

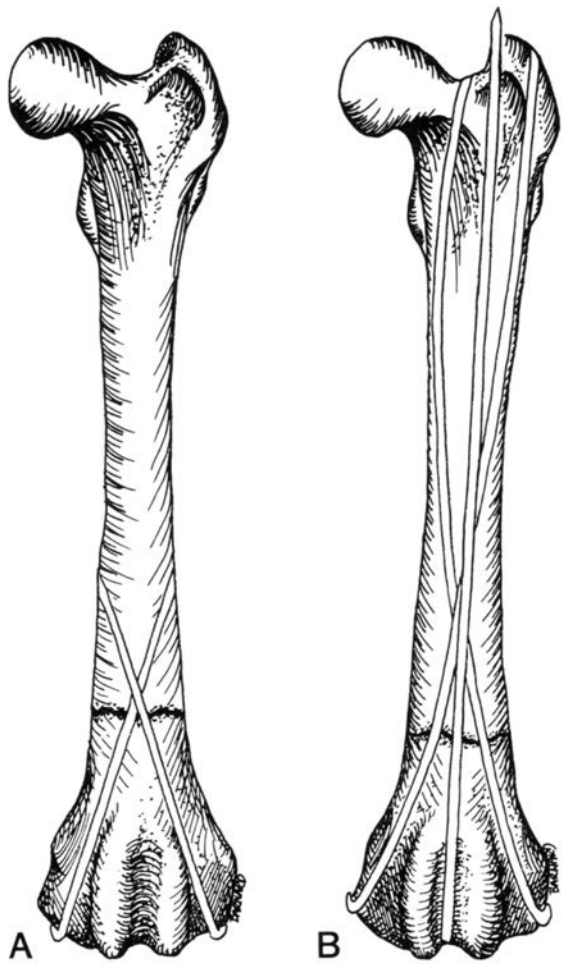

Figure 61-11. A transverse distal metaphyseal femoral fracture can be stabilized by cross-pins driven from the condyles **A.** or by double intramedullary pins driven in a Rush pin technique from the condyles and one intramedullary pin driven from the trochlea **B**.

Physeal Fractures

Most distal physeal fractures occur in immature animals (4 to 12 months old) because the zone of hypertrophy is structurally much weaker than the surrounding bone, tendons, and ligaments. The most common fractures are Salter I (involvement of the growth plate only) and Salter II (involvement of the growth plate and metaphysis), which fortunately do not involve the germinative or growth layer of the physis. Few complications associated with

premature closure of the physis have been noted. Rapid healing can be expected because of the adjacent rich blood supply.

External support alone infrequently allows for normal reduction and bone union and subsequent normal functional use. As with any joint, immobilization of the stifle may lead to adhesion formation and loss of joint motion. Most distal physeal fractures, however, require internal fixation by some type of pinning procedure.

Antegrade introduction of a single Steinmann pin from the trochlea just cranial to the origin of the cruciate ligaments provides maximum purchase in the small distal segment. Reduction of the fracture before pin placement is ideal. Careful handling of the distal segment is important because of the softness of the bone and the presence of articular cartilage. Over-zealous use of bone forceps may result in significant damage. Placement of the pin in the distal segment before reduction, using the pin as a lever, is possible if done carefully (Figure 61-12A). The pin may pull out of the bone, resulting in enlargement of the hole, if the veterinary surgeon is not careful. The pin is driven proximally, exiting through the trochanteric fossa (Figure 61-12B). After the distal end is cut, the pin is retracted proximally until the blunt end is seated just below the cartilaginous surface of the trochlea (Figure 61-12C). Stabilization of these fractures is aided by the interlocking of metaphyseal protuberances in epiphyseal fossae, providing rotational stability.

Retrograde placement of the pin avoids damage to the articular cartilage, but it may not always provide adequate purchase in the distal segment. If this method is used, the pin is placed along the caudal aspect of the femur to allow for maximum purchase in the distal segment.

Other methods of fixation include double pinning, modified Rush pinning, and cross-pinning (See Figure 61-11). With all methods, the pins are started just lateral and medial to the trochlear ridges

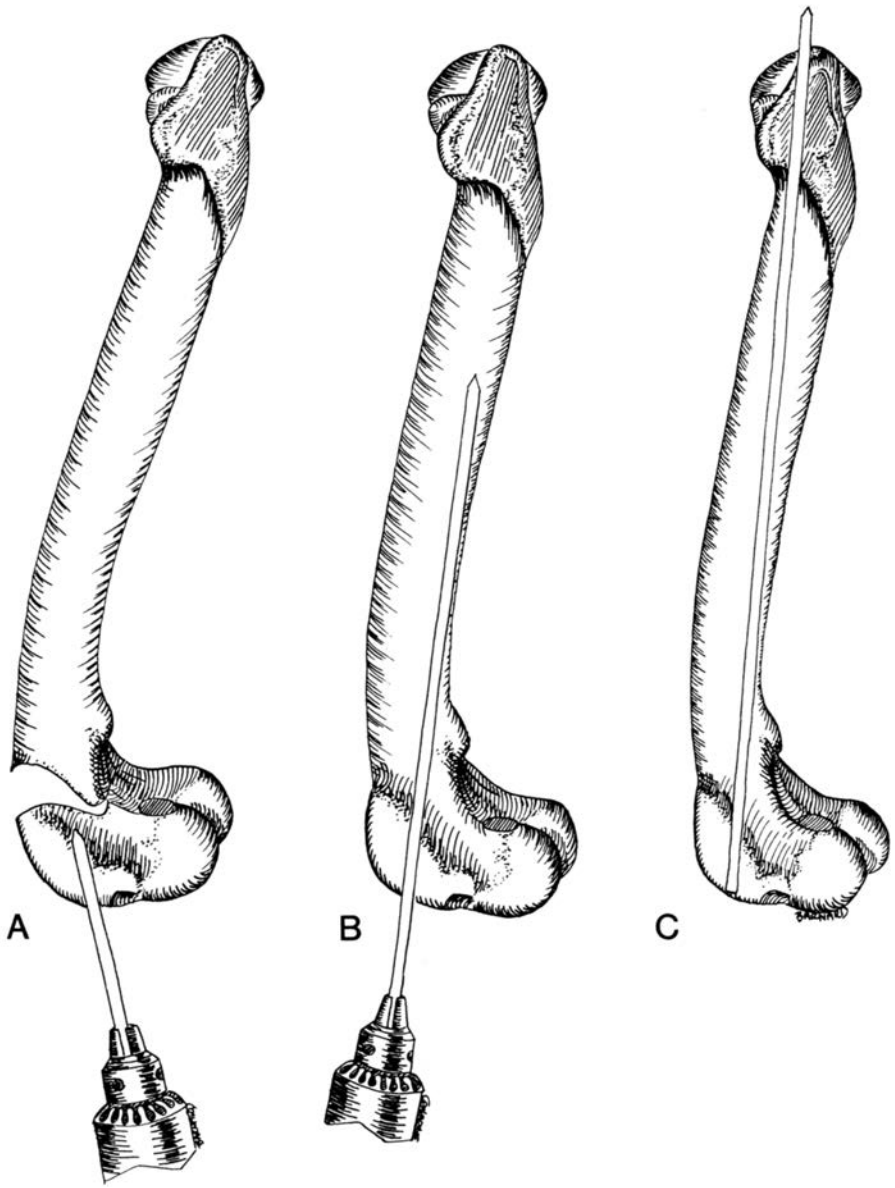

Figure 61-12. Single intramedullary pinning of a Salter I or II fracture of the distal femoral physis. **A.** The pin is placed through the epiphysis. **B.** After the fracture is reduced, the pin is driven up the caudal surface of the shaft, exiting through the trochanteric fossa. **C.** The pin is cut distally and retracted proximally until embedded below the articular surface.

and cranial to the collateral ligaments (Figure 61-13). Larger, less flexible pins are used with cross-pinning fixation. The pins must cross above the fracture line. Exiting of the pins too close to the fracture may lead to failure with weightbearing. Placement of the pins in retrograde fashion results in less than maximum purchase in the distal segment.

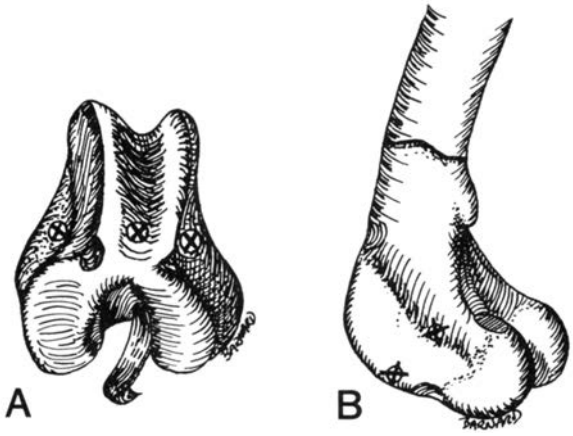

Figure 61-13. Craniocaudal **A.** and lateral views **B.** of the placement of intramedullary pins into the distal femoral segment. The lateral and medial pins are placed cranial to the collateral ligaments on either side of the trochlear ridges. The pin placed through the trochlea is just cranial to the origin of the cranial cruciate ligament. Normograde placement of these pins provides maximum purchase in the distal segment.

Epiphyseal Fractures

Excellent radiographic technique is required to demonstrate distal epiphyseal fractures because displacement is often minimal. If not stabilized, these fractures result in degenerative joint disease because of the articular involvement.

The medial condyle is most often involved. Exploration of the joint is required to remove any cartilage and bone fragments and to inspect the menisci and cruciate ligaments. Lag screw fixation, the recommended repair technique, achieves accurate realignment of the articular surfaces and compresses the fracture. In small dogs and cats, multiple Kirschner wires or a single wire and lag screw can provide good fixation (Figure 61-14).

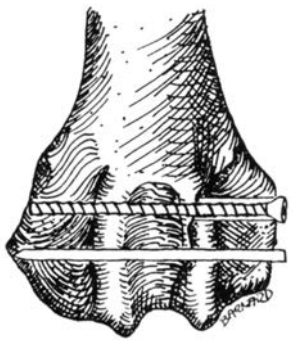

Figure 61-14. Condylar or epiphyseal fractures of the distal femur usually involve the articular surface. Lag screws and Kirschner wire fixation provide rigid fixation.

Postoperative Management and Complications

Physical therapy is an important part of the total treatment regimen in all animals with femoral fractures.

The soft tissue structures around a fracture also sustain trauma, and the bruised and swollen muscles require appropriate therapy after fracture fixation.

Fractures of the Femoral Head and Neck

All animals require strict confinement for the first 4 to 6 weeks after repair of a femoral head and neck fracture. The owner should be instructed on the method of physical therapy of the hip joint to help to restore early limb function.

Radiographic evaluation at 4 to 6 weeks usually reveals thinning of the femoral neck. In most cases, this thinning is normal, but if pronounced lameness is still apparent at this time, these findings suggest avascular necrosis and possible failure of the fixation. If the animal is recovering use of the limb, radiographic evaluation usually is delayed until 6 to 8 weeks after stabilization. Radiographic evaluation after complete healing has occurred usually reveals a thickening of the femoral neck and some evidence of degenerative joint disease. Removal of the implants is not recommended unless complications occur.

Other Femoral Fractures

Physical therapy should be instituted within 2 to 3 days of the surgical procedure. Gentle flexion and extension of the hip and stifle joints for 3 to 5 minutes, a minimum of three times daily, assist in the early return of limb function. This is especially important in an immature dog with a fractured femur, which is prone to quadriceps muscle contraction and tie-down. If this syndrome is allowed to progress to the stage of severe stifle hyperextension, the prognosis for return of limb function is poor. Walking the animal on a leash during the first 4 weeks postoperatively also encourages use of the limb and a return of the normal range of motion in all joints.

Pin migration into the stifle results in damage to the trochlear groove and the patella and, ultimately, in degenerative joint disease. Migration proximally may cause open wounds and possibly osteomyelitis. Sciatic nerve entrapment may result from pin migration or formation of fibrous tissue at the proximal end of adequately seated pins. Clinical signs include acute onset of lameness, pain in the hip region, and eventual knuckling of the paw and hypalgesia over the area of nerve distribution. Exploration and freeing of the nerve from the fibrous tissue are required to allow recovery; in addition, the pins should be shortened or removed if complete fracture healing has occurred. Return of normal limb function depends on the degree of nerve damage sustained in such cases.

Repair of Patellar Fractures

Derek B. Fox

Pathophysiology

The patella is a large sesamoid bone which is responsible for redirecting the forces generated from the contraction of the quadriceps muscle group to the patellar ligament and tibia. As such, it is under continuous tension during pelvic limb weight bearing. Fractures of the patella are uncommon and constitute less than 1% of all fractured bones in the small animal. It is thought that patellar fractures occur by one of two injury mechanisms: either through hard falls during which the animal lands on its feet, thus causing a sudden overload of tensile forces across the patella, or from direct impact such as vehicular trauma. The mechanism of the injury often dictates the mode of failure of the patella and subsequent fracture type. Patellar fractures can be transverse, longitudinal or comminuted with varying degrees of displacement. Overloading injuries from high falls typically fracture the patella in a transverse fashion whereas direct trauma from impacts can lead to comminuted fractures.

Acutely, patellar fractures result in a non-weight bearing lameness of the affected limb. Swelling and crepitus is palpable over the distal quadriceps tendon, patella and patellar ligament. Animals with patellar fractures are usually unable to extend the stifle for some time following the injury. If left untreated, organizing fibrous tissue will eventually form within the fracture allowing the animal to minimally bear weight on the limb, however the swelling on the cranial surface of the stifle will persist. Direct palpation of the fractures is not possible due to abundant inflammation of the overlying soft tissues. Definitive diagnosis of patellar fractures can be achieved with standard radiography. In addition to orthogonal views, oblique positioning can be useful in tangentially highlighting subtle fissure fractures. In addition, the appearance of non-displaced fractures can be enhanced by stressing the patella by flexing the stifle while taking the radiograph.

Treatment

There are three objectives for patellar fracture repair: 1) re-establish the function of the quadriceps mechanism, 2) anatomically reduce the articular chondral surface of the patella to minimize secondary osteoarthritis and 3) apply appropriate fixation to the fracture to optimize osseous union.

Surgical Repair

Prior to surgical reduction of the fracture, the stifle must be examined either arthroscopically or via arthrotomy for evaluation of the articular surface of the patella as well as for additional injury, including cruciate or meniscal damage. Arthrotomies can be completed either medially or laterally without risk of patellar vascular impairment as the patella possesses a complex interior vascular network instead of being supplied through a single nutrient vessel. Because of the large tensile forces constantly applied to the patella, most fractures are displaced to some degree. Repair strategies must be directed at countering the distracting pull of the quadriceps. For most transverse and some comminuted fractures, this can be accomplished with a variety of tension band configurations (Figure 61-15). In each case, the wire must be placed on the cranial, or tension surface, of the patella. Placement of the tension band on either the medial or lateral surface will result in malreduction of the fracture. The extensiveness of the repair is often dictated by the size of the animal and the complexity of the fracture. Non-displaced transverse fractures in medium to smaller-sized animals can be treated with single cerclage wires placed through the quadriceps tendon and patellar ligament (Figure 61-15A and B). Larger and less compliant animals will benefit from the addition of Kirschner wires and the application of the orthopedic wire in a pin and tension band fashion (Figure 61-15C-F). Passage of orthopedic wire through the quadriceps tendon and patellar tendon should be kept as close to the patella as possible. This can most easily be accomplished by placing a hypodermic needle just proximal and distal to the patella through which the orthopedic wire can be passed. The tension band should be tightened sufficiently to provide compression across the fracture lines.

To combat individual bone segment rotation around a single wire (Figure 61-15C), the Kirschner wires can be applied in pairs in both parallel and crossed fashion. Kirschner wires can also be used to align separate fragments encountered with comminuted fractures (Figure 61-15E). When applying Kirschner wires to the patella, pre-drilling is necessary as the bone is very dense. Retrograde application allows greater placement accuracy. Fragment reduction is most optimally accomplished with the leg in extension and a bone holding forceps placed longitudinally across the patella. Although uncommon, pure longitudinal patellar fractures can occur and can be treated with modifications of the aforementioned techniques in addition to lag screwing.

Post-operative care for a standard repair includes keeping the limb immobilized and in extension within a soft padded-bandage for several days following surgery. The animal should have restricted activity for the ensuing 4 to 6 weeks to minimize repetitive cyclic tensile load on the repair. Gentle physical therapy, such as passive range of motion, is appropriate to help combat severe quadriceps muscle atrophy during the post-operative convalescent period. Additional radiographs should be completed to document healing and to examine for implant migration which is not uncommon. Implants can be removed following radiographic union if they are the source of pain or are unstable.

Patellectomy

If small chondral or osteochondral fragments are not able to be incorporated into the repair, or appear unstable following fracture reduction, they may be removed. In certain cases, there exist highly comminuted, irreparable fractures of the distal apical third of the patella only. In this situation, the proximal patella is salvaged while removing the distal fragments

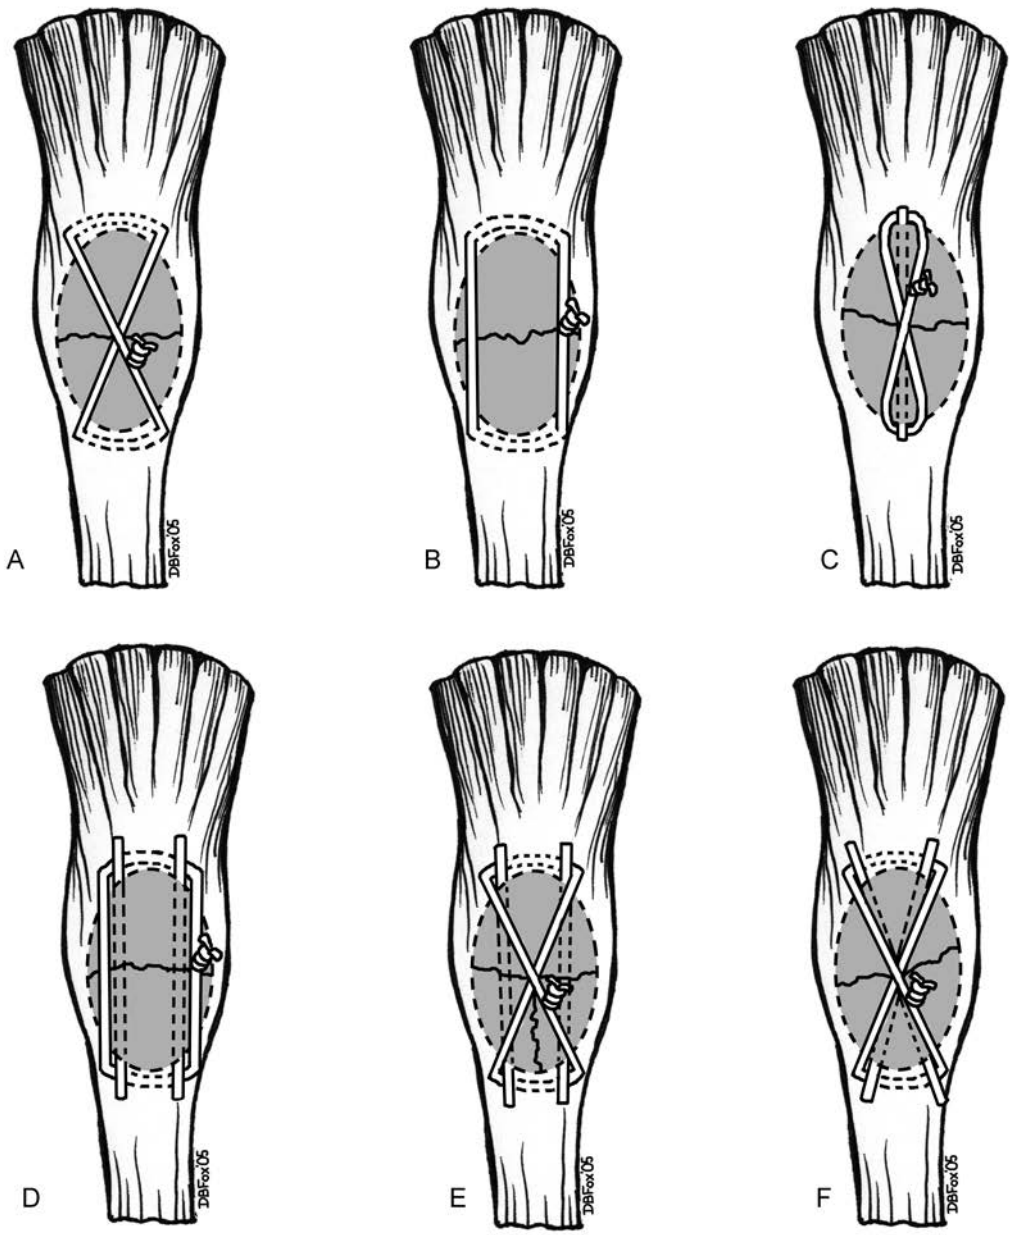

Figure 61-15. Techniques for patellar fracture repair. **A.** Figure-of-eight tension band fixation. **B.** Circumferential cerclage wire fixation. **C.** Single Kirschner wire with figure-of-eight tension band. **D.** Parallel Kirschner wires with circumferential cerclage wire. **E.** Parallel Kirschner wires with figure-of-eight tension band fixation of a comminuted fracture. **F.** Crossed Kirschner wires with figure-of-eight tension band.

constituting a partial patellectomy. This is completed from the articular surface of the patella with ronguers or forceps and scalpel. Because this may weaken the junction of the patellar ligament and potentially lengthen the quadriceps mechanism, surgical reinforcement and imbrication of the ligament may be indicated with 4-0 stainless steel or heavy gauge non-absorbable suture following partial distal patellectomy (Figure 61-16). Occasionally, partial patellectomy will result in the surgical transection of the patellar ligament which will require primary repair. Patellar ligament repair techniques can be reinforced with the placement of a temporary patello-tibial cerclage wire which protects the ligament from tensile forces during healing (Figure 61-17).

For large, highly comminuted and irreparable patellar fractures, total patellectomy can be completed. However with the propagation of degenerative joint disease and altered quadriceps function, the prognosis for return of normal function of the limb is very poor. Therefore, preservation and, if possible, reconstruction of the larger fragments of the fractured patella is advantageous over total patellectomy.

Non-surgical Treatment

If financial constraints prohibit surgical treatment of patellar fractures, conservative management may be considered. Non-surgical care consists of keeping the limb immobilized in extension for 4 to 6 weeks. Complications associated with this technique include advanced osteoarthritis associated with the non-anatomic reduction of chondral fractures on the articular surface of the patella and prolonged joint immobilization. In addition, non-unions and delayed unions may occur with the development of fibrous interpositional tissue within the fractures. These complications necessitate the need for diligent and aggressive physical therapy following the period of immobilization. The prognosis for non-surgically treated displaced patellar fractures is guarded.

Surgical Repair of Patellar Luxations

Guy B. Tarvin and Steven P. Arnoczky

Introduction

Problems involving the patella are frequent causes of lameness in small animals. The most common problem is patellar luxation. Medial luxation is the most frequent type occurring over 75% of the time and is the most prevalent type in small dogs and cats. Lateral luxation occurs most frequently in larger breed dogs and is much less common than medial luxation.[1] Although traumatic patellar luxations may occur, in the authors' experience they are very rare. There is strong evidence that the majority of patellar luxations are heritable in nature[2] and appropriate recommendations such as neutering/OHE and a removal of affected individuals from breeding stock should be part of the treatment regimen encouraged by the Veterinarian.

Functional Anatomy

The patella can be described as the ossified portion of the quadriceps tendon. Although the patella itself is a passive structure in the body, it plays an important role in a dynamic system referred to as the extensor mechanism of the stifle. Movement of the patella is under direct influence of this mechanism, and knowledge of the mechanics of this system is essential in the treatment of patellar dysfunctions.

The primary extensor group of muscles of the stifle is the quadriceps femoris. Three of the four muscles in this group, the vastus lateralis, the vastus medialis, and vastus intermedius, originate from the proximal femur, whereas the fourth, the rectus femoris, originates from the ilium; all four converge to form the quadriceps tendon.[3] This tendon primarily attaches to the proximal portion of the patella; however, a thin portion crosses over the cranial surface of the patella to blend with the patellar ligament.

The patellar ligament is a strong band of fibrous connective tissue that courses from the patella to the tibial tuberosity. When the quadriceps muscle group contracts, the resulting force pulls on the patella, the patellar ligament, and the tibial tuberosity, causing extension of the stifle. During this motion, the patella rides in the trochlear groove. A cross section of the patella reveals a convex articular surface. The corresponding trochlear groove is concave and therefore allows for an intimate articulation between the femur and patella. On both sides of the patella and attached to the joint capsule are the parapatellar fibrocartilages. These structures articulate with the trochlear ridges and increase the surface area and thus disperse the force of the quadriceps muscles.

Normal alignment of the extensor mechanism is necessary for stability of the stifle joint. Dysfunction of this mechanism results in abnormal joint mechanics and joint instability.[5] Such instability not only causes degenerative joint disease but also places increased stress on other supporting structures, such as the cranial cruciate ligament, the collateral ligaments, and the menisci.[3]

Pathogenesis and Diagnosis

Medial patellar luxation is one of the most common patellar problems presented to the veterinary practitioner.[1,5-7] This disorder can be either congenital or traumatic. The congenital form, which is more common, usually is observed in small breed dogs[1,8] and may cause minimal to severe gait abnormalities. The clinical picture often is one of an obese animal with varus (bow-legged) deformity of the rear limbs. The animal often crouches, owing to the inability to extend the stifles fully, with its toes pointed inward. Often, the owner describes a skipping or hopping type of gait in which the animal skips one or more steps on the involved limb. This gait, which is generally transient, is caused by the patella's riding up and over the medial trochlear ridge and being "trapped" on the medial aspect of the joint. Bilateral limb involvement is not unusual. Medial patellar luxations, unless traumatic, rarely cause acute lameness. Although medial patellar luxations sometimes coexist with acute lameness, these luxations usually are chronic; thus, other causes of acute lameness should be pursued. Those dogs with a history of patellar luxation and a sudden onset of pain in the stifle should be examined carefully to rule out cruciate ligament injury.

The incidence of medial patellar luxations in cats is much lower than that of dogs. Abyssinians and Devon Rex breeds may be predisposed to congenital medial patellar luxations.[1] The authors find that many of the same diagnostic and treatment protocols can be applied to cats suffering from medial patellar luxations.

Various causes of congenital medial patellar luxation have been proposed.[7,9-11] Its pathogenesis, however, probably involves a combination of underlying bony abnormalities, any of which may be a cause or an effect of the disorder. Any of the following abnormalities can result in congenital medial patellar luxation, coxa vara, medial displacement of the quadriceps tendon, external femoral torsion, medial deviation of the distal femur, shallow trochlear groove, internal rotation and medial deviation of the proximal tibia.[7,11] Some degree of each deformity may be present in all cases.

Diagnosis is primarily based on palpation. After observing the patient ambulate and assessing conformation, a thorough general and orthopedic evaluation of the patient is performed. To evaluate the patellar mechanism, the authors prefer to have the pet stand on the ground and approach it from the rear. Both stifles are palpated to assess the position of the patella. With one hand over the patella, the other hand gently flexes and extends the stifle. Internal and external rotation of the tibia can also be incorporated during this maneuver. Spontaneous luxation may occur. If no luxation occurs, gentle medial and then lateral pressure is applied to the patella to determine if it will luxate. In the normal stifle the patella may ride up on the trochlear ridge but should not easily luxate. In immature or young patients, some degree of joint laxity is normal. In the young patient, if the patella remains in place but can be luxated only with digital pressure, the authors recommend to follow that patient. In our experience, many of these patients will stabilize once mature. The surgeon should not forget to assess other structures of the stifle such as the cranial cruciate ligament for integrity.

Radiographs to include the hips and stifles are useful to assess for concurrent problems such as aseptic necrosis of the femoral head in young small breed dogs and hip dysplasia in larger breeds. They are also useful in assessing the amount of coxa vara, coxa valga, and femoral and tibial torsion.

Repair of Patellar Luxations

Because the presenting symptoms and signs of medial patellar luxation vary in severity, each patient should be handled individually. Numerous methods exist for the repair of medial patellar luxation,[5-7,12-16] and a single technique may not work or may not be indicated for all degrees of medial patellar luxations. The following discussion presents our treatment approach, which is based on the grading system of Putnam.[11]

Grade I Luxations

In a grade I medial patellar luxation, the stifle joint is almost normal, and the patella luxates only when the joint is extended and digital pressure is applied. Animals with grade I medial patellar luxation often have no clinical signs when presented. Indications for surgical treatment should be weighed carefully because it is difficult to suggest operating on a clinically normal animal. That these asymptomatic animals may be prone to future ligamentous or bony abnormalities,[17] owing to the abnormal pull across the joint, may justify them as surgical candidates. We recommend, however, that these animals not be operated on until they become clinically symptomatic for the disease.

The bony structures of the joint in grade I luxation are nearly normal; that is, the tibial tuberosity and the femoral trochlea are properly formed and have proper anatomic relationships within the joint. When surgical treatment is considered necessary, these two structures should be checked at the time of operation.

Surgical Approach and Assessment

For most medial patellar luxations(regardless of grade) a lateral parapatellar incision is made, and the extensor mechanism is visualized. Before opening the joint capsule, one should examine the alignment of the tibial tuberosity and the patella. These structures should be in a straight line and be parallel to the long axis of the limb when viewed from a craniocaudal direction. In grade I medial patellar luxation, these structures usually line up well. The lateral joint capsule is then opened, and the patella is retracted medially to permit visualization of the trochlear groove. The groove is examined for depth and any degenerative changes. If the groove is normal in appearance, no reconstructive procedures are needed for the trochlea.

Creation of Lateral Restraint

In most cases of grade I medial patellar luxation, the only repair required is the creation of a lateral restraint to prevent medial displacement of the patella. This can be accomplished by imbricating the lateral joint capsule with an interrupted Lembert suture pattern. In smaller animals (15 kg or less), 2-0 monofilament synthetic absorbable suture is used; in larger animals, 1-0 monofilament synthetic absorbable suture usually suffices. Another technique that has worked well is the use of a single suture of 1-0 or 2-0 nylon passed around the lateral fabella and through the quadriceps tendon just proximal to the patella. The suture is then directed distally along the medial border of the patella and is passed through the patellar ligament immediately distal to the patella. The suture is tied on the lateral aspect of the joint and restricts medial displacement of the patella. This technique works especially well in large dogs.[4]

The patella is now examined by placing a varus stress on the stifle and by internally rotating the tibia. If the patella does not luxate through a range of motion with the limb in this position and with digital pressure applied to the patella, the repair is sufficient. If the patella still has a tendency to luxate, a medial releasing incision is created by making a longitudinal parapatellar incision through the fibrous portion of the joint capsule; this incision is not closed. These procedures work well if the tibial tuberosity and femoral trochlea are normal. If these structures are abnormal, soft tissue procedures alone are not capable of overcoming the problem.

Grade II Luxations

The patella usually lies in its normal position in grade II luxation, but luxates with flexion of the joint and remains luxated until relocated by manual pressure or extension of the joint. Animals with grade II medial patellar luxation usually have some form of gait disturbance. They are also more likely to develop degenerative changes than are animals with grade I luxation because of the greater degree of malarticulation.

Trochleoplasty

The tibial tuberosity and trochlear groove are evaluated as described for grade I luxations. If the trochlear groove is shallow, it is corrected first. There are several options to deepen the trochlea. One is to perform a trochleoplasty. This is performed by first making two parallel incisions into the trochlear cartilage with a scalpel blade. These incisions delineate the medial and lateral boundaries of the new trochlear groove. The groove should be wide enough to permit proper seating of the patella while maintaining an adequate lateral and, especially, medial trochlear ridge. The cartilage between the incisions is removed with a bone rongeur or a high-speed drill.[7] In younger dogs, the cartilage can easily be removed with a No. 15 scalpel blade. The groove must be deepened uniformly to the level of bleeding subchondral bone to ensure the regeneration of fibrocartilage.[16] The new groove should be of sufficient width to accommodate the patella, it should have a well-developed medial ridge, and it should be of sufficient depth to discourage luxation (Figure 61-18).

After this type of trochleoplasty, fibrocartilaginous tissue forms over the articulating surface of the deepened trochlear groove.[16] Although this newly generated fibrocartilage surface does not possess the same physical properties of articular (hyaline) cartilage, it was thought to be sufficiently similar to be clinically effective, and indeed this technique has given good results over the years. Nonetheless, preservation of the normal hyaline cartilage surface of the trochlear groove would be expected to enhance the results of the deepening procedure.[18] To that end, a newer procedure, the trochlear wedge recession technique, was developed to deepen the trochlear groove without destroying the cartilage present.[18,19]

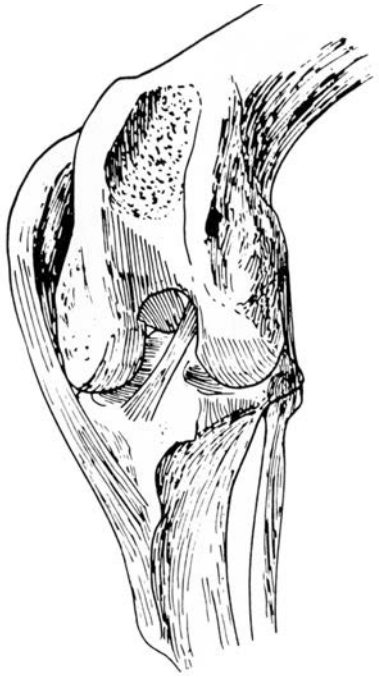

Figure 61-18. Trochleoplasty is performed to widen and deepen the femoral trochlear groove. (From Arnoczky SP, Tarvin GB: Surgery of the stifle: the patella. *Compend Contin Educ Pract Vet* 2:200, 1980.)

Trochlear Wedge Recession Technique

In this technique, an osteochondral wedge is removed from the trochlear groove with a fine-tooth bone saw. As in the previously described trochleoplasty, an adequate trochlear ridge must be maintained on the medial and lateral aspect of the trochlear groove. To accomplish this, the saw cuts are started at the highest point on the medial and lateral trochlear ridges (Figure 61-19A). The cuts are then directed to intersect at a point just proximal to the femoral origin of the caudal cruciate ligament. Care is taken not to extend the osteochondral wedge into the intercondylar notch. The osteochondral wedge is then removed to reveal a V-shaped trochlear bed (Figure 61-19B). Owing to the width of the saw blade used to remove the wedge, the wedge of bone is actually smaller than the created bed, therefore, when the osteochondral wedge is replaced into the groove, the wedge is naturally recessed, resulting in a deepened trochlear groove. If additional depth is required (at least 50% of the patellar depth should be seated in the groove), approximately 1 to 1.5 mm of additional bone can be removed by making another set of saw cuts parallel to the first (Figure 61-19C). The wedge is then replaced in the bed, so the original cartilage surface is recessed (Figure 61-19D). The friction of the cancellous bone surfaces (plus the compressive force of the articulating patella) keeps the wedge in place, and no fixation appliances are needed. Even more recently, a third option (Figure 61-20) the rectangular recession trochleoplasty has been suggested as an improvement on the trochlear wedge recession.[20] An experimental in vitro study indicates that the rectangular recession has increased patellar articular surface contact, less subchondral bone exposure, recesses a larger percentage of the trochlea, and results in greater resistance to patellar luxation with the stifle extended as compared to the trochlear wedge recession.[21] However the rectangular recession is more technically difficult to perform. To date no clinical studies comparing the two have been performed.

Transposition of Tibial Tuberosity, Lateral Imbrication, and Medial Releasing Incision

If the tibial tuberosity is deviated medially, this deviation is corrected by transplanting the attachment of the patellar ligament to a more lateral position. This transplantation is done by osteotomy of the tibial tuberosity. Care is taken to preserve the distal fascial attachment of the osteotomized portion of the tibial tuberosity to the distal tibia as this enhances stability to the repair. The osteotomized portion of tibial tuberosity is placed more lateral under the cranial tibialis muscle.[5,6,12,14,15] The tibial tuberosity is then fixed in place by one or two small Kirchner wires (Figure 61-21). The patella is then tested in the previously described manner for stability. Little, if any, tendency for luxation should be noted. If some tendency for medial luxation still exists, the tibial tuberosity can be moved farther laterally, or the joint capsule can be imbricated laterally. A medial releasing incision can be added if necessary (Figure 61-22).

Transposing the tibial tuberosity with the aforementioned technique, does result in rotation of the patellar ligament and caudalization of the insertion of the ligament on the tibia (Figure 61-23A). It has been proposed that this rotation and caudalization may predispose the patellar articular cartilage to abnormal wear with subsequent degenerative joint disease. A modification of the tibial tuberosity transplant has therefore been proposed by L'Eplattenier and Montavon[2] in which the osteotomy is created further caudally and is angled rostrally from medial to lateral in a transverse plane (Figure 61-23B). This allows the osteotomized

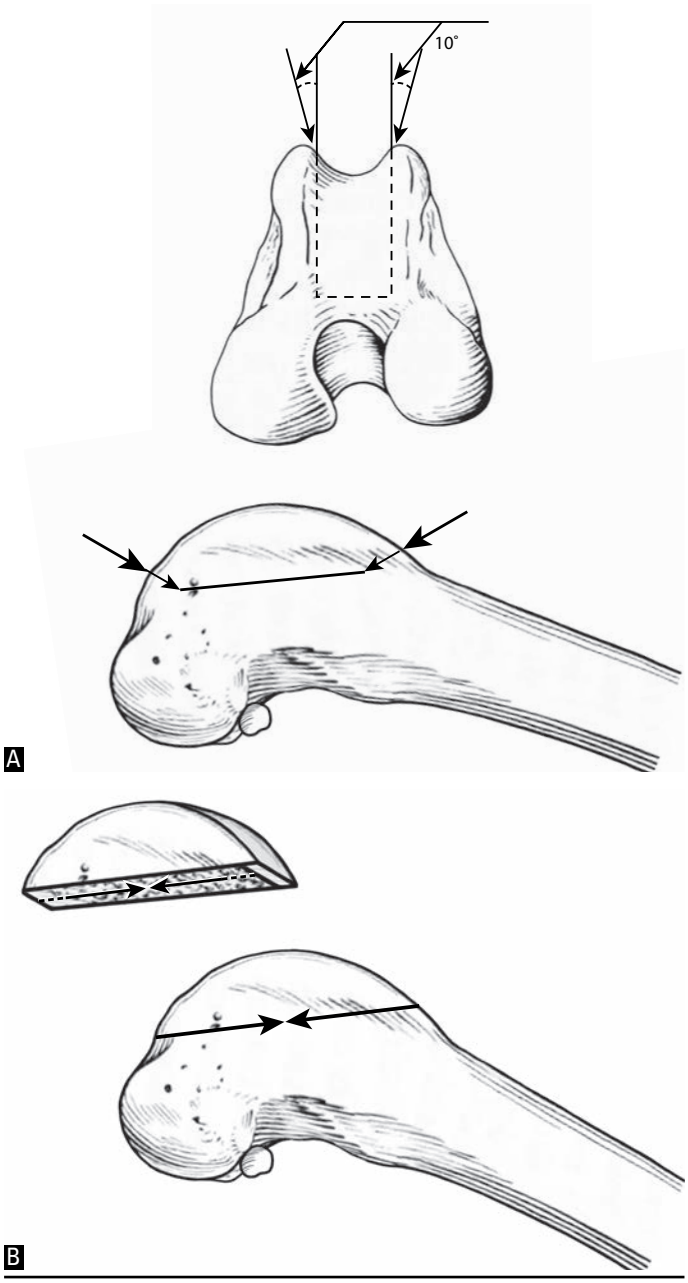

Figure 61-20. Talcott, et. al. described a rectangular recession trochleoplasty. **A.** Two views indicating location and angulation of the cuts. In the skyline view on the left, the cuts are made at an angle of about 10 degrees to perpendicular. In the lateral projection on the right the transtochlear cuts are made at 90 degrees to the trochlear surface. Talcott, et. al recommend making the proximal transtrochlear cut proximal to the patellar articulation. **B.** The rectangular wedge is undermined by alternating between the proximal and distal ends and eventual completely elevated. The bed is then deepened by removing more subchondral bone and the wedge is then replaced.

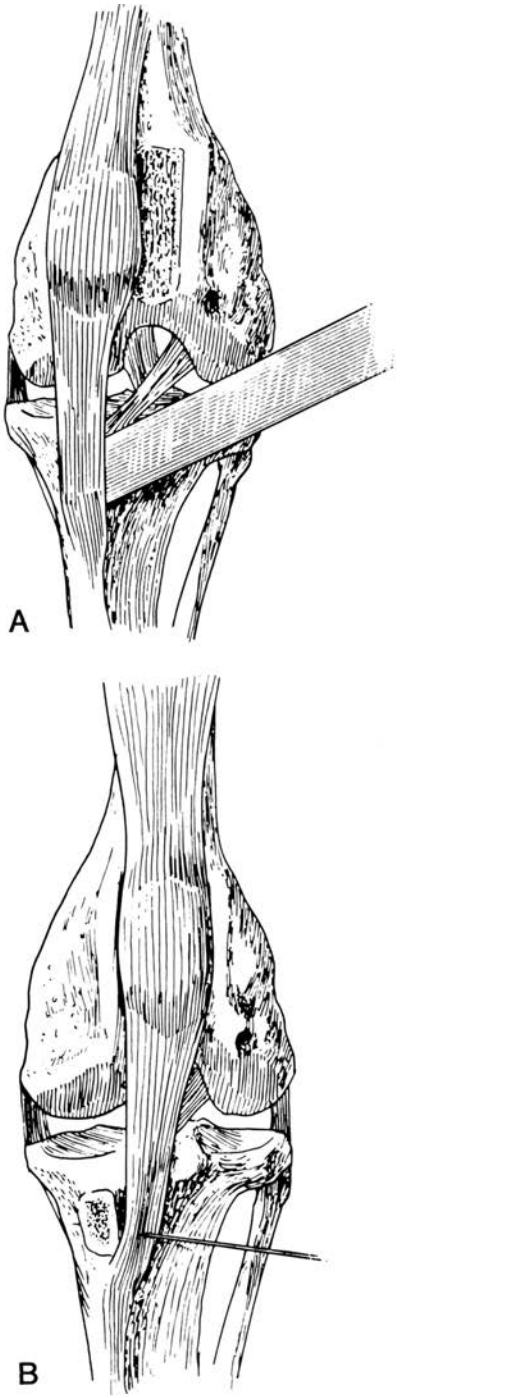

Figure 61-21. Transposition of tibial tuberosity. **A.** Osteotomy of the tibial tuberosity. The fascial extension of the patellar ligament onto the tibial crest is left intact. **B.** Lateral transplantation and fixation of the tibial tuberosity with a Kirshner wire. portion of the tibial tuberosity to be "slid" laterally to realign the patella within the trochlear groove(See Figure 61-23B). If performed correctly, it also allows for cranialization of the patellar ligament insertion. This cranialization may actually relieve stress on the articular surface of the patella.[2] Tibial tuberosity transposition has worked well in our hands. L'Eplattenier and Montavon report good success with this technique but admit that at this time there is no comparative data to demonstrate any superiority of this technique over the first technique described in this chapter for tibial transposition. At this time, we recommend using either technique as good results can be expected from both. Perhaps future scientific data may become available to determine if one is superior to the other.

Grade III Luxations

The patella is luxated most of the time, but it may be reduced with the limb in the extended position in grade III medial patellar

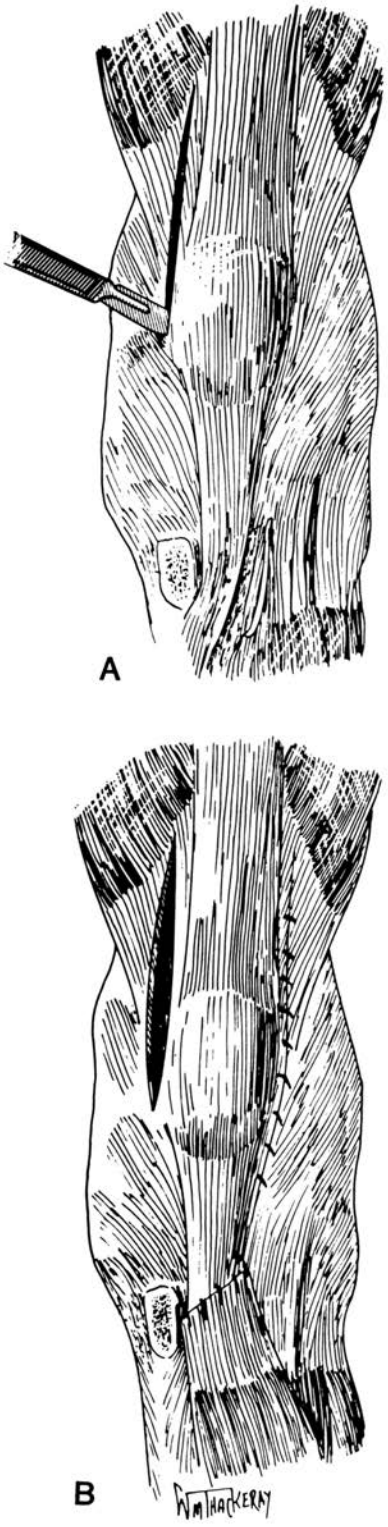

Figure 61-22. A. Medial releasing incision. **B.** Lateral imbrication of the joint capsule (From Arnoczky SP, Tarvin GB: Surgery of the stifle: patella. *Compend Contin Educ Pract Vet* 2:2000, 1980.)

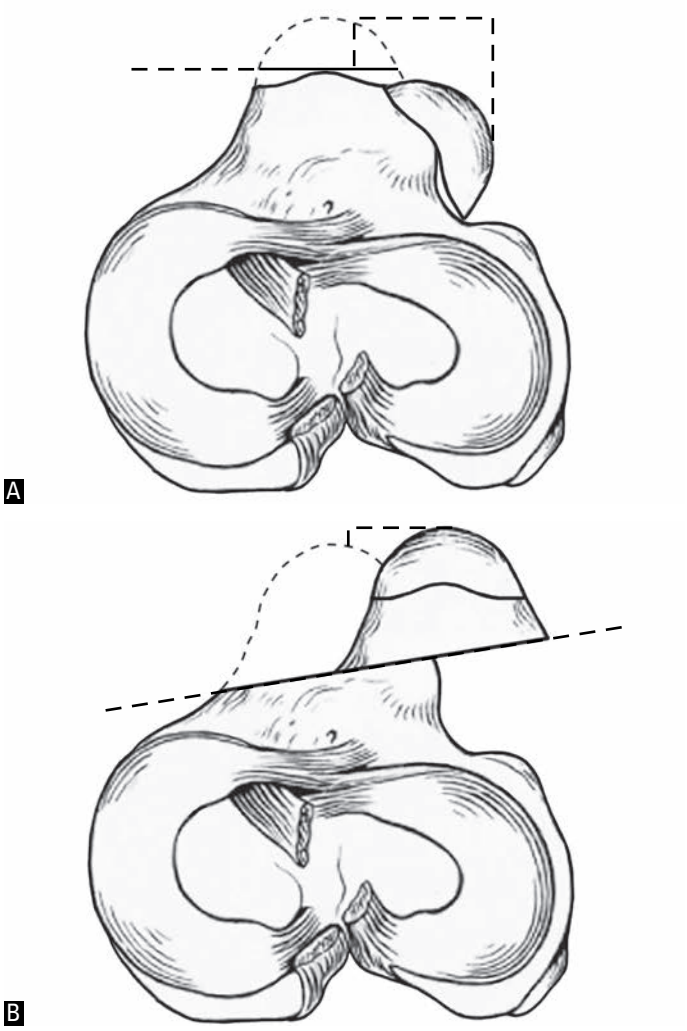

Figure 61-23. A. In the standard tibial tuberosity transposition caudalization and rotation of the fragment occurs. **B.** By creating a more caudal and angled osteotomy, the fragment can be slid to redirect the patellar tendon without caudalizing or rotating the fragment. (Redrawn with permission from L'Eplattenier H, Montavon P, Patellar luxations in dogs and cats: management and prevention. *Compend Cont Educ Pract Vet* 2002;24, 292.)

luxation. All the techniques used in treating grade II medial patellar luxations will probably be needed to correct grade III luxations. The same format for examining the structures should be followed to assess the necessity of each procedure.

If the tendency for luxation remains after correction with these techniques, the medial releasing incision may be inadequate or medial rotary instability of the tibia may be present. The medial releasing incision can be extended proximally to incise a portion of the vastus medialis muscles. If rotational instability is present, it can be corrected with a lateral suture of heavy nonabsorbable material placed around the lateral fabella and though a drill hole in the tibial crest (Figure 61-24). This suture is tightened to externally rotate the tibia and thus help realign the extensor mechanism. Usually, a combination of the aforementioned techniques are sufficient to correct a grade III medial patellar luxation.

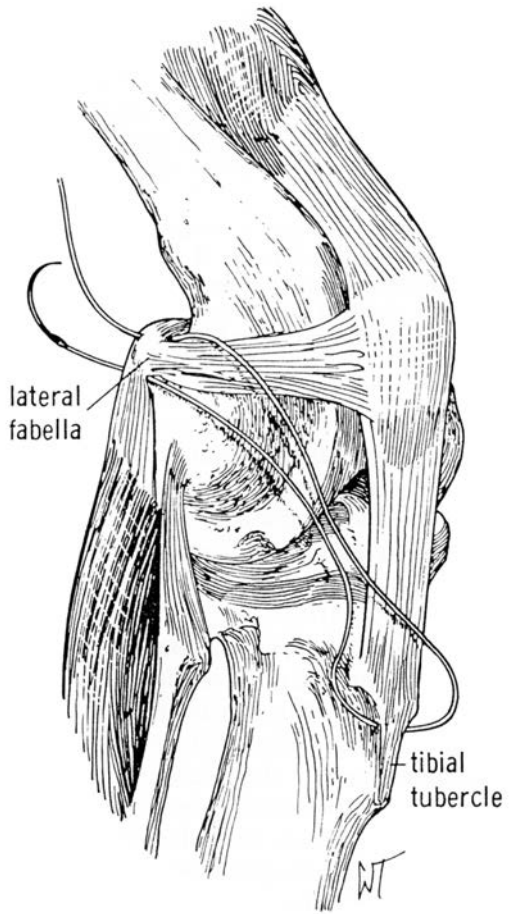

Figure 61-24. Placement of lateral derotational suture. (Arnoczky SP, Tarvin GB: Surgery of the stifle: patella. *Compend Contin Educ Pract Vet* 2:2000, 1980.)

Grade IV Luxations

The patella is dislocated and cannot be reduced without surgical intervention in grade IV medial patellar luxation. If diagnosed early, this least common type of luxation should be corrected at an early age to prevent the resulting bony deformities of the femur and tibia. In most cases; however, the patients already have severe bony deformities and the previously discussed techniques are inadequate to correct the disorder. These patients usually require osteotomies (derotational, cuneiform) of the tibia or femur to correct the anatomic structures and thereby the mechanics of the patella.[5,6]

Lateral Patellar Luxations

Lateral patellar luxations, which are not as common as medial patellar luxations, occur most often in large breed dogs.[1,5,6] The disorder can be congenital of traumatic. In the congenital form, this condition is often associated with hip dysplasia, and thus simple correction of the resulting patellar alignment may eliminate the signs and symptoms but may not correct the underlying problem. Isolated deformities, such as genu valgum, also may cause lateral patellar luxations. The deformities causing lateral malalignment of the extensor mechanism are coxa valga, increased anteversion angles, lateral displacement of the quadriceps tendon, internal femoral torsion, laxity of medial fascia and contraction of lateral fascia, and external rotation and lateral deviation of the proximal tibia. These disorders are, for the most part, the opposite of those causing medial luxations.

As in medial patellar luxations, the severity of the lesion varies widely. Affected animals usually have a valgus (knock-knee) deformity of the rear limbs and are first seen in a crouched stance with the toes pointing outward. Correction of this disorder is based on the grading system described for medial luxations. In each case, the structures of the stifle are assessed and are corrected in the same stepwise manner as for medial patellar luxation with the following obvious modifications to the procedures: 1) medial (not lateral) imbrication; 2) lateral (not medial) releasing incision; 3) medial (not lateral) transposition of the tibial tuberosity; and 4) medial (not lateral) derotational suture.

The prognosis for grades I to III medial and lateral patellar luxations is good and success has been reported as high 90%.[2] Most patients improve clinically but degenerative joint disease does progress in a majority of cases. In our experience, grade IV luxations offer a poor prognosis, may require several surgeries including osteotomies, and still remain lame.

Postoperative Care

After surgical repair of both medial and lateral patellar luxations, patients should be fitted with a soft, padded bandage for 2 weeks and have restricted exercise for a minimum of 6 to 8 weeks. In the case of bilateral patellar luxations, the most severely affected limb is usually operated on first, and at least a 4 week healing period is observed before the second limb is treated. In the authors' opinion, simultaneous bilateral repairs have a higher degree of failure and are seldom recommended.

Fabellar Suture Stabilization Technique for Treatment of Cranial Cruciate Ligament Rupture

Susan L. Schaefer

Introduction

The purpose of the Fabellar Suture Stabilization Technique is to provide extracapsular stabilization of the stifle following partial or complete rupture of the cranial cruciate ligament. The technique described here is a modification of Flo's original modified retinacular imbrication technique[1] as the fabellar-patella stabilizing suture is no longer incorporated and the location of the tibial suture hole has been revised. The overall objective is to place stabilizing sutures from the lateral and medial fabella to the tibial tuberosity. The intention is for these sutures to mimic the activity of the cranial cruciate ligament in the sagittal plane, eliminating cranial drawer movement when tightened. The lateral suture alone should eliminate most drawer movement. The medial suture plays a more secondary role in stifle stabilization. While these sutures stabilize the stifle acutely, it is theorized that fibrous tissue laid along the suture track maintains long term stability. Suture size and the number of sutures used vary on a per case basis and will be reviewed in the discussion.

Surgical Technique

Prior to extra-articular stabilization of the stifle an arthrotomy should always be performed and the joint thoroughly examined. A medial or lateral arthrotomy may be used. A medial arthrotomy generally allows for easier access to the medial meniscus if a menisectomy is indicated. Any remaining tags of the cranial cruciate ligament are removed and both menisci are examined. Damage to the medial meniscus is seen in over 50% of cases with cranial cruciate ligament rupture.[2] Damage to the lateral meniscus has also been reported but is more commonly limited to small radial tears in the cranial horn.[3] The damaged portion of affected menisci should be removed. The joint capsule is then closed with a synthetic absorbable suture in a simple interrupted pattern.

The fabellar suture stabilization technique is begun by identifying both fabellae. The fabellae are located along the caudomedial and caudolateral aspect of the distal femur. In surgery, their position can be approximated by moving either medially or laterally at the level of the distal third of the patella. An incision is made through the insertions of the sartorius medially and the biceps femoris laterally for fabella identification and suture placement. Medially, a longitudinal incision is made in the fibrous insertion of the caudal head of the sartorius muscle at the level of the patella (Figure 61-25). With the caudal sartorius muscle retracted caudally, the medial fabella should be palpable under the medial head of the gastrocnemius muscle (Figure 61-26). Laterally, a slightly curved longitudinal incision is made in the fibrous insertion of the biceps femoris muscle (Figure 61-27). With this muscle retracted caudally,

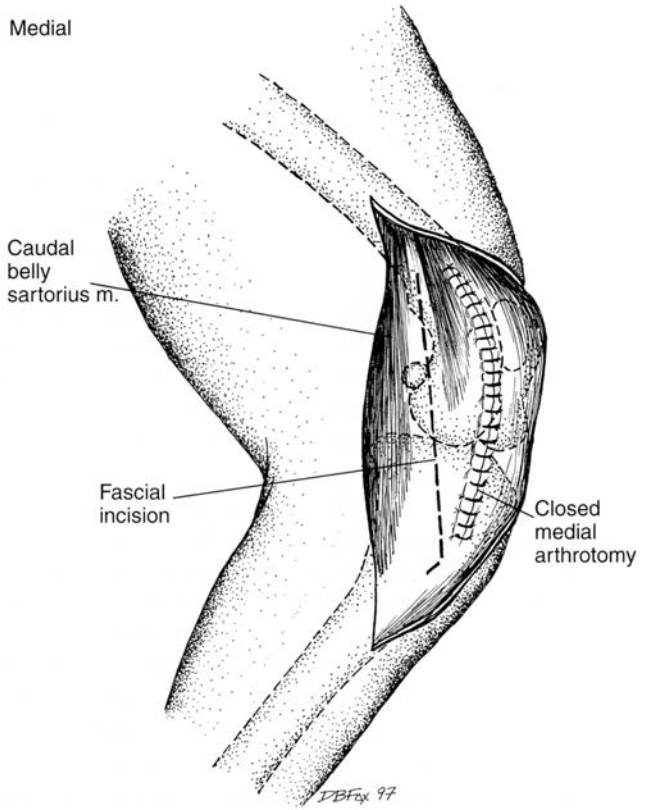

Figure 61-25. Medial aspect of the left stifle. Approach to the medial fabella is made through an incision in the fascia along the cranial boarder of the caudal belly of the sartorius muscle. A medial arthrotomy has been performed and closed.

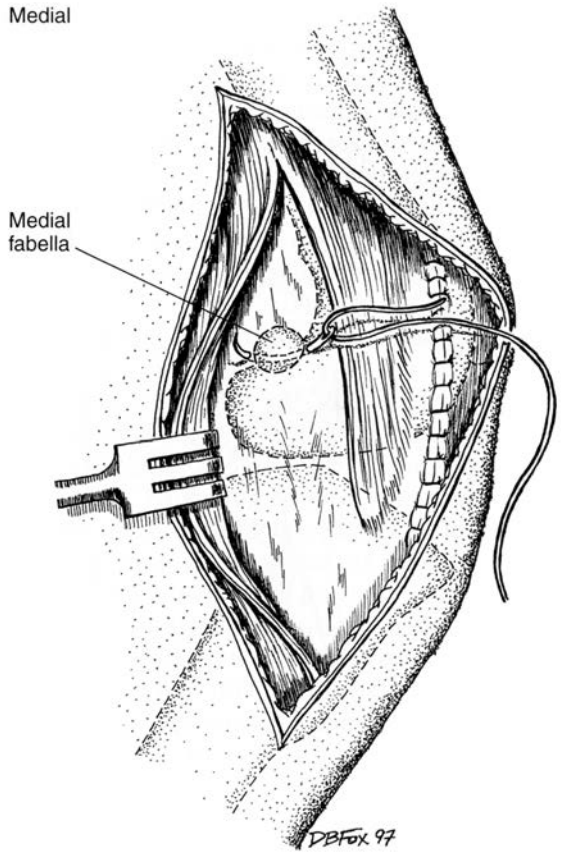

Figure 61-26. Medial aspect of the left stifle. Retraction of the caudal head of the sartorius muscle allows for palpation of the medial fabella and for medial suture placement. The needle should be passed in a cranial-to-caudal direction. The suture should anchor behind the proximal aspect of the fabella to avoid suture pullout into the soft tissue distally.

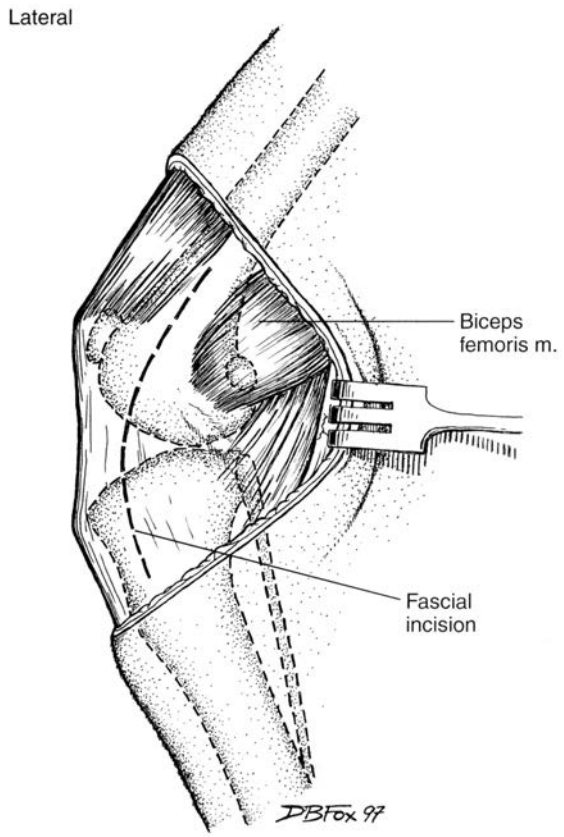

Figure 61-27. Lateral aspect of the left stifle. Exposure to the lateral fabella is made through an incision in the fibrous insertion of the biceps femoris muscle.

the lateral fabella should be palpable under the lateral head of the gastrocnemius muscle (Figure 61-28). On the lateral aspect of the stifle joint the peroneal nerve should then be identified. This nerve lies underneath the biceps femoris muscle and runs in a caudo-proximal - craniodistal direction. Locating this nerve is essential to avoid damaging it during suture placement.

To place the fabellar sutures, the stifle is held in moderate flexion with the overlying muscle (sartorius or biceps femoris) retracted. The fabellar-femoral junction is identified by placing a curved hemostat around the caudal aspect of the fabella and rocking the sesmoid up or outward, away from the femur. Once the junction is identified the needle is passed around the proximal third of the fabella in a cranial to caudal direction (See Figure 61-27 and 61-28). Care must be taken on the lateral side to avoid the peroneal nerve. Correct suture placement is confirmed by lifting up on both ends of the suture and palpating the fabella to insure that the suture is well locked behind the bone. If two sutures are to be placed on a side, a double length of the suture material is threaded through the needle to the midpoint. Heavy, non-absorbable suture should be used. Ethylene oxide sterilized, monofilament nylon fishing leader (20-80# test, Hard Nylon leader, Mason Tackle Co, Otisville, MI) with a heavy, half curved Martin's uterine needle is commonly used.

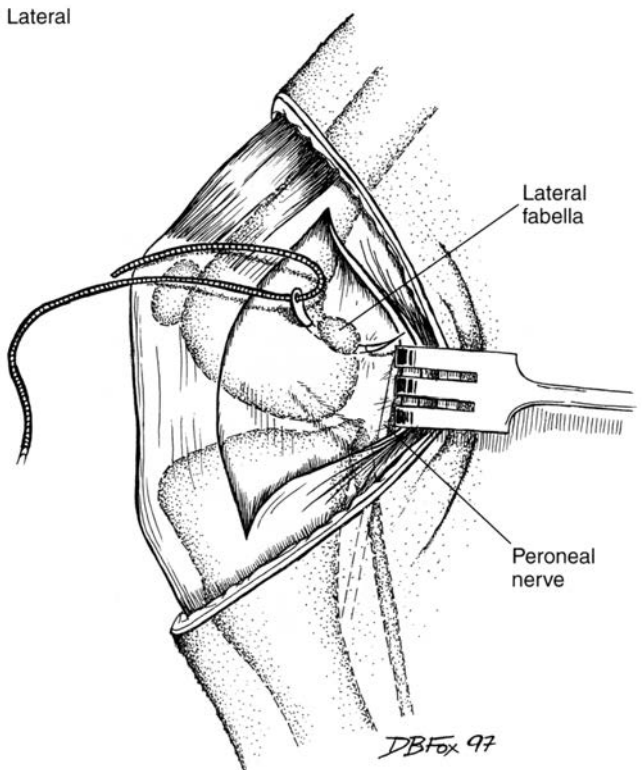

Figure 61-28. Lateral aspect of the left stifle. Retraction of the biceps femoris muscle allows for palpation of the lateral fabella and for lateral suture placement. The peroneal nerve, running in a craniaodistal direction from behind the joint, should be avoided during suture placement.

A hole is then drilled in the tibial tuberosity for fabellar suture anchoring. This hole is placed just caudal to the patella tendon insertion and in line with (distal to) the cranial edge of the extensor groove (Figure 61-29). This is a more isometric point than previously described distal locations.[4] This should place the tibial hole just below the tibial attachment of the cranial cruciate ligament. With the tibial suture hole at the approximate isometric point, slacking of the suture during either flexion or extension should be minimal (Figure 61-30). The caudal strand of each suture is then passed through this hole with either the Martin's uterine needle or threaded through a 14 or 16 gauge needle. All sutures can be passed through the same hole. Once a suture is brought through the tibia it is then passed back under the patella tendon. For example, the caudal strand of a lateral fabellar suture is first passed through the tibia from lateral to medial and then passed under the patellar tendon from medial to lateral. To confirm correct tibial hole placement, the sutures are threaded into position and the matching ends can be wrapped lightly around one another and held under tension. The stifle is then gently put through a range of motion. The sutures should move less than 2 mm relative to one another with correct tibial placement.[5] The lateral sutures are tied or secured with a crimp tube first as they alone should eliminate most drawer movement. To tie the lateral suture, the limb is held at the angle of flexion which produces the most "cranial drawer" with an assistant externally rotating the tibia and pushing it in "caudal drawer". This manipulation removes any instability while the sutures are being secured. Following lateral stabilization the medial sutures are secured with the stifle held in mild flexion (Figure 61-31).

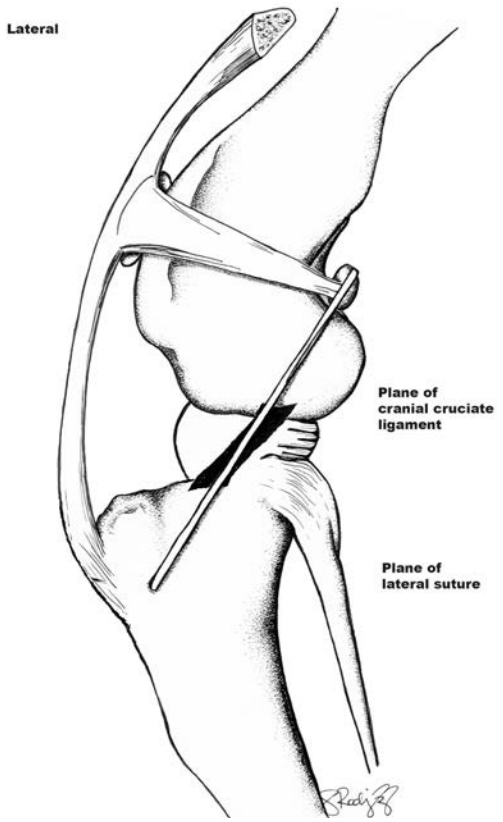

Figure 61-30. Lateral aspect of the left stifle. Correct placement of the tibial hole ensures that the plane of the fabellar suture approximates the plane of the cranial cruciate ligament.

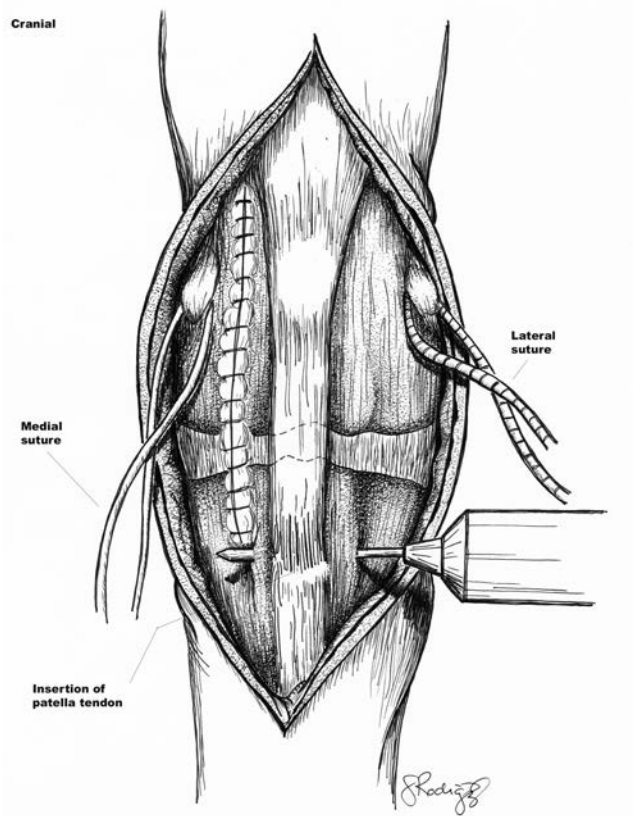

Figure 61-29. Cranial aspect of the left stifle. The hole in the tibial tuberosity is placed just caudal to the insertion of the patella tendon and just distal to the cranial aspect of the extensor groove.

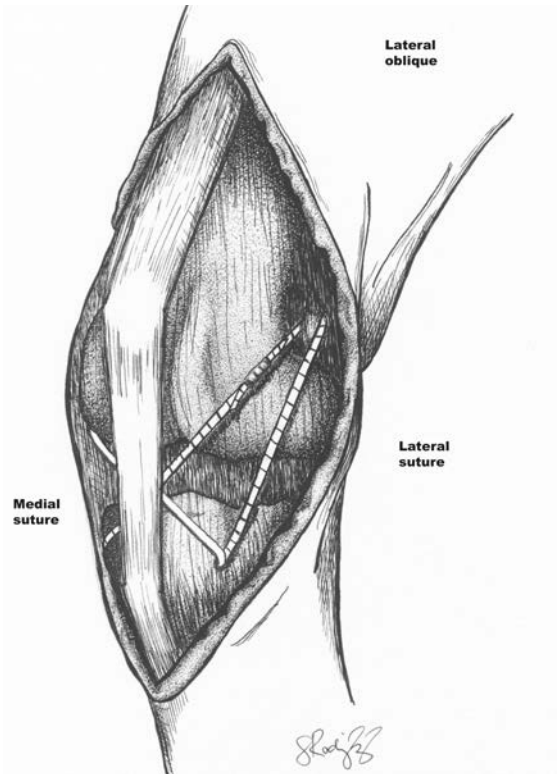

Figure 61-31. Lateral oblique of the left stifle. Both sutures have been placed using the isometric point in the tibial tuberosity.

The suture can be secured by using either two interlocking slip knots, a surgeons throw or a crimp tube. If monofilament nylon is used with a knot, a smooth faced needle holder may be applied to lightly hold the first throw while the second throw is being prepared. No less than four throws should be used. Alternatively, an aluminum crimp tube can be used to secure monofilament nylon sutures (Securos, Charlton, MA.) The advantage of the crimp tube is that it has a low profile and is less likely to produce a seroma than a large suture knot. In addition, the position of the crimp tube can be monitored radiographically. If crimp tubes are used postoperative radiographs should be taken to confirm post-op location of each tube. Following suture placement both the sartorius fascia and biceps femoris fascia are closed in an imbricating fashion. The subcuticular tissue and skin are closed in a routine fashion.

Postoperative Care

The incision should be iced 3x/day for 10 to 15 min for the first 3 to 5 days. This can begin as the animal is recovering from anesthesia. The animal's activity should be restricted for 6 to 8 weeks with no running or jumping and short leash walks only. Animals will benefit from specific physical therapy of the limb during this 6 to 8 week period 6. (See Table 61-1 for a recommended postoperative activity regime.) Following this 6 to 8 week period the dog is slowly reintroduced to normal levels of activity over a 4 week period. If animals are overactive during the recovery period immature fibrotic tissue can be stretched resulting in joint instability. Adequate exercise restriction is essential for clinical success. Weight loss should be recommended if indicated and owners should also be advised that contralateral cranial cruciate ligament rupture may occur in 30 to 40% of cases.

Discussion

Although some surgeons reserve this technique for smaller dogs, consistent success has been reported over a wide range of weights. The number of sutures placed is determined by the weight of the animal, body condition, activity level and the degree of joint instability. The following are only general guide lines for the number of sutures placed. Dogs weighing under 40 pounds receive two fabellar sutures (two lateral). Dogs weighing 40 to 80 pounds receive three sutures (two lateral, one medial). In dogs weighing greater than 80 pounds or in those with severe instability four sutures are placed (two lateral, two medial). Dogs with chronic cruciate ligament rupture and minimal instability may only receive one or two sutures (one lateral or one lateral and one medial). If monofilament nylon (fishing leader) is used, the strength of the material selected should roughly correspond to the weight of the animal (40 pound test for a 40 pound animal, 80 pound test for an 80 pound animal). On rare occasions, in cases of chronic cruciate injury with no "drawer" movement present, fabellar stabilization sutures are unnecessary following arthrotomy. The

Table 61-1. Activity Guide for Post-op Fabellar Suture Stabilization Technique

Post-Op Week 1-2	1. Slow walking on short leash to urinate or defecate.
	2. Passive Range of Motion (PROM) exercises – 10-15 reps, 3x/ day slowly.
	3. Massage leg (from toes to hip) before and after both walks and PROM.
	4. Ice surgical area 15 min 3x/day after walks and PROM.
	5. Starting day 6 apply a warm compress for 10-15 min before massage and PROM. If at any time the warm compress increases swelling, return to ice only.
Post-Op Week 3-4	1. Therapeutic activities are progressed slowly.
	-Continue PROM and massage as needed.
	-Multiple short, slow walks – (5-15 min) 3x/day, to tolerance.
	-Begin walking on inclines when there is consistent use of the leg.
	-Begin underwater treadmill exercises
	2. Initiate gentle strengthening and proprioceptive exercises.
	3. Use warm compress before PROM and walking and then ice after activity.
Post-op Weeks 5-7	1. Continue gentle strengthening and proprioceptive exercises.
	2. Continue to progress slow leash walks (15-20 min) 3x/day, to tolerance.
	3. Ascend / Descend stairs in controlled fashion.
	4. May initiate straight line trotting on a long lead and swimming with gentle water entry.
Post-Op Weeks 8-12	1. Increase intensity / duration of leash walks: 20-30 min on long lead 3x/day, to tolerance.
	2. Gradually introduce and return to off-leash activity.
	3. Begin running in straight line on long lead.
	4. Return to prior level of activity at end of 12 weeks.

Neuromuscular Electrical Stimulation (NMES) can also be incorporated into the rehabilitation plan immediately after surgery. Recommended frequency is 2-3x/week for 3-4 weeks. (Used with permission: Courtney Arnoldy, PT, CCRP).

primary causes of lameness in these animals is often chronic inflammation, meniscal damage or osteophyte formation.

Complications are uncommon (less than 10%) but include suture rupture, meniscal damage and seroma formation due to suture irritation. Suture rupture and meniscal damage are the most common causes of poor recovery. Clinically these patients may show either lack of full recovery or full recovery followed by a return of lameness. Meniscal damage should be suspected if a popping or clicking noise is heard on ambulation or palpated on examination. If a meniscectomy has already been adequately performed suture rupture should be suspected. If poor recovery is seen with the formation of large seromas over the suture knots suture irritation should be suspected. In dealing with animals with poor or inadequate recovery from the Fabellar Suture Technique simple fabellar suture removal should be attempted first if meniscal damage is not suspected or a meniscectomy has been previously performed. Suture removal as early as 12 weeks postoperatively should not increase drawer movement. Lameness usually resolves within two weeks if it was the result of suture problems. Suture replacement is rarely required and only in cases of gross stifle instability. If lameness persists following suture removal and a meniscectomy has not been previously performed, a repeat arthrotomy and medial meniscectomy are advised.

Tibial Plateau Leveling Osteotomy for Treatment of Cranial Cruciate Ligament Rupture

Ross H. Palmer

Introduction

Cranial cruciate ligament incompetence is a leading cause of lameness in the dog. Many surgical treatments have been described that aim to restore stifle joint stability and minimize the progression of subsequent osteoarthritis. Historically, most surgical techniques were designed to replace the function of the pathologic cranial cruciate ligament through some means of substitution using autologous tissues or synthetic materials and these methods have been described exhaustively elsewhere. More recently, tibial plateau leveling osteotomy (TPLO) was described by Dr. Barclay Slocum utilizing techniques that alter the mechanical forces acting upon the stifle in order to render the cranial cruciate ligament unnecessary.[1] The biomechanics of the TPLO have been discussed elsewhere.[2-5] The purpose of this chapter is to provide a detailed description of the TPLO procedure and its preoperative planning.

Preoperative Planning

Precise patient positioning is required when making radiographs for accurate measurement of tibial plateau angle (TPA) and other aspects of preoperative planning.[6-8] These mediolateral and caudocranial radiographs are most commonly performed with the patient under general anesthesia immediately prior to the TPLO surgery. TPA is measured on a mediolateral radiograph of the stifle with the tibia parallel to the radiographic film (Figure 61-32). The dog is placed in lateral recumbency with the affected limb down. The lateral surface of the hip, stifle, and hock are placed on the same surface. When using table-top radiographic technique, all these structures can be placed upon a large radiographic cassette or upon a smaller cassette with an adjacent spacer. The "up" leg is pulled cranially (rather than abducted at the hip) in order to keep all three structures in contact with the cassette. The "down" leg is positioned with the stifle and hock flexed to approximately 90 degrees. It is essential to center the

Figure 61-32. Dog positioned for mediolateral radiograph of stifle for preoperative TPLO planning. Dog in lateral recumbency with the affected limb down. Stifle and hock flexed to approximately 90 degrees with lateral surface of hip, stifle and hock at same level (in contact with radiographic cassette). Radiographic beam is centered on stifle but includes stifle and hock. Contralateral limb is pulled cranially.

beam upon the center of the tibial plateau while collimating the beam to include the tarsus. A cranial or proximal shift of the stifle from the center of the beam erroneously increases the measured TPA.[7] A caudal or distal shift of the stifle from the center of the radiographic beam erroneously decreases the measured TPA. Properly positioned radiographs display superimposition of the medial and lateral femoral condyles (unless there is a significant varus/valgus and/or torsional deformity of the femur) and distinct visualization of the medial condylar portion of the tibial plateau. The slope of the tibial plateau is defined by a line joining a point at the cranial-most edge of the medial tibial condyle with its caudal-most point (Figure 61-33). The tibial functional axis is defined by a line joining a point at the intersection of the superimposed medial and lateral intercondylar tubercles with a point at the center of the talus. Next, a line is drawn perpendicular to the tibial functional axis. The TPA is defined as the angle formed between the perpendicular and the tibial plateau line. The author has measured TPA's varying from 10° to 53° in dogs with cranial cruciate ligament incompetence, but the majority of TPA measurements in large breed dogs fall between 18° and 30°.[6,8,9]

Figure 61-33. Mediolateral TPLO planning radiograph shows superimposition of femoral condyles and approximately 90 degrees of flexion in stifle and hock. Tibial plateau slope (TPS) is defined by a line joining a point at the cranial-most edge of the medial tibial condyle with its caudal-most point. The tibial functional axis is defined by a line joining points at the intersection of the superimposed medial and lateral intercondylar tubercles and at the center of the talus. The line drawn perpendicular to the tibial functional axis represents the theoretic orientation of a completely level tibial plateau. Tibial plateau angle (TPA) is measured as the angle formed between the perpendicular and the TPS.

In addition to TPA measurement, the mediolateral radiograph is used for detailed preoperative planning.[3,10-12] Imaging Software or transparent templates are superimposed on the radiograph to evaluate the suitability of the various sizes of TPLO saw blades, jigs and bone plates. The desired point of insertion of the most proximal jig pin into the tibia is along the tibial functional axis immediately distal to the articular surface of the tibia. This critical point is marked on the mediolateral radiograph for intraoperative reference (Figure 61-34). Next, templates of available saw blade sizes (varying radius and circumference) are used to determine appropriate saw blade size. A properly sized blade should allow centering of the osteotomy about the most proximal end of the tibial functional axis, while the proximal end of the osteotomy is positioned midway between the cranial point of the tibial plateau and the tibial tuberosity. The distal end of the proposed osteotomy should be perpendicular to the tibial functional axis. The proposed osteotomy is marked upon the film for intraoperative reference. Next, a template for the appropriate size of bone plate is used to be certain that the planned osteotomy position will permit the desired implant placement (Figure 61-35). The extent of "coving" of the caudal tibial surface (created by the popliteal notch) is noted on the medio-lateral radiograph as the separation of the two cortical lines extending distally from the tibial plateau. This

Figure 61-34. A template corresponding to various sizes of TPLO saw blades is superimposed on mediolateral radiograph to select proper size of saw blade and to plan its orientation centered about the most proximal point of the tibial functional axis *(white arrow)*. The intersection of the three lines *(black arrow)* indicates the proposed insertion point of the proximal jig pin (as close to the proximal point of the tibial functional axis as the anatomy will permit).

Figure 61-35. Imaging software or a transparent template corresponding to different sizes of TPLO plates (3.5 mm Slocum-style plate shown) is used to plan the position of the implants relative to the stifle joint and the planned positions for osteotomy and the proximal jig pin.

observation helps the surgeon avoid inadvertent laceration of the popliteal vessels during periosteal elevation of the tissues from the caudal surface of the tibia and know how to best position the screws through the bone plate to maximize screw purchase.

The caudocranial TPLO radiograph is used to evaluate the alignment of the tibia, the degree of attachment of the fibular head to the proximal tibia, and identify palpable landmarks that can help the surgeon avoid intra-articular placement of screws and jig pins. The stifle is locked in full extension to minimize physiologic rotation in the stifle and the contralateral hip is abducted by suspending the thigh over a rolled towel (or foam block) to position the limb for caudo-cranial radiography (Figure 61-36). When the stifle is properly positioned (patella superimposed in the center of the distal femur and the fabellae are bisected by their respective femoral cortex), the medial margin of the tuber calcis on the superimposition of the center of the distal tibia suggests the absence of internal or external tibial torsion (Figure 61-37). On a properly positioned radiograph, lateral shifting of the medial margin of the talus suggests internal tibial torsion. Conversely, external tibial torsion shifts the medial margin of the tuber calcis medially. These radiographic observations should be correlated with direct visualization of limb alignment because internal rotation of the stifle cannot be definitively distinguished from internal tibial torsion on properly positioned caudocranial radiographs of cranial cruciate ligament deficient stifles.[13] Fibular head-proximal tibial synostosis is noted, if present, as this can restrict rotation of the tibial plateau and can lead to iatrogenic fibular fracture. The radiographic position and contour of the

Figure 61-36. Dog positioned for caudocranial stifle radiograph for TPLO planning. The stifle is locked in full extension to minimize physiologic rotation in the stifle and the contralateral hip is abducted by suspending the thigh over a rolled towel to position the limb for caudocranial radiography.

Figure 61-37. Caudocranial radiograph of stifle shows corresponding position of the medial margin of the tuber calcis *(black arrowheads)* superimposed on the center of the distal tibia *(arrow)*, suggesting the absence of tibial torsion. Note also the position of the fibular head relative to the articular surface of the tibia. This is correlated with palpation of the fibular head.

fibular head with respect to the stifle articular surface is noted and correlated with palpation findings. In some patients the fibular head is very palpable and extends proximal to the stifle joint while in others it is barely palpable at a point a centimeter or more distal to the articular surface. The position of the fibular head relative to the proposed insertion point of the proximal jig pin is noted so that proper jig pin position can be confirmed at the time of placement.

Surgical Technique

Patient Preparation

The affected hindquarter is shaved from the dorsal and ventral midlines to the mid-metatarsus. The patient is positioned in dorsal recumbency and the patient's midline is shifted slightly from the middle of the surgical table toward the affected limb to minimize the need for the surgical assistant to lean across the table. The foot is wrapped routinely being sure to keep the wrap distal to the hock so that the talocrural joint can be fully flexed and extended. The surgeon should closely evaluate limb alignment and correlate palpation observations to radiographs positioned on a radiographic viewer in the operating room. A routine hanging limb preparation is then performed. Draping is performed in a routine manner being sure to leave the hip, stifle and hock freely mobile and palpable.

Surgical Approach

A craniomedial skin incision is made from the suprapatellar joint pouch proximally to a point several centimeters distal to the distal end of the tibial crest. The subcutaneous tissues are gently dissected to reveal the cranial and caudal bellies of the sartorious muscles and the patellar ligament. A fascial incision is made starting between the sartorius muscle bellies proximally and extends through the tendinous insertion of the pes anserinus muscle group (caudal belly of the sartorius, gracilis, and semitendinosus muscles) approximately 6 to 10 mm medial to the tibial crest. Distally, the fascial incision shifts to the cranial midline of the tibia to release the medial border of the cranial tibial muscle. The cranial tibial muscle is elevated from the lateral surface of the proximal tibia. Starting at the distal end of the surgical field, thumb forceps are used to lift the semitendinosus from the medial tibial surface while the back of a scalpel handle is used to bluntly elevate it to reveal the firm insertions of the gracilis and sartorius muscles on the medial aspect of the tibial crest (just cranial to the medial collateral ligament). The shiny white insertion of the medial collateral ligament is visualized. The insertions of the gracilis and sartorius muscles are sharply incised using care to protect the medial collateral ligament. The elevated pes anserinus is preserved as a distinct layer as it is separated from its firm adherence to the underlying fascia of the stifle using sharp dissection (Figure 61-38.).

Arthrotomy and Meniscal Procedures

A medial parapatellar arthrotomy is performed routinely (not necessary with diagnostic and therapeutic arthroscopy). Care is taken to avoid incising the cranial belly of the sartorius and vastus medialis as the arthrotomy is extended proximally. The cranial and caudal cruciate ligaments, medial and lateral menisci, long digital extensor tendon and joint cartilage are evaluated. TPLO should be aborted if the caudal cruciate ligament (CdCL) is ruptured because the technique is reliant upon an intact CdCL for stifle stabilization.[4,5] The cranial cruciate ligament is debrided as appropriate. Placement of a small Hohmann retractor between the caudal cruciate ligament and the tibial plateau facilitates visualization of the menisci while protecting the caudal cruciate ligament from inadvertent laceration. Frequently medial meniscal pathology is present and can vary from partial-thickness tearing to a full-thickness "bucket-handle" tear to a severe crushing injury. The pathologic segment of the medial meniscus should be excised with a #11 blade or a Beaver blade using caution to protect the caudal cruciate ligament in the process. Suction is essential and headlight illumination is helpful. Surgical "release" of the caudal body of the medial meniscus has been theorized

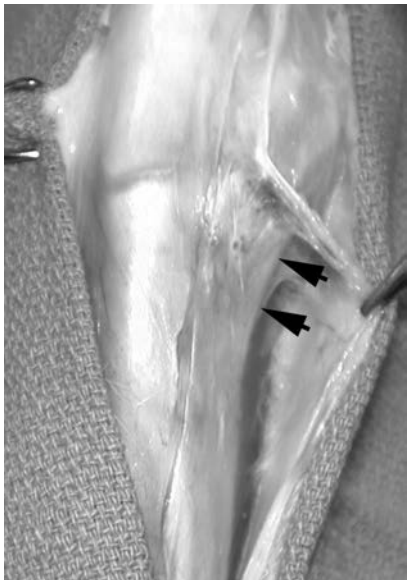

Figure 61-38. A canine pelvic (right) limb specimen. The pes anserinus muscle group is preserved as a distinct layer as it is elevated from the tibia and fascia of the stifle. The medial collateral ligament *(arrows)* is visualized deep to the pes anserinus muscle group.

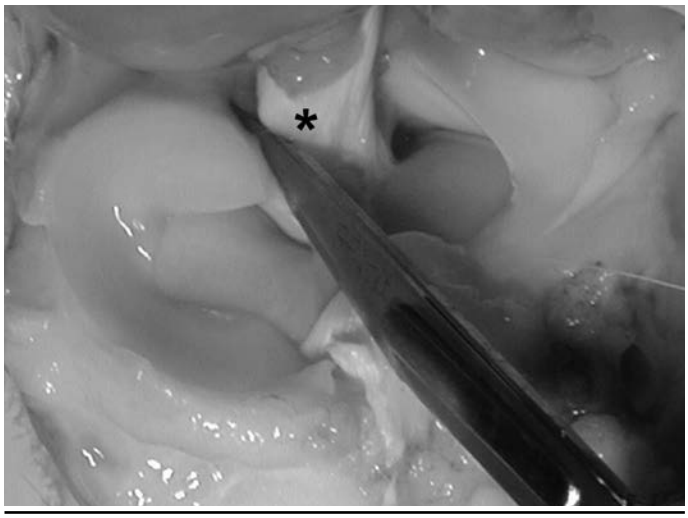

Figure 61-39. A canine (left) stifle specimen. Meniscal release being performed by transection of the caudal tibial ligament of the intact medial meniscus. Note the cutting surface of the scalpel blade is directed away from the caudal cruciate ligament *(*)*. At surgery, the caudal cruciate ligament is further protected by placing a Hohmann retractor between it and the caudal horn of the medial meniscus.

to decrease the incidence of delayed meniscal injury, but the associated risks and benefits are still debated.[14-16] Release of the medial meniscus is performed by transecting its caudal tibial insertion with a #11 blade. Caution is used to preserve the caudal cruciate ligament during medial meniscal release (Figure 61-39). Alternatively, the medial meniscus can be released via a mid-body transection as described later. The caudal body of the medial meniscus should snap caudally as the release is completed. If the caudal body folds cranially, it should be removed.

TPLO Preparation

In preparation for the TPLO, a deep incision is made along the caudal edge of the tibial insertion of the medial collateral ligament effectively separating it from the popliteus and semimembranosus muscles. Next, the muscles are elevated from the caudal surface of the tibia using great care. First, the index finger of one hand is placed between the cranial tibial muscles and the lateral margin of the tibia to identify the caudolateral edge of the tibia. Next, an AO elevator in the opposite hand is used to slowly and deliberately elevate the muscles from the caudal surface of the tibia using care to keep the elevator blade in firm contact with the "coved" caudal surface of the tibia until it reaches the surgeon's opposite index finger at the tibia's caudo-lateral edge (Figure 61-40). Laceration of the popliteal vessels may occur if the elevator is not kept in contact with the tibia. Soft tissue elevation adequate to safely perform the osteotomy is confirmed by correlating surgical landmarks with the preoperative planning radiographs. If indicated, release of the medial meniscus can be performed at mid-body at this time by directing a #11 scalpel blade from the caudal margin of the medial collateral ligament toward the tubercle of Gerdy along the craniolateral margin of the tibial plateau. Opening the tips of a small hemostat within the medial meniscal incision confirms that the release incision is complete. Next, radio-opaque marked gauze sponges are packed around the tibia to retract the surrounding soft tissues from the tibia.

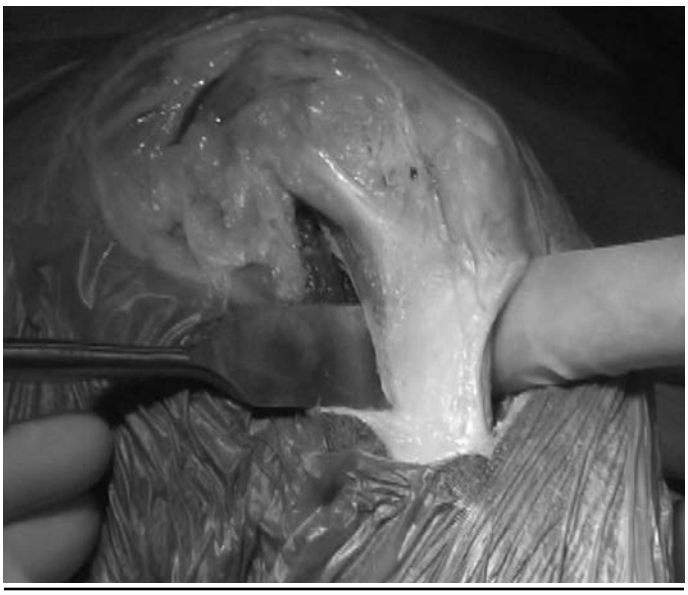

Figure 61-40. Muscles are elevated from the caudal surface of the (left) tibia using great care to prevent laceration of the popliteal vessels. First, the index finger of one hand is placed between the cranial tibial muscles and the lateral margin of the tibia to identify the caudo-lateral edge of the tibia. Next, a broad elevator in the opposite hand is used to slowly and deliberately elevate muscles from the caudal surface of the tibia using care to keep the elevator blade in firm contact with its "coved" contour until the elevator reaches the surgeon's opposite index finger at the tibia's caudolateral edge.

Jig Placement

Proper insertion point and orientation of the most proximal jig pin are essential because it functions as the axis around which the tibial plateau will rotate and as a visual guide for orientation of the osteotomy. Regional landmarks should be correlated to the radiographs to determine the desired insertion point for the pin. Often, the properly positioned pin must penetrate the fibers of the medial collateral ligament just distal to the articular surface of the tibial plateau. The exact location of the proximal tibial articular surface can be identified by sliding a freer periosteal elevator under the tibial surface of the caudal body of the medial meniscus starting immediately caudal to the medial collateral ligament (Figure 61-41). An assistant holds the limb with stifle and tarsus flexed to approximately 90 degrees and the hip in a neutral position such that the stifle is pointed directly upward. The jig is assembled and a slow-speed, high-torque, power drill is used to insert the proximal jig pin from medial to lateral into the tibia. The jig pin should be perpendicular to the sagittal plane of the stifle in both the craniocaudal direction and proximodistal direction (Figure 61-42). When the jig pin is properly oriented, the proximal joint of the jig will be in the same sagittal (flexion/extension) plane as the stifle joint. The distal joint of the jig will be 'out of plane' with the talocrural joint if there is notable tibial varus/valgus or torsional malalignment. After seating the pin into or through the lateral tibial cortex, it must be cut flush with the surface of the jig to allow for proper passage of the saw blade in later stages of the procedure. Next, a small soft tissue corridor is established for the distal jig pin being sure to avoid the medial saphenous vessels. The distal jig pin is inserted in a similar manner using care to keep it parallel to the proximal pin

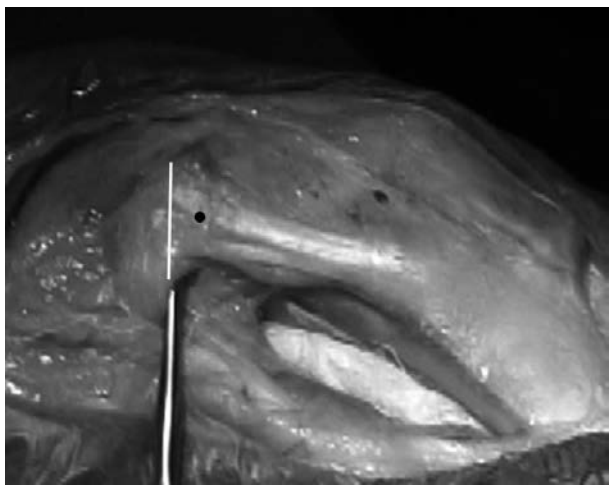

Figure 61-41. Intraoperative photo of (left) stifle. Note placement of gauze sponges to isolate the tibia from all caudal and lateral soft tissues. The exact location of the proximal tibial articular surface can be identified *(white line)* by sliding a freer periosteal elevator under the tibial surface of the caudal body of the medial meniscus starting immediately caudal to the medial collateral ligament. This maneuver helps define the desired point for insertion of the proximal jig pin *(black dot)*.

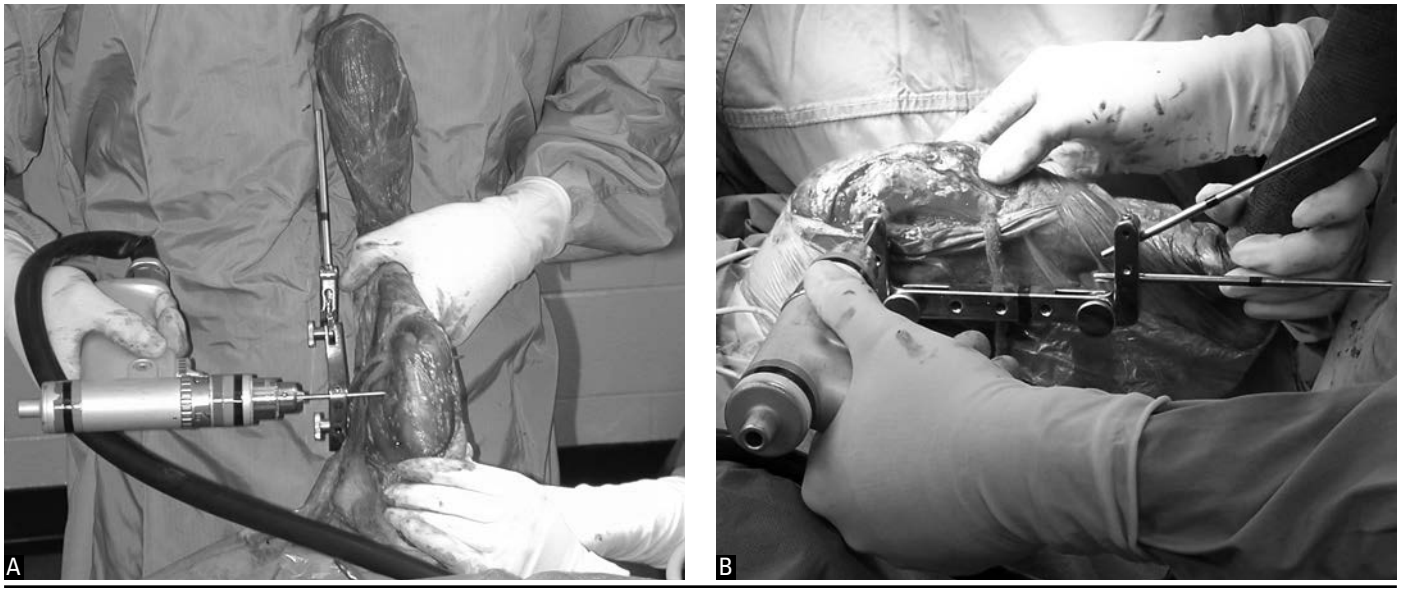

Figure 61-42. A. and **B.** The TPLO jig is assembled and slow-speed, high-torque, power drilling is used to insert the proximal jig pin from medial to lateral into the tibia. The jig pin should be perpendicular to the sagittal plane of the stifle in both the cranio-caudal direction and proximo-distal direction. Note that an assistant holds the limb with stifle and tarsus flexed to approximately 90 degrees and the hip in a neutral position such that the stifle is pointed directly upward.

in all planes. The jig is secured firmly to each of the jig pins by tightening appropriate set screws. The desired position for the osteotomy is determined by comparison of the regional anatomy to the marked radiograph. A small zone of periosteal elevation is used to mark this location and to prepare the tibia for osteotomy. The surgeon temporarily places the bone plate upon the medial tibial cortex to confirm that the plate will fit appropriately with the position of the planned osteotomy.

Osteotomy

The limb can either be positioned with the hip in the neutral position and the stifle pointed upward (as for jig placement) or the hip can be abducted to place the limb as flat as possible on the surgical table. The assistant places a small Hohmann retractor under the patellar ligament to retract it away from the saw blade. An appropriately sized TPLO saw blade is positioned in the desired location upon the medial tibial cortex. The surgeon uses one hand to stabilize the saw blade until the kerf of the osteotomy begins to stabilize the blade. At this point, the axis of the saw blade (like the most-proximal jig pin) should be perpendicular to the sagittal plane of the stifle in both the craniocaudal direction and proximodistal directions. Surgical assistant(s) help the surgeon to keep the saw blade properly aligned while cooling it with an irrigation solution. Before completing the osteotomy, the saw blade is temporarily removed and a small, sharp osteotome is used to create reference marks indicating the displacement needed along the osteotomy to accomplish satisfactory tibial plateau leveling (Figure 61-43). This chord length is geometrically derived and has been recorded in chart form for simplicity. Leveling the tibial plateau to an angle of approximately 6.5° eliminates cranial tibial subluxation by converting cranial tibial thrust into caudal tibial thrust that must be constrained by the intact caudal cruciate ligament.[5] Progressive leveling from 6.5° toward 0° further increases caudal cruciate ligament strain. The currently recommended postoperative TPA is 5°.[17] The preoperative TPA and the radius of the saw blade influence the amount of tibial plateau rotation required to achieve a TPA of 5°. The osteotomy is completed and the gauze sponges are removed. An appropriately sized Steinmann pin is temporarily inserted into the plateau segment from cranio-medial toward the popliteal notch of the tibia with a slight proximal to distal orientation being sure to engage but not penetrate the caudal tibial cortex to minimize risk of popliteal hemorrhage. A Jacob's chuck is applied to the temporary pin such that the pin can be used as a "handle" and the tibial plateau is slowly rotated about the proximal jig pin until the reference marks are aligned. The surgeon verifies that

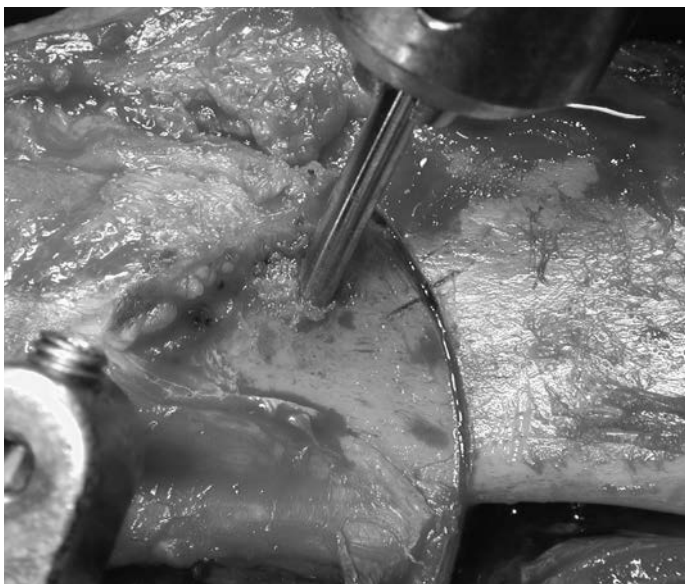

Figure 61-43. Before completing the osteotomy, the saw blade is temporarily removed and a small, sharp osteotome is used to create reference marks indicating the displacement needed along the osteotomy to accomplish satisfactory tibial plateau leveling. This chord length is geometrically derived and has been recorded in chart form for simplicity. After the osteotomy is complete, the tibial plateau segment is rotated about the proximal jig pin until the reference marks are aligned.

cranial tibial thrust instability is satisfactorily controlled. No effort is made to keep the medial surface of the tibial segments flush as this will typically create tibial malalignment.[9] Instead, as the tibial plateau is rotated about the proximal jig pin, the surgeon may slightly translate the distal segment medially or laterally to ensure a normal proximal-to-distal course of the patellar tendon. An appropriately sized Kirschner wire is passed across the osteotomy from the proximal-most end of the tibial tubercle into the tibial plateau to provide temporary stabilization during subsequent bone plate application. It is very important that this K-wire penetrate the tibial tubercle proximal to the insertion of the patellar ligament in order to minimize the risk of tibial tubercle fracture (Figure 61-44). The K-wire must also penetrate the medial tibial cortex to effectively maintain the rotation during plate application. The surgeon should verify proper plateau rotation and secure fixation before removing the temporary Steinmann pin ("rotation handle"). Next, the surgeon should extend and flex the stifle while evaluating the tibia for torsional or varus/valgus mal-alignment. Varus/valgus mal-alignment is corrected by sliding the jig out or in on the distal jig pin. Torsional mal-alignment can be corrected by bending the distal jig pin either cranially or caudally (Figure 61-45). Large tibial alignment adjustments create large osteotomy gaps and/or medial cortical surface "stair-steps". Large gaps may require autogenous cancellous bone grafting. The edge of the saw blade can be used to level out any "stair-steps" at the osteotomy site in the region of the proposed plate placement.

Figure 61-44. An appropriately sized Kirschner wire is passed across the osteotomy from the proximal-most end of the tibial tubercle into the tibial plateau to provide temporary stabilization during subsequent bone plate application. It is very important that this K-wire penetrate the tibial tubercle proximal to the insertion of the patellar ligament in order to minimize the risk of tibial tubercle fracture. The K-wire must also penetrate the medial tibial cortex to effectively maintain the rotation during plate application. Note the alignment of the reference marks indicating that the calculated TPA correction has been achieved.

Bone Plate Application

A variety of TPLO-specific plate designs are commercially available. The following discussion pertains to the original Slocum-style TPLO plate design. The bone plate is contoured for a precise fit against the medial tibial cortex to avoid inducing tibial malalignment. Typically this requires two bends and a twist within the plate. The first bend is placed between the third and fourth screw holes in the plate. A second, more-subtle, bend is often needed through the second hole in the plate. Next, an internal twist of the proximal section of the plate is made between the third and fourth holes. Occasionally, a slight bend and/or twist are needed through the fifth hole to keep the distal end of the plate in contact with the bone. The plate is held in the desired location and a cortical screw is placed in the fourth hole using standard screw insertion techniques. Next, cortical screws are placed in the fifth and sixth holes. Next, cortical or cancellous screws (as appropriate) are placed in the second, third and first holes respectively. The screws in the proximal section of the plate are inserted in compression mode provided no tibial alignment adjustments were made. If, however, tibial alignment corrections were made, the screws in the proximal segment are inserted in neutralization mode to avoid shifting the osteotomy. Occasionally, it is necessary to remove the jig, jig pins, and/or Kirschner wire before inserting a screw into the most proximal hole of the plate. Care must be used to avoid placement of these proximal screws into the stifle joint. An aiming guide can be used if needed, but judicious correlation of palpable landmarks (such as the fibular head) to the preoperative radiographs is usually efffective. Cancellous bone grafting is not necessary for most congruent osteotomies, but may be indicated for incongruent osteotomies. The jig is removed. Stifle stability, limb alignment,

Figure 61-45. Varus/valgus mal-alignment is corrected by sliding the jig in or out on the distal jig pin. Torsional mal-alignment can be corrected by bending the distal jig pin either cranially or caudally. Example: Sliding the jig out on the distal pin (white arrow) will correct tibial varus. Bending the distal jig pin cranially (black arrow) will correct internal tibial torsion.

and implant placement are assessed (Figure 61-46). The surgical field is lavaged thoroughly with a physiologic irrigation solution. The joint capsule is apposed routinely with a continuous suture pattern. The popliteus muscle is apposed to the medial collateral ligament. The pes anserinus muscle group is apposed to the insertion remnant left on the tibial crest using stifle flexion to ease tension during closure. Subcutaneous tissues may be closed in one or two layers. Skin is apposed routinely.

Postoperative mediolateral and caudocranial radiographs are made using the same patient positioning described previously and the TPA is measured. The radiographs are evaluated for proper jig pin, osteotomy, and implant placement. Some surgeons prefer to apply a soft padded bandage to minimize patient self-mutilation and to reduce swelling and bruising in the region of the surgical site.

Figure 61-46. Illustration of completed TPLO using an anatomically pre-contoured, locking TPLO plate. (Images courtesy of Synthes Inc, West Chester, PA. © 2010 Synthes, Inc. or its affiliates.)

Postoperative Care

Recovery from TPLO consists of three stages: 1) incisional healing, 2) bone healing, and 3) physical rehabilitation/reconditioning. During the two week incisional healing, self-mutilation must be prevented through the use of a protective bandage and/or a restraint collar. The duration for bone healing is variable, but typically lasts 8 to 12 weeks. During this time, running, jumping, free access to furniture, stairs, slippery surfaces, other pets, and the yard must be avoided. Confinement to a large crate in a quiet room works nicely when the patient is unsupervised. Short walks at a slow pace on a short leash are encouraged several times per day. Sling support of the hindquarters may be indicated for patients with multi-limb disability, poor strength or balance, and for patients who are required to traverse slippery surfaces or steps. Bone healing is monitored radiographically in 4 to 8 week intervals until healing is documented. As bone healing is progressing, slow and methodical increases in patient activity are encouraged as part of their physical rehabilitation. This begins with increasing lengths of leash walks each week progressing to slow and methodical increases in supervised time off of the leash.

Complications

A wide variety of complications have been reported for the TPLO.[12,18,19] Intra-operative complications including extreme hemorrhage, intra-articular placement of screws and jig pins, and iatrogenic fracture of the tibial crest can be avoided with attentive preoperative planning and surgical technique. Postoperative soft tissue complications include seroma/hematoma, dehiscence, infection, and bandage irritation and can usually be treated routinely.

More severe postoperative complications including tibial crest fracture, fixation failure, and patellar desmitis typically cause a sudden and sustained increase in patient discomfort and lameness. Tibial crest fracture is predisposed by the tension of the patellar ligament on the tibial tubercle. Improper placement of the temporary K-wire distal to the insertion of the patellar ligament on the tibial tubercle creates a stress-riser that increases the risk of tibial crest fracture. Likewise, a shift of the osteotomy too far cranially (not centered appropriately or too large a saw blade) creates a thin tibial crest segment that is at risk of fracture. Placement of a tension band may prevent this complication in "at risk" patients. It has been suggested that tibial plateau rotation should not be performed to such an extent as to leave the tibial tubercle unsupported and that a cranial closing wedge ostectomy should supplement TPLO when patients with excessive tibial plateau angles are encountered.[11] This surgical treatment is quite complex and is beyond the scope of this chapter.

TPLO fixation failure may result from catastrophic loading of the limb in excess of fixation strength or from repetitive low-energy loading leading to fatigue failure. Improper orientation of the osteotomy may increase the relative loading on the implants (less load borne by the bone segments). Likewise, iatrogenic fibular fracture during TPLO likely increases mechanical demand on the implants due to loss of the caudolateral buttressing effect of the fibula. Osteomyelitis often causes increased lameness, patient discomfort and draining tracts or incisional drainage. Bacterial culture and antimicrobial sensitivity testing of fluids obtained by deep surgical site aspirate are used to select appropriate antimicrobial therapy. Implant removal may be indicated upon completion of osteotomy healing.

Neoplasia has been reported at the site of previously performed

TPLO procedures.[20-22] It is unclear, currently, if this is related to the procedure, the implants, or is an incidental location of the disease. The benefit of elective plate removal following bone healing has not been established.

Technique Variations

Many variations of the surgical technique have been described including minimal dissection around the tibia, no application of surgical sponges, jig-less application, and the use of pre-contoured and locking plate systems.

"Over-the-Top" Patellar Tendon Graft for Cranial Cruciate Ligament Repair

Guy B. Tarvin and Steven P. Arnoczky

Introduction

The cranial cruciate ligament constrains joint motion. It prevents cranial subluxation of the tibia on the femur (cranial drawer sign), hyperextension of the stifle joint, and, along with the caudal cruciate ligament, excessive internal rotation of the tibia on the femur.[1] Excessive forces during extremes of any of these movements may damage this ligament.[2] Although excessive trauma causes acute rupture of the cranial cruciate ligament, most cruciate ligament lesions are thought to result from chronic degenerative changes within the ligaments themselves.[2,3] Variations in conformation, valgus (knock-knee) and varus (bowleg) deformities of the stifle, and repeated minor stresses can result in progressive degenerative joint disease. As these joint changes develop, the cruciate ligaments undergo alterations in their microstructure and may be more susceptible to damage from minor trauma.[4]

Because rupture of the cranial cruciate ligament results in progressive degenerative joint changes within the joint,[3,5,6] most such injuries should be repaired. In the authors' experience, many large breed dogs present with partial cranial cruciate ligament tears. The authors currently recommend repair in these cases even though they may not be grossly unstable (see diagnostics below). The cranial cruciate ligament has poor healing capabilities and eventually will completely tear. During that process, degenerative joint disease will progress leading to a poorer prognosis. We must stress; however, that each patient needs to be assessed individually as other factors may make surgical repair either unnecessary or not in the best interests of the patient. For example in some chronic cases of cranial cruciate ligament rupture, severe degenerative joint changes are present and these patients have an unfavorable prognosis after

surgical repair. In these patients, conservative management with anti-inflammatory drugs and somatic pain relievers may provide adequate palliative care and an equal, if not superior, result than surgical intervention. Moreover, concurrent joint diseases such as rheumatoid arthritis and systematic lupus erythematosus, may obviate the repair of the ligament insufficiently. A final exception would be the smaller patients, such as cats and small dogs (less than 15 kg.), with isolated cranial cruciate ligament injuries. One study demonstrated that conservative therapy(nonsurgical) had a high degree of clinical success.[7]

Diagnosis of cranial cruciate ligament insufficiency is based on historical and clinical evidence of rear limb lameness. Palpation of the stifle is the most useful tool to make a diagnosis of cranial cruciate ligament insufficiency. In acute complete ruptures, instability of the stifle is present when applying the cranial drawer test or tibial compression test.[7] In incomplete tears or chronic complete tears with secondary periarticular fibrosis, these tests will not be as dramatic and may not be conclusive. In many chronic cases, medial collateral ligament hypertrophy secondary to the injury may be palpated. This finding can support the diagnosis of cranial cruciate ligament disease. Radiographs are usually not necessary to establish a diagnosis but can be useful in assessing secondary degenerative joint disease and stifle effusion.[7] In early partial tears joint effusion is a helpful finding to establish a diagnosis. In the rare case in which all these diagnostic tests fail to establish a diagnosis, nuclear scintigraphy can be used to pinpoint the cause of lameness. The clinician should always evaluate the entire limb for other abnormalities. The contralateral limb should also be evaluated because bilateral cranial cruciate ligament disease is not uncommon.[7]

Many methods of repair have been devised to treat cranial cruciate ligament insufficiency. These can be categorized as either extra-articular or intra-articular repairs. Whereas extra-articular repairs stabilize the joint by tightening or altering the position of extra-articular structures, intra-articular repairs anatomically replace the cranial cruciate ligament with some type of graft. The over-the-top procedure[8] is an intra-articular repair that uses a patellar tendon graft to replace the cranial cruciate ligament. This procedure was designed for use in dogs weighing more than 15 kg. In our experience, the over-the-top patellar tendon graft provides a functional replacement for the cranial cruciate ligament and thereby limits any abnormal joint motions.

Surgical Technique

The animal is placed in lateral recumbency, and the affected limb is prepared for an aseptic surgical procedure. A lateral parapatellar skin incision is made extending from the midshaft of the femur to the proximal tibia. The subcutaneous and fascial tissues are dissected free, and the patellar ligament is clearly defined. The patellar ligament is incised longitudinally between the junction of the middle and medial thirds of its width. The incision is extended over the patella and into the patellar tendon, where it is directed in a proximo-lateral direction to incorporate the fascia lata (Figure 61-47A). The incision proximal to the patella should be made 1 to 1.5 times the distance from the patella to the tibial tuberosity; this incision ensures an adequate length of graft in dogs of all sizes. The incision into the fascia is also made 1 to 2 centimeters lateral to the medial boundary of the fascia lata with the vastus medialis.

An osteotome is placed in the groove of the patella created by the scalpel blade. A handsaw can also be used to deepen this groove to allow better purchase with the osteotome. A craniomedial wedge of bone is removed with the medial third of the patellar tendon with the ligament attatched (Figure 61-47B). If power equipment is available, use of an oscillating saw can also be employed to make the patellar wedge. Extreme care should be taken during the osteotomy to preserve the entire articular surface of the patella. To complete the harvest of the graft, the surgeon begins at the proximal extent of the incision in the fascia lata. A scissors is used to cut the fascia lata transversely in a medial direction to where it blends into the vastus medialis. The distal portion of the fascia lata is then elevated from the underlying muscle and grasped with a thumb forceps. The scissors is used to cut the medial border of the fascia strip distally in a direction parallel to the first fascial incision. As the incision approaches the suprapatellar joint pouch, the scissors can be directed medially if necessary to incorporate more joint capsule and parapatellar fibrocartilage. This can be employed if the surgeon feels that the graft needs reinforcing in this area. The medial third of the patellar ligament is then dissected free to the level of the tibial tuberosity. In doing so a medial arthrotomy is created. An incision through the infrapatellar fat pad is necessary to mobilize the graft, but the fat pad should not be stripped from its ligamentous attachments because it provides much of the blood supply to the patellar ligament graft. An autogenous graft consisting of fascia, patellar tendon, a patellar bone wedge, and patellar ligament with a distal attachment to the tibial tuberosity is thus created (Figure 61-47C).

The remnants of the ruptured cranial cruciate ligament are then removed through the medial arthrotomy, and the joint is inspected for further pathologic features. The authors find it useful to use a curette to debride the intercondylar notch of osteophytes and cranial cruciate ligament remnants. This aids in graft passage. The patella, joint capsule, and soft tissues are retracted laterally to expose the lateral femoral condyle and fabella (Figure 61-47D). The lateral fabella is located by palpation, and a small vertical incision is made in the femorofabellar ligament. With the joint in extreme flexion, curved hemostatic forceps are inserted into the incision and passed over the top of the lateral femoral condyle and into the intercondylar notch; one must take care to preserve the causal joint structures by staying close to the bone. The tips of the hemostatic forceps are gently manipulated until they can be seen within the joint (Figure 61-47D and E). The surgeon then grasps the free end of the graft directly or grasps a suture that has been placed in the free end of the graft with the hemostat. The graft is pulled through the joint and over the top of the lateral condyle by gentle traction on the hemostat. Flexing and extending the joint during this maneuver facilitates passage of the graft.

After the graft has been pulled though the joint, it is held under gentle traction, and the joint is tested for craniocaudal stability. Once cranial drawer motion has been eliminated, the graft is attached to the lateral femoral condyle. The authors feel that the graft should be tightened and attached to the lateral femoral

condyle with the stifle in full extension. Functional studies of the canine cranial cruciate ligament indicate that its maximum length and therefore its most taut state occur at full extension.[1] Since the graft's attachment sites closely mimic those of the normal cranial cruciate ligament, it is logical to assume that the graft should also be most taut in extension. If the graft would be tightened with the stifle in some degree of flexion, the graft would become more taut as its attachment sites become farther apart in extension. In this scenario, extension would be constrained by the graft or the graft would be stretched and be more prone to fail. Therefore, the authors secure the graft with traction maintained and the stifle in full extension. The graft is sutured to the tissues of the lateral femoral condyle with simple interrupted sutures of nonabsorbable suture material (Figure 61-47F). The authors also find that a small titanium bone staple and belt loop also offers secure and quick fixation of the graft (Figure 61-48). In our experience using bone staples, implant complications (i.e. reaction, irritation, or loosening) are extremely rare.

The arthrotomy is closed in a routine manner. During closure of

The proximal portion of the incision is directed laterally to incorporate the fascia lata. **B.** Placement of osteotome to remove craniomedial wedge of patella with accompanying soft tissue. The inset shows cranial view of the patella indicating the extent of the osteotomy, which does not extend to the caudal articular surface of the patella. **C.** The graft is completed by incising the joint capsule, patellar tendon, and fascia lata parallel to the initial incision and by freeing the graft at its proximal end. **D.** Lateral view of the stifle showing retraction of the patella and soft tissues of the joint laterally to expose the lateral femoral condyle and fabella. Arrows indicate the path of the hemostatic forceps over the top of the lateral femoral condyle and into the joint. **E.** Cranial view of flexed stifle showing tips of the hemostatic forceps emerging lateral to the caudal cruciate ligament and grasping the sutures in the free end of the graft. Also note that a notchplasty has previously performed. **F.** Lateral view of the stifle showing the graft passing through the joint and over the top of the lateral femoral condyle. The graft is then sutured to the soft tissues of the lateral femoral condyle. (From Arnoczky SP, Tarvin GB, Marshall JL, et al. The over-the-top procedure: a technique for anterior cruciate ligament substitution in the dog. J Am Anim Hosp Assoc 1979;15:283.)

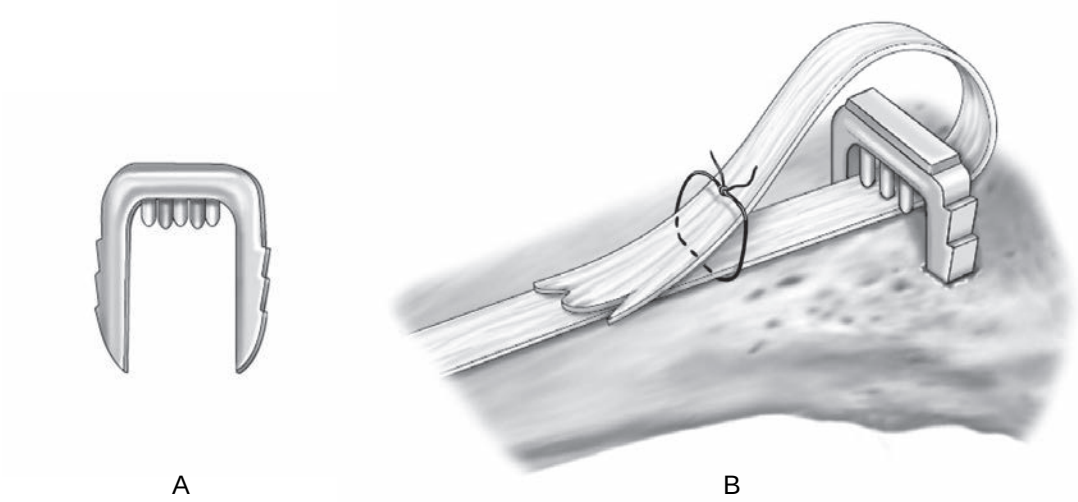

Figure 61-48. A. Another method of attaching the proximal portion of the graft utilizes a 6mm wide by 15 mm long ACL staple(VeterinaryInstrumen tation, 62 Cemetery Road, Sheffield, U.K.). **B.** The staple is placed over the graft and driven into the bone of the lateral femoral condyle. The distal end of the graft is folded back on itself in a manner similar to a belt loop and suture on itself with 2-0 nonabsorbable suture material.

the medial arthrotomy, care should be taken to avoid excessive tension on the patella and patellar ligament, which may predispose the joint to a medial luxation of the patella. If tension is a problem, loose approximation sutures should be placed in the joint capsule, and the subcutaneous soft tissues should be used to cover the arthrotomy defect.

Postoperatively, the limb is placed in a modified Robert Jones dressing for 2 weeks, and the animal's activity is restricted for a total of 8 to 12 weeks. In larger dogs (over 30 kg) a lateral splint may be added for the first 2 to 4 postoperative weeks.

The biologic fate of the patellar tendon graft within the joint was investigated in an experimental study.[9] The results of this study demonstrate that the blood supply of the graft is disrupted at the time of surgery, and approximately 20 weeks are needed for the graft to become completely revascularized. During this period, the graft undergoes ischemic necrosis, and its strength may be at risk. In an effort to minimize this revascularization process, one of the authors (SPA.) and his colleagues proposed a modification of the over-the-top technique in which the medial vascular supply of the patellar tendon graft was carefully preserved and maintained.[10] They suggested that if a "vascularized" patellar tendon graft were used to reconstruct the cranial cruciate ligament, the revascularization and remodeling process would be eliminated, or at least minimized. Furthermore, the use of vascularized patellar tendon graft would prevent, or at least minimize, any changes in the material strength of the graft secondary to the ischemic changes or revascularized process. However, a subsequent study evaluating the strength of vascularized and non-vascularized patellar tendon grafts failed to demonstrate any significant differences in any of their biomechanical parameters with time.[11] It thus appears that there is no inherent advantage of preserving the blood supply to the graft at the time of surgery.

Several other modifications of the over-the-top graft technique have been proposed and have produced good results[8,10,12] Although these techniques use other tissues for the graft (fascia lata, lateral aspect of the patellar tendon) and may include the addition of other ancillary stabilization procedures (lateral imbrication suture), they all incorporate the over-the-top femoral positioning of the intra-articular graft. The over-the-top positioning allows the most consistent placement of the graft in the most biomechanically and anatomically correct position (Figure 61-49). In our opinion, this positioning may be the most important consideration in intra-articular reconstructions of the cranial cruciate ligament. Indeed, an evaluation of two over-the-top techniques by Denny and Barr suggests that this biomechanically correct placement

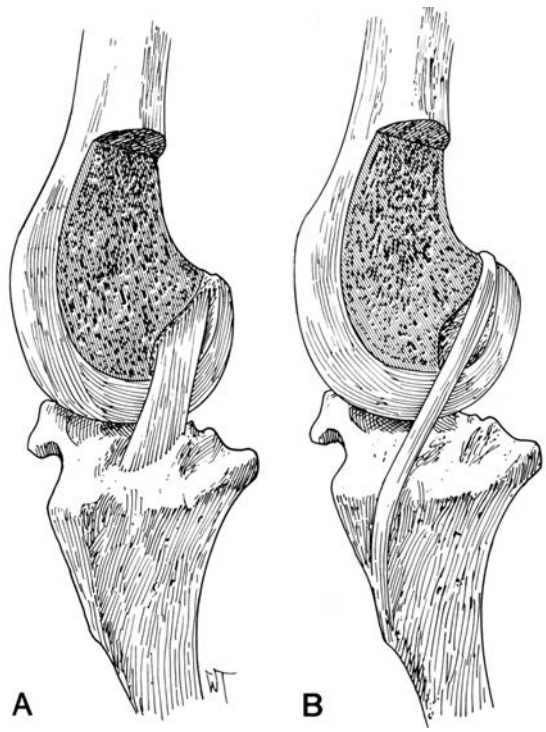

Figure 61-49. Schematic illustration of the normal anatomy and spatial orientation of the cranial cruciate ligament **A.** and the orientation of the patellar tendon graft within the joint that is achieved with the over-the-top technique **B.** (From Arnoczky SP, Tarvin GB, Marshall JL, et al. The over-the-top procedure: a technique for anterior cruciate ligament substitution in the dog. J Am Anim Hosp Assoc 1979;15:283.)

of the graft, and not the type of graft used, is responsible for the success of this repair technique.[13]

In summary, successful repair of insufficiency of the cranial cruciate ligament depends on the reestablishment of joint stability. Although this end can be accomplished by the aforementioned techniques, other components of the stifle (patella, menisci, collateral ligaments) must not be overlooked when evaluating the joint. These structures work in concert to allow normal joint motion, and failure to recognize concurrent patellar malalignment or meniscal injury in cranial cruciate ligament insufficiency may result in less than optimal postoperative function.

Treatment of Caudal Cruciate Ligament Rupture by Lateral and Medial Imbrication

Joseph Harari

Surgical Technique

The primary purpose of these extracapsular procedures is to reduce caudal displacement of the tibial plateau relative to the femoral condyles, and the secondary purpose is to reduce excessive internal tibial rotation.

The animal is placed in dorsal recumbency, and a lateral parapatellar approach is used for a stifle joint arthrotomy. The joint is examined for concurrent ligamentous or meniscal injuries, which are treated accordingly. The remnants of the caudal cruciate ligament (CaCL) are resected, and the joint is lavaged with sterile saline or lactated Ringer's solution. Joint capsule closure is performed using 2-0 or 3-0 monofilament nylon, polypropylene, or polydioxanone suture material placed in a continuous pattern while a cranially directed force on the tibia is used to reduce caudal drawer motion.

Extracapsular imbrication is performed by placing a single mattress suture of size 1 or 2 nonabsorbable suture (polypropylene or nylon) on the lateral and medial aspects of the joint between the head of the fibula (laterally) or proximal tibial (medially) and just proximal or distal to the patellar (Figure 61-50). The direction of these sutures mimics the orientation of the CaCL to reduce abnormal caudal displacement and internal rotation of

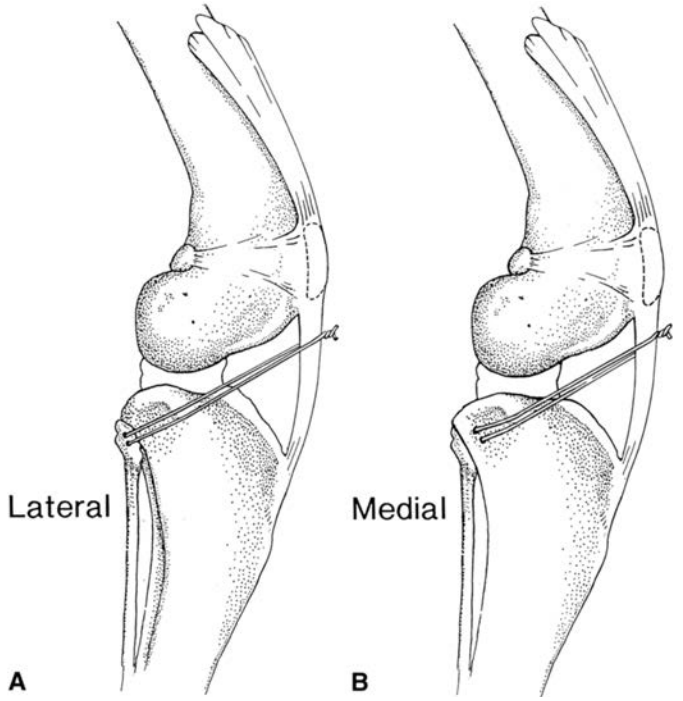

Figure 61-50. Extracapsular imbrication of a caudal cruciate ligament-deficient stifle joint using nonabsorbable mattress sutures. **A.** Lateral view. **B.** Medial view. (From Harari J. Caudal cruciate ligament injury. Vet Clin North Am Small Anim Pract I993;23:826.)

the proximal aspect of the tibia. To perform lateral imbrication, the suture is passed into the quadriceps tendon above or below the patella, is directed caudodistally under or through the head of the fibula, and then is directed cranioproximally to be tied along the lateral aspect of the stifle joint while caudal drawer motion and internal tibial rotation are reduced and the normal standing angle of the joint is maintained. To place the medial imbrication suture, the skin incision is displaced medially, and subcutaneous tissues are dissected to reveal the medial retinaculum of the stifle joint. The mattress suture is placed in the quadriceps tendon above or below the patella and is oriented caudodistally through the caudal aspect of the proximal tibia. The suture is then directed cranioproximally and is tied along the medial aspect of the stifle joint. Placement of medial and lateral sutures in the quadriceps tendon prevents unilateral displacement of the patella or tendon.

The lateral retinaculum opened during the arthrotomy can be closed with 0 or 2-0 nonabsorbable sutures placed in a mattress pattern resembling the direction of the lateral imbrication suture. The subcutaneous tissues and skin are closed in a routine manner. Postoperatively, a soft, padded limb bandage is used for 2 weeks, and exercise is restricted for 1 month to protect soft tissue healing.

Lateral and medial imbrications are recommended for midsubstance ligamentous tears. Bone avulsion injuries involving the origin or insertion of the CaCL can be repaired by stabilization of bone fragments with a small bone screw or with Kirschner or orthopedic wires (Figure 61-51).[1] Small unattachable fragments can be removed (along with the CaCl), and extracapsular imbrication can be performed. Alternatively, medial collateral ligament and popliteal tendon entrapment with bone screws have been described for midsubstance Ca CL tears.[2]

Surgical stabilization of a CaCL-deficient stifle joint is variable for human and veterinary patients. In human patients, unidirectional (anteroposterior) instability due to in-continuity tears is treated with physical therapy designed to strengthen the quadriceps muscles while surgical stabilization of avulsion injuries is recommended.[3] In animals, persistent caudal drawer motion in experimental and clinical patients after resection with or without surgical stabilization has not been consistently associated with lameness or lack of limb function.[4-6] This finding has been attributed to the lack of importance in stabilization of the canine stifle joint by the CaCL at normal angles of the limb. At our clinic, therefore, surgical stabilization of tears of this ligament is not routinely performed. An arthrotomy or arthroscopy is performed to remove proliferative ends of the damaged ligament and to inspect the joint for concurrent meniscal or cranial cruciate ligament lesion.[6] Bone avulsions are reattached if technically feasible. A caudomedial stifle joint arthrotomy is necessary to attach or resect avulsion of the CaCL tibial insertion.[1] Long-term, objective clinical evaluations of affected stifle joints, therefore, are warranted to delineate the natural progression of CaCL-deficient canine stifle joints. Recently, a high incidence (88%) of dogs with CrCL injury Synovitis, and concomitant CACL lesions has been described.[7]

Treatment of Collateral Ligament Injuries

Erick L. Egger

The collateral ligaments are important stabilizing elements in the stifle joint. Injury to the collateral ligaments usually is caused by trauma and often is associated with disruption of either the cranial or caudal cruciate ligament.

Anatomic Features

The medial collateral ligament originates on the medial epicondyle of the femur and passes distally in the joint capsule. It passes over the medial lip of the tibial plateau, where an underlying bursa allows the ligament to slip back and forth as the joint moves. The ligament attaches to the medial shaft of the tibia with a long, narrow insertion.[1] The medial collateral ligament is positioned over the central axis of the stifle to remain tight throughout flexion and extension of the joint.[2] The lateral collateral ligament originates on the lateral epicondyle of the femur and passes distally in the joint capsule to insert on the fibular head.[1] The lateral collateral ligament is caudal to the central axis of the joint.[2] This results in a tight ligament in extension, which limits internal rotation and contributes to craniocaudal stability. The ligament loosens as the joint flexes, allowing the tibia to rotate internally.

Diagnosis and Treatment Options

The clinical diagnosis of isolated collateral injuries can be difficult. With the joint held in full extension, varus and valgus forces occasionally result in angulation away from the side with ruptured ligament. However, if both cruciate ligaments are intact, they will greatly reduce or prevent this instability. Some increase in rotational movement may occur. Evidence of a widened joint space on one side on radiographs taken while the joint is stressed may aid in the diagnosis. Collateral rupture in the presence of a cruciate disruption is readily revealed by the presence of varus or valgus angulation of the joint when stress is applied and a dramatic increase in rotational instability with the stifle extended.

Management of collateral ligament injuries varies with the severity of injury and resultant instability. A stretched or isolated torn collateral ligament without gross instability can often be managed with external coaptation. A contoured lateral splint fashioned of plaster or Hexcelite (Hexcel Medical Products, Dublin, CA) in a padded bandage is used to stress the joint toward the injured collateral ligament. This coaptation must be maintained for at least 3 to 4 weeks. Collateral ligament injuries resulting in gross instability are repaired by suturing or other internal fixation procedures.

Surgical Technique

Because the collateral ligaments are extrasynovial, blood supply is adequate to allow simple ruptures to heal if the ends are adequately apposed. A three-loop pulley pattern of monofilament nonabsorbable material such as nylon or polypropylene can be used to suture collateral ligaments[3] (Figure 61-52). Each pass of the suture is a different distance from the torn ends and axially at a 120° rotation from the previous passage. In one study,

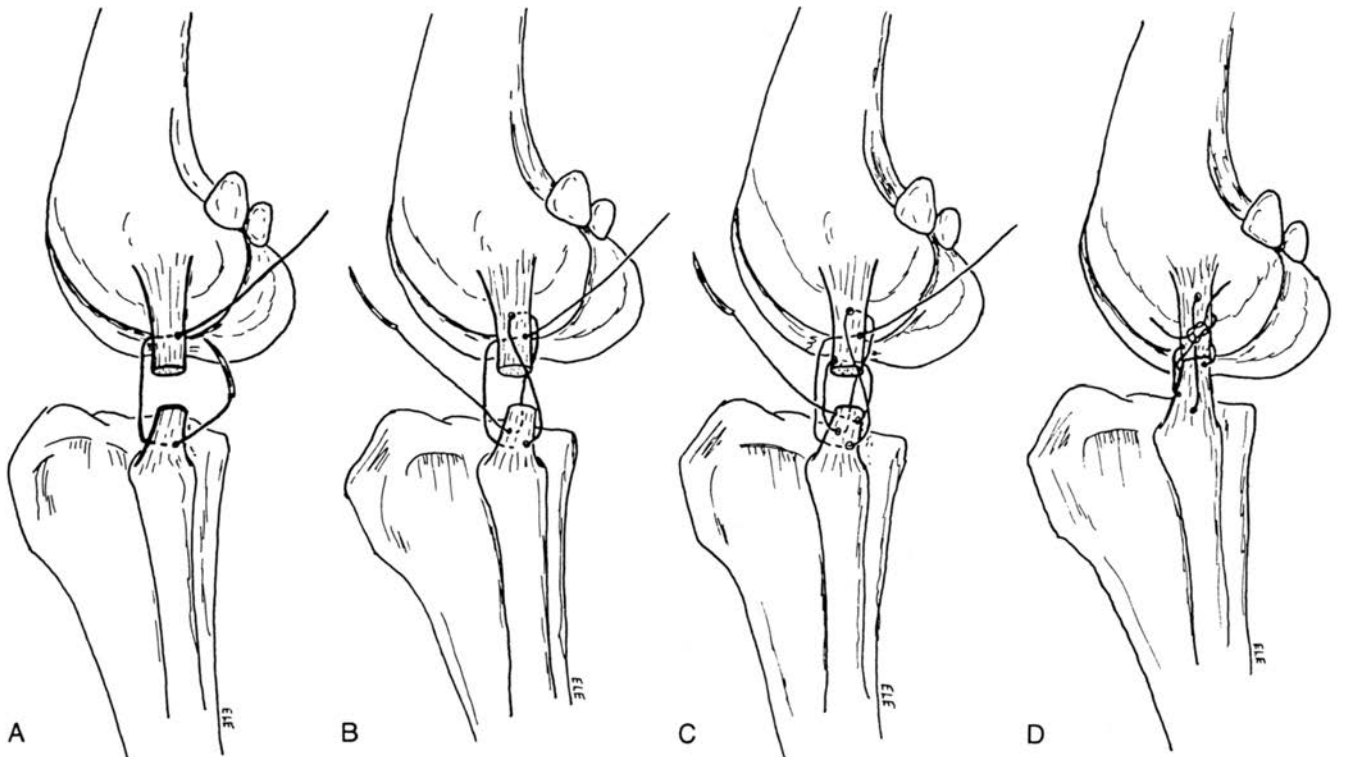

Figure 61-52. Primary suturing of a collateral ligament rupture. **A.** First loop of suture pattern. **B.** Second loop of suture placed at 120° rotation to the first. **C.** Third loop of suture again rotated. **D.** Suture pulled tight and tied.

this three-loop pulley pattern tolerated approximately 25% more tensile load and allowed only 34% as much distraction before failure under tension as the locking-loop pattern in canine collateral ligaments.[4]

Suturing of severely traumatized ligaments may not provide adequate support. For these cases, a large figure-of-eight suture of nylon or polypropylene can be placed between bone screws seated at the collateral ligament's attachments to provide additional support while the tissues heal (Figure 61-53).

Care must be taken to tighten a lateral collateral ligament repair only in moderate extension because overtightening of this area prevents normal range of motion. Cases in which the ligament has been torn away from the bone are best managed by fixation with bone screws. A spiked washer (Synthes, Paoli, PA) can be used to trap the ligament without compromising its vascularity (Figure 61-54). Any concurrent injury (e.g., a torn meniscus or cruciate ligament rupture) should be dealt with, and then the joint should be externally supported with a lateral splint for 3 to 4 weeks while the collateral ligament heals.

Avulsion fractures of the ligament's bony attachments are best handled by surgical reduction and fixation (Figure 61-55). One or two Kirschner wires are driven through the fragment to hold reduction. A figure-of-eight tension band wire is then passed behind the Kirschner wires and through a transverse hole in the bone. This wire is tightened to counteract the pull of the ligament. The Kirschner wires should be cut off and bent back to reduce soft tissue irritation. Alternatively, a bone screw can be

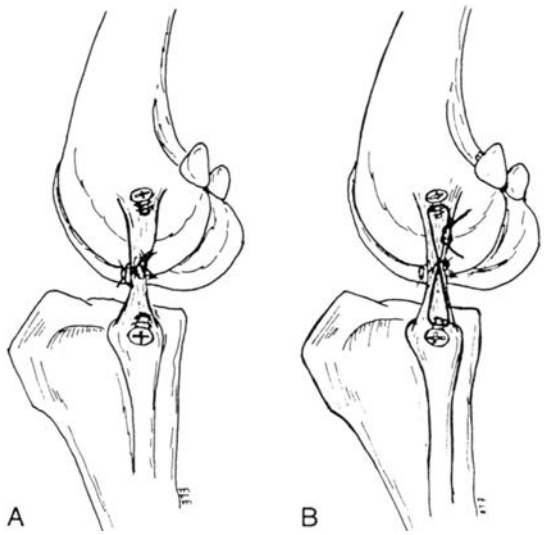

Figure 61-53. Figure-of-eight support of weak collateral ligament repair. **A.** Collateral ligament repaired as well as possible and bone screws placed at both attachments of the ligament. **B.** Figure-of-eight suture placed around the screw head.

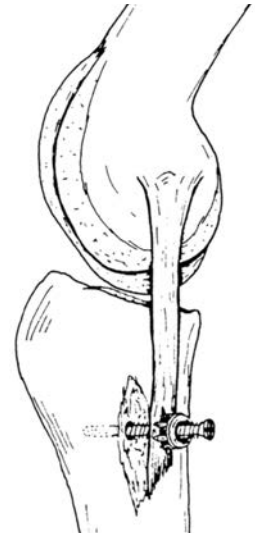

Figure 61-54. Reattachment of an avulsed ligament with a spiked washer and a bone screw.

Fixation of an avulsion fracture of the attachment of a collateral ligament. **A.** Avulsion of the proximal attachment of the medial collateral ligament. **B.** Fixation of the fragment with two Kirschner wires. **C.** Placement of a figure-of-eight wire to counteract the ligament pull.

used if the avulsion fragment is large enough. Because internal fixation of a fracture should result in a stable repair, extended external coaptation is usually not indicated. However, a soft, padded bandage may be used for several days postoperatively to control soft tissue swelling.

Osteochondritis Dissecans of the Canine Stifle

Ron Montgomery

Overview of OCD of the Stifle

Osteochondritis dissecans (OCD) in dogs occurs most often at the humeral head (~ 75% of OCD cases). OCD of the stifle has been reported to be the second most common location in European dogs, but in the U.S.A. the stifle is a less common site than the elbow or hock. Either frequency of OCD in the stifle differs due to unknown factors at different geographic locations, or OCD of the stifle is underdiagnosed in the U.S.A.

OCD can only occur in dogs with a systemic defect in endochondral osteogenesis called osteochondrosis. Since only juvenile bones grow, OCD necessarily develops in juveniles, although diagnosis may be after osseous maturity. Rapid growth is part of the pathogenesis of OCD. Consequently, OCD almost exclusively affects large breed dogs, and about 75% of the cases are in males. In addition, OCD affects the same joint bilaterally in at least half of the cases, even if the lameness is unilateral. OCD in two different joints of a single patient (stifle and shoulder), however, is uncommon.

Diagnosis

The presenting complaint for dogs with OCD of the stifle is unilateral or bilateral rear leg lameness, usually with an insidious onset. The signalment is almost exclusively a young, large dog (generally one less that 12 months old and greater than 30 pounds). The differential list includes trauma (Salter-Harris fractures, avulsions, luxations, fractures, etc.), and the juvenile bone and joint diseases of the rear limbs of large breed dogs (hip dysplasia, panosteitis, patella luxation, OCD of the stifle or hock, HOD, and Osgood-Schlatter's disease). Under diagnosis of stifle OCD may occur due to its insidious onset, often mild clinical signs, and/or inappropriately stopping examination once another diagnosis has been made. A complete orthopaedic examination is indicated because multiple orthopaedic problems can, and often do, occur concurrently.

Examination of a canine stifle with OCD may yield pain at full extension or full flexion, have an audible click while going through a range of motion, and have joint effusion palpable on either side of the patellar tendon. Arthrocentesis is a simple procedure that can confirm that the stifle does have pathology based only on the gross characteristics of the synovial fluid (volume > 0.5 ml, yellow color, decreased viscosity). Stifle pathologies such as patella luxation, collateral ligament rupture, avulsion of a cruciate ligament or fracture are readily diagnosed or ruled out. The remaining stifle diagnoses that could present like stifle OCD are rare (e.g. avulsion of long digital extensor origin or popliteus insertion, isolated meniscal tears, etc.).

Confirmation of stifle OCD can usually be accomplished by radiographs (Figure 61-56). However, not visualizing an OCD lesion on radiographs does not rule out the diagnosis, especially if the lesion is small and/or not depicted in skyline view. The lateral view should be oblique to avoid superimposition of the femoral condyles, with the lateral femoral condyle more caudal. OCD lesions have been reported most often on the lateral femoral condyle (94%), but have also been reported on the medial femoral condyle, the patella, and the trochlear ridge. CT is highly reliable in diagnosing or ruling out OCD. Other imaging modalities reported as useful for diagnosis of OCD of the stifle include MRI and ultrasonography. Exploratory arthrotomy, either via arthroscope or open procedure, is also reasonable if some type of pathology of the stifle is indicated by orthopaedic examination and synovial fluid analysis.

Surgical Technique

Arthroscopy involves the lowest morbidity for exploring the stifle and treatment of an OCD lesion. A limited arthrotomy (Figure 61-57) provides much less morbidity than a full arthrotomy of the stifle, if the parapatellar fibrocartilage is not transected and the patella is not dislocated. The parapatellar skin incision extends from the mid-patella level to just distal to the tibial plateau. Incisions through the retinaculum and then the joint capsule are successively slightly shorter to facilitate complete closure. A self retaining retractor (e.g. Gelpi, Wallace) is placed and firmly distracted to provide visibility of the femoral condyle and intercondylar notch area. Flexion and extension will facilitate visualization of the weight bearing surface of the condyle. Preoperative identification of the OCD location (i.e. medial or lateral condyle) is beneficial when using a limited arthrotomy. If necessary for exploration, the incision can be extended to a standard parapatellar approach to the stifle. OCD flaps are removed in most cases. However, some OCD lesions of the stifle can be quite large, and reports of fixing them in situ with bone pegs, pins, etc. has been reported. Once the OCD flap has been removed, the defect ("bed") from which it originated should be evaluated. The defect will likely fill with fibrocartilage, if a blood supply is present. If the OCD bed is red, then granulation tissue is present and it should not be significantly disturbed. If the bed is white (e.g. eburnated bone), then forage into the medullary cavity with a 0.062" K-wire (or smaller) at multiple locations will supply blood to the site with considerably less morbidity than curettage.

Figure 61-56. Radiographs of stifles with OCD lesions. The lesion may appear flat (craniocaudal image) or concave (mediolateral image). Oblique mediolateral projection with the lateral femoral condyle more caudal helps visualizing an OCD lesion. Not visualizing an OCD lesion on radiographs does not rule out the diagnosis.

Figure 61-57. Limited arthrotomy to the lateral femoral condyle. The same approach can be performed medially, or on either side of the patellar tendon.

Prognosis

Long term prognosis depends primarily on the amount of preexisting degenerative joint disease, plus the size and location (weight bearing vs. non-weight bearing areas) of the OCD lesion. Short term morbidity is most affected by the surgical technique. Morbidity from arthroscopy is typically only a few days at most. Limited arthrotomy morbidity is only slightly longer than for arthroscopy, if the patella is not destabilized. Deeply curetting the OCD bed rather than forage can extend the postoperative morbidity for weeks.

Chapter 62

Tibia and Tarsus

Repair of Tibial Fractures

Ann L. Johnson

Introduction

Tibial fractures commonly occur in dogs and cats. Specifically, tibial fractures range from 9 to 18% of fractures occurring in dogs.[1] Proximal and distal fractures in immature animals are generally physeal fractures, most often Salter-Harris Type I or II. In mature dogs, proximal metaphyseal fractures may be single or comminuted and may cause loss of integrity of the tibial plateau. Distal tibial fractures in mature dogs often involve malleolar fractures, and are generally associated with road trauma. (See next section on malleolar fractures). Tibial diaphyseal fractures encompass the following: greenstick or incomplete fractures in immature animals; transverse, short oblique, long oblique and spiral reducible fractures; and comminuted fractures which may be reducible (one butterfly fragment) or nonreducible (multiple fragments). The tibia may be treated with cast, intramedullary pins and orthopedic wire, interlocking nail, external fixator, or bone plate and screw fixation. The surgeon should consider the mechanical, biological and clinical environment of the fracture and the patient before choosing the appropriate implant system for treating diaphyseal fractures.[2]

Preoperative Assessment and Management of Animals with Tibial Fractures

Animals that have received an external blow severe enough to cause a tibial fracture often have concurrent external or internal organ system injury. Cardiovascular, pulmonary, urinary, and neurologic systems should be examined thoroughly to detect any abnormalities prior to anesthesia and surgical repair of the fracture. A minimum database should include a complete blood count, chemistry profile, urinalysis and radiographs of the affected tibia. It is often useful to take radiographs of the contalateral tibia for comparison and to serve as a template for plate contouring. Because 33 to 42% of fracture patients have some degree of pulmonary injury, preoperative evaluation should include thoracic radiographs.[3] Fractures of the tibia are best managed preoperatively with a modified Robert Jones bandage to reduce or prevent soft tissue swelling which interferes with landmark identification. Prophylactic antibiotics should be administered in contaminated cases (open injuries), cases with severe trauma (significant soft tissue bruising and swelling or multiple bone fractures), and cases requiring lengthy operative times (2 hours or longer). Prophylactic antibiotics are also effective in closed tibial fractures and should be administered intravenously at the time of anesthetic induction, repeated every 2 to 4 hours, and discontinued at completion of surgery.[3]

General Issues with Tibial Fracture Management

Issues unique to the tibia include the presence of minimal soft tissue coverage on the medial surface of the bone. The paucity of soft tissues increases the possibility of open fractures and potentially decreases the extra-osseous blood supply, both of which can delay bone healing. Minimal soft tissue coverage of bone plates results in tissue irritation and cold hypersensitivity which may require plate removal to resolve. However, the minimal muscle coverage on the medial side is an advantage for placing an external fixator while minimizing muscle trauma.

The tibia is an ideal bone for external fixator application because it is straight from the lateral perspective and allows the potential for all frame constructions including use of the circular and hybrid fixators. Conversely, the tibia can be a difficult bone for placing an intramedullary pin or nail because of the S shaped curve apparent from the cranial perspective and the presence of the joints directly above and below the bone. In order to prevent untoward stifle joint penetration with intramedullary implants, only antegrade implant pin placement is recommended. The S shape of the tibia also contributes to the requirement for accurate plate contouring to avoid angular deformity.

Clinically Relevant Anatomy of the Tibia

The tibia articulates with the femur proximally, the tarsus distally and the fibula both proximally and distally on the lateral side. The lateral collateral ligament of the stifle inserts on the fibular head. The medial collateral ligament of the stifle inserts on the caudal proximal portion of the medial surface of the tibia. The proximal epiphysis of the tibia is triangular in shape with the articular surface on the caudal half. The tibial tuberosity where the patella ligament inserts encompasses the cranial half of the proximal epiphysis. The tibial tuberosity continues distally forming the tibial crest on the cranial surface of the tibia. The proximal tibial metaphysis is flat medially with minimal soft tissue coverage and concave laterally where the extensor muscles are located. The tibial diaphysis is round in cross section and describes an S shaped curve when viewed from the cranial aspect. The tendons of the cranial tibial and long digital extensor muscles cross the cranial surface and the medial saphenous vein crosses the medial surface of the distal tibia. The medial malleolus of the distal tibia and lateral malleolus of the fibula extend distal to the articulating surfaces of the distal tibia and talus. The long and short parts of the medial and lateral collateral ligaments arise from the medial malleolus of the tibia and the lateral malleolus of the fibula respectively and are essential for hock stability.

Proximal Tibial Fractures

Physeal Fractures

Salter I and Salter II fractures of the proximal tibial physis occur in immature dogs and cats. Animals usually present with a nonweight bearing lameness of the affected limb subsequent to a traumatic episode. Palpation of the proximal tibia reveals soft tissue swelling, instability and crepitus. Radiographs are used to confirm the diagnosis of proximal physeal fracture. The epiphysis is generally displaced caudally to the metaphysis.

Physeal fractures which are minimally displaced may be stabilized with a cast applied to the leg with the stifle in extension. However, in many cases adequate fracture reduction cannot be obtained without surgical manipulation. Surgical treatment consists of open reduction and stabilization with two or three Kirschner wires. A medial approach through skin, subcutaneous tissue and crural fascia over the proximal diaphysis of the tibia may be used to expose the fracture.[4] The fracture is reduced by extending the stifle and gently levering the epiphysis into position. Reduction is maintained with pointed reduction forceps while the fracture is stabilized with two or three Kirschner wires or small intramedullary pins (Figure 62-1). The implants may be bent to prevent migration and aid removal.[5]

Postoperatively, the patient should be confined to a small area with activity limited to leash walking. Follow up radiographs may be made at 3 and 6 weeks after treatment. Physeal fractures generally heal within three to four weeks. If a cast is used, it should be removed as early as possible. Physical therapy may be necessary to restore range of motion to the stifle. Premature closure of the physis usually occurs because of the trauma inflicted on the growing cells during the initial injury. Owners of very immature animals should be warned of the potential for growth deformities.

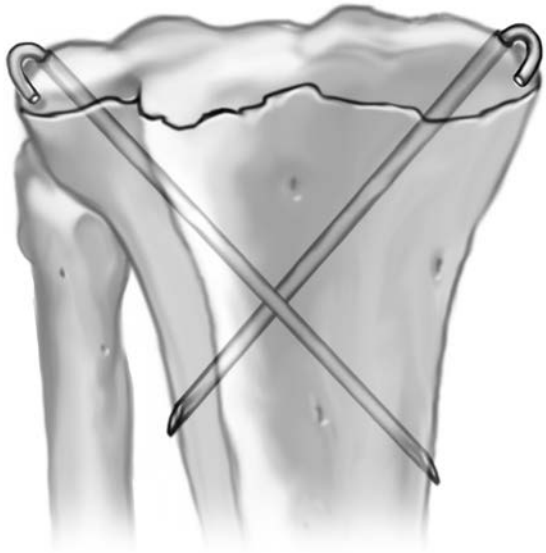

Figure 62-1. Fractures of the proximal tibial physis may be stabilized with two Kirschner wires or small intramedullary pins.

Avulsion of the Tibial Tuberosity

Avulsion of the tibial tuberosity also occurs in immature dogs and cats. The tibial tuberosity is the insertion point for the patella ligament and is subjected to avulsion forces when the quadriceps muscle is contracted. Animals usually present with considerable joint effusion, soft tissue swelling and lameness. Radiographs are made to confirm the diagnosis. In some cases, confusion may exist over the appearance of the physis. Radiographs should be made of the opposite limb to verify the presence of an avulsion versus irregular ossification of the tuberosity. Obtaining flexed and extended stifle views may be useful to confirm the mobility of the avulsed fragment.

Avulsions of the tibial tuberosity which are minimally displaced may be stabilized with a cast applied to the leg while the stifle is extended. Surgical treatment consists of open reduction and stabilization with two Kirschner wires and figure of eight orthopedic wire functioning as a tension band. A medial approach is used to expose the fracture.[4] The avulsed tibial tuberosity is reduced by extending the stifle and securing the tuberosity to the tibia with a pointed reduction forceps. The tuberosity is secured with a tension band wire (Figure 62-2).[5] Postoperative radiographs should be evaluated for fracture reduction and implant placement.

Postoperatively, the patient should be confined to a small area with activity limited to leash walking. Follow up radiographs may be made at 3 and 6 weeks after treatment. If a cast is used, it should be removed in 3 to 4 weeks. Physical therapy may be necessary to restore range of motion to the stifle. In very immature animals, the tension band wire should also be removed at 3 weeks to allow physeal growth. Premature closure of the tibial tuberosity physis in a very young animal may adversely affect stifle conformation. Additional implant removal may be required if soft tissue irritation occurs.

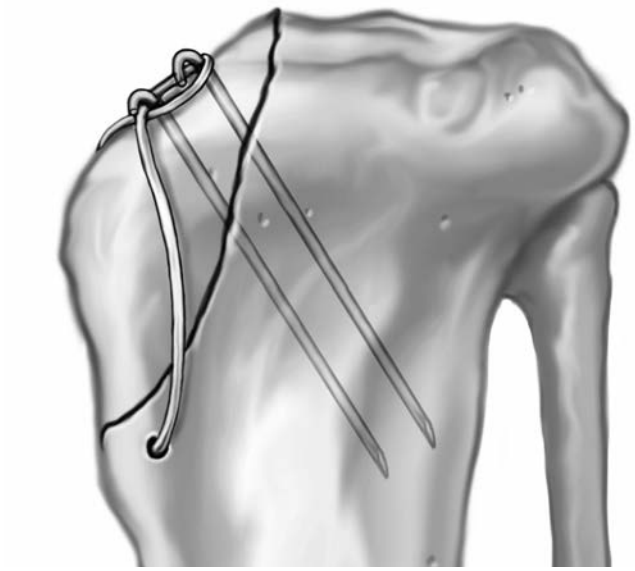

Figure 62-2. An avulsion fracture of the tibial tuberosity may be stabilized with two Kirschner wires and figure of eight orthopedic wire functioning as a tension band.

Proximal Metaphyseal Fractures

Proximal metaphyseal fractures in mature dogs are uncommon. These fractures may involve the articular surface, and may be either single or comminuted fractures. They are generally managed with a buttress plate application to shore up the tibial plateau.(Figure 62-3) The addition of a cancellous bone autograft may be necessary if there is bone loss.

Tibial Diaphyseal Fractures

Tibial diaphyseal fracture stabilization has been described using casts, intramedullary pins and orthopedic wire, interlocking nails, bone plates and screws, and linear and circular fixators. The keys to optimal fracture fixation include accurate decision

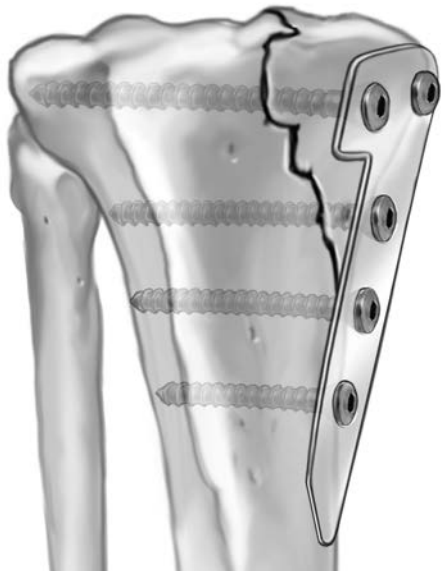

Figure 62-3. Tibial plateau fractures are usually managed with buttress plate application to shore up the tibial plateau.

making to guide reduction technique and implant choice, and preoperative fracture planning for the procedure.

Implant systems are chosen after an assessment has been made of the mechanical, biological and clinical environments of the fracture and the patient. The mechanical environment is influenced by the size and activity of the patient, the type and reducibility of the fracture, and the presence or absence of multiple limb injury or pre-existing disease. The mechanical environment dictates how much load the implant must support. The biological environment is influenced by the age and health of the animal, the location of the fracture, the energy involved in creating the fracture, and the presence and condition of the surrounding soft tissues. The biologic environment can also be disturbed with open anatomic reduction techniques. The biologic environment dictates the length of time the implant must function. The clinical environment includes the intended function of the animal, the attitude of the animal and the client's ability to care for the animal. If the mechanical environment is poor, the implant system must be relatively strong. If the biological environment is poor, the implants must be able to function for a prolonged time period and should purchase the bone with an interlocking hold (bone screws and positive profile threaded pins). Some fixation systems, especially external fixation systems are inappropriate for certain animals and clients.[2]

After the appropriate implant system has been selected, preoperative fracture planning includes selecting a reduction technique and predetermining where implants will be placed. Epidural anaesthesia with a local anaesthetic agent and a narcotic, combined with general anaesthesia, provides analgesia and profound relaxation of the muscles of the rear limb and is a useful aid to tibial fracture reduction. Reducible fractures, single fractures and fractures with one or two large fragments are treated with open reduction, anatomical reconstruction and rigid stabilization to restore the bone column and promote load sharing between the bone and the implant, and enhance the mechanical environment. Transverse and short oblique fractures may be reduced by exposing the fracture and tenting the bone ends out of the incision then pressing the reduced fracture back into position. Alternatively, a limited approach may be made and a lever used to manipulate the bone back into position. Long oblique or spiral fractures may be reduced by exposing the fracture and distracting the bone segments to approximate the fracture surfaces while using pointed reduction forceps to manipulate the bone segments into reduction.[6]

Non-reducible fractures, or comminuted fractures with multiple small or large fragments where fragment reconstruction would not restore the bone column should be treated with closed indirect reduction or "open but do not disturb the fragments" indirect reduction techniques to preserve the biological environment.[7] The tibia is particularly suitable for the indirect reduction techniques essential to the success of "biologic" treatment of non-reducible fractures. Distraction of the major bone segments may be achieved with the hanging limb technique or by using an intramedullary pin to push the distal segment away from the proximal segment. As the bone ends are distracted the tension on the surrounding soft tissues guides the fragments into alignment.[6]

In addition to choosing the reduction technique, it is helpful for preoperative planning for the surgeon to draw the fracture lines on an outline of the intact tibia. The implants should then be drawn onto the tibia in the order and location in which the surgeon intends to place them. The fracture plan may be taken into the operating room to serve as a guide.[8,9]

Diaphyseal tibial fractures which are treated with open reduction will often benefit from the addition of a cancellous bone autograft, or cancellous bone allograft with demineralized bone matrix. Cancellous bone autograft may be harvested from the ipsilateral proximal humerus which is accessible when the animal is positioned for surgery. The donor site must be prepared for aseptic surgery prior to moving the animal into the operating room. The graft is usually harvested after the fracture has been stabilized. Alternatively, cancellous bone allograft with demineralized bone matrix is available commercially and eliminates the the need for preparing a donor site.

Treatment of Tibial Diaphyseal Fractures with a Cast

Full cylinder casts which incorporate the hock and the stifle are a very effective fixation for stable fractures in young dogs or cats when the fracture shares the load of weight bearing with the cast and will heal quickly. Greenstick or incomplete fractures of the tibia fit these criteria. The cast should be applied with the limb positioned slightly in extension and with varus angulation to overcome the contraction of the extensor muscles lying on the lateral side of the tibia.[10] Postoperatively the animal must be confined to a small area with very limited activity allowed. The client must be willing to protect the cast from adverse environments. Weekly rechecks will minimize cast related complications.

Operative Treatment of Tibial Diaphyseal Fractures

Treatment of Tibial Diaphyseal Fractures with Intramedullary Pins and Orthopedic Wire

An intramedullary (IM) pin may be combined with multiple cerclage wires to stabilize long oblique or spiral tibial fractures in immature animals (Figure 62-4). A medial approach is made to the fracture area. The IM pin is placed in an antegrade manner starting at a point on the edge of the tibial plateau midway between the tibial tuberosity and the medial tibial condyle. The pin is driven into the medullary canal to exit at the fracture. The fracture is reduced and secured with pointed reduction forceps. The cerclage wire is applied. The IM pin is then driven distally to insert in the distal metaphysis. Care must be taken to avoid penetrating the articular cartilage. Using a similar length pin as a guide pin can help the surgeon determine the location of the inserted pin. The exposed end of the pin is cut below the level of the skin.[11]

Figure 62-4. An intramedullary pin may be combined with cerclage wires to stabilize long oblique fractures in immature dogs and cats.

Treatment of Tibial Diaphyseal Fractures with an Interlocking Nail

Interlocking nails can be used effectively to treat a wide variety of mid diaphyseal tibial fractures. Because the screws or bolts securely lock the nail to the respective bone segment, the interlocking nail not only provides resistance to bending, but also resists rotational and axial loading forces and can effectively bridge a nonreducible fracture. An open approach is used to reconstruct reducible fractures. An open but don't touch approach is used when major segment alignment is the goal. The nail selected should correspond to the width of the medullary canal at the isthmus of the bone. The interlocking nail is inserted in a normograde manner starting at the cranio-medial aspect of the tibial plateau. A medial parapatellar approach is used to expose the point of insertion. Flexing the stifle 90 degrees facilitates nail insertion. The medullary canal is prepared for nail placement by inserting a series of progressively larger Steinmann pins or by using a hand reamer. The nail is inserted using the extension and the insertion tool. The insertion tool is removed and the drill-guide jig attached to the extension. Using the drill guide jig, the interlocking nail is secured in place with two screws each placed through the proximal and distal fracture segments and the nail[12] (Figure 62-5).

Figure 62-5. An interlocking nail can be used to treat comminuted nonreducible fractures of the tibial diaphysis.

Treatment of Tibial Diaphyseal Fracture with External Fixators

External fixators may be applied to stabilize most tibial diaphyseal fractures. The stiffness of the fixator may be manipulated by adding fixation pins and using biplaner or bilateral frames to manage a wide variety of fractures in most dogs and cats. The hanging limb technique may be used for positioning the limb and to aid reduction of the fracture.[6] The patient is placed in dorsal recumbency and the affected limb is suspended from the ceiling and draped out in the hanging position. The table can be lowered to allow the animal's weight to fatigue the muscles and help align the joints. For single fracture lines the fragments may be levered into position through a limited surgical approach to the fracture. For closed reduction of comminuted fractures, proximal and distal fixation pins may be placed initially and then manipulated to align the joint surfaces. The reduction is maintained by securing the connecting bars.

A type Ia external fixator is applied to the cranial medial surface of the tibia. Positive profile or Duraface end threaded fixation pins are placed in the metaphysis of each segment and about 1 centimeter on either side of the fracture line. At least two and preferably three fixation pins are placed in each bone segment. The pins are secured to a connecting rod creating a unilateral, uniplanar frame (Figure 62-6). To apply a type Ib frame, an additional unilateral frame is placed on the cranial lateral surface of the tibia to create a unilateral, biplanar frame (Figure 62-7). Type Ib frames may be connected with articulating rods. A type II frame is applied to the tibia by inserting transfixation pins through the metaphyses and securing them to the connecting rods. Fixation pins are then placed about a centimeter on either side of the fracture. These pins can be unilateral, secured only to the medial connecting bar, or transfixation pins which are secured to both connecting bars. Additional pins are placed when there is adequate bone[13] (Figure 62-8). This frame is a bilateral, uniplanar construct. Rarely, a type III frame is applied by adding a unilateral frame to the cranial surface of the tibia forming a bilateral, biplanar frame.

Treatment of Tibial Diaphyseal Fractures with Bone Plates and Screws

Bone plates and screws may be used to stabilize both single and comminuted tibial diaphyseal fractures. Single transverse or short oblique fractures should be anatomically reduced and stabilized using the bone plate as a compression plate (Figure 62-9). Long oblique fractures should be anatomically reduced and compressed with lag screws. The reconstructed bone is then protected with a bone plate used as a neutralization plate (Figure 62-10). A comminuted nonreducible fracture should be realigned and bridged with a bone plate functioning as a bridging plate (Figure 62-11A). The plate may be combined with an IM pin when stabilizing comminuted nonreducible fractures to reduce strain on the plate and extend fatigue life of the fixation (Figure 62-11B).[14,15]

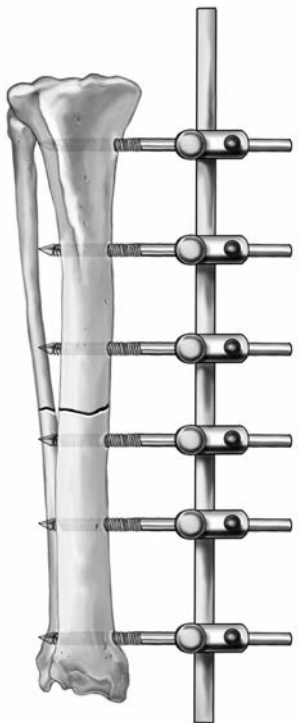

Figure 62-6. A type Ia external fixator is applied to the cranial medial surface of the tibia. Optimally, three pins are positioned above the fracture and three fixation pins positioned below the fracture.

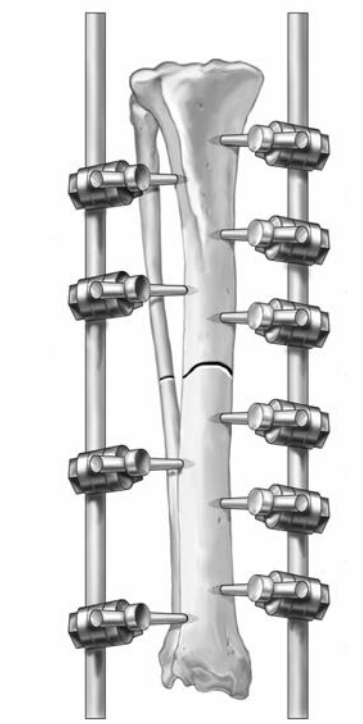

Figure 62-7. A type Ib external fixator is constructed by combining two type Ia frames. The first frame is applied to the cranial medial surface of the tibia and the second frame applied to the cranial lateral surface of the tibia.

A cranial medial approach to the shaft of the tibia is used to expose the fracture site and the medial surface of the bone for plating.[16] When treating comminuted nonreducible fractures, an open but don't disturb the fragments technique should be used to expose the proximal and distal bone segments with minimal disturbance of the fracture hematoma and bone fragments.[7] Cranial caudal radiographs of the contralateral intact tibia are useful to serve as a template for plate contouring. The tibia has an S shaped curve which must be reproduced when contouring the plate to avoid a valgus deformity of the limb postoperatively.

General Postoperative Treatment of Tibial Diaphyseal Fractures

Postoperative treatment starts with radiographs made of the tibia to document fracture reduction or appropriate limb alignment, and implant placement. Radiographs of comminuted fractures treated by realigning the limb should be evaluated closely to determine that the proximal and distal joint surfaces are parallel to each other and the joints are not rotated in relationship to each other. Mal-aligned limbs with varus or valgus deformity which are treated with external fixators may be corrected postoperatively by loosening the distal fixation clamps and realigning the limb. Mal-aligned limbs treated with plates cannot be corrected without a second surgical procedure. The surgeon must make the decision about severity of the mal-alignment and act appropriately.

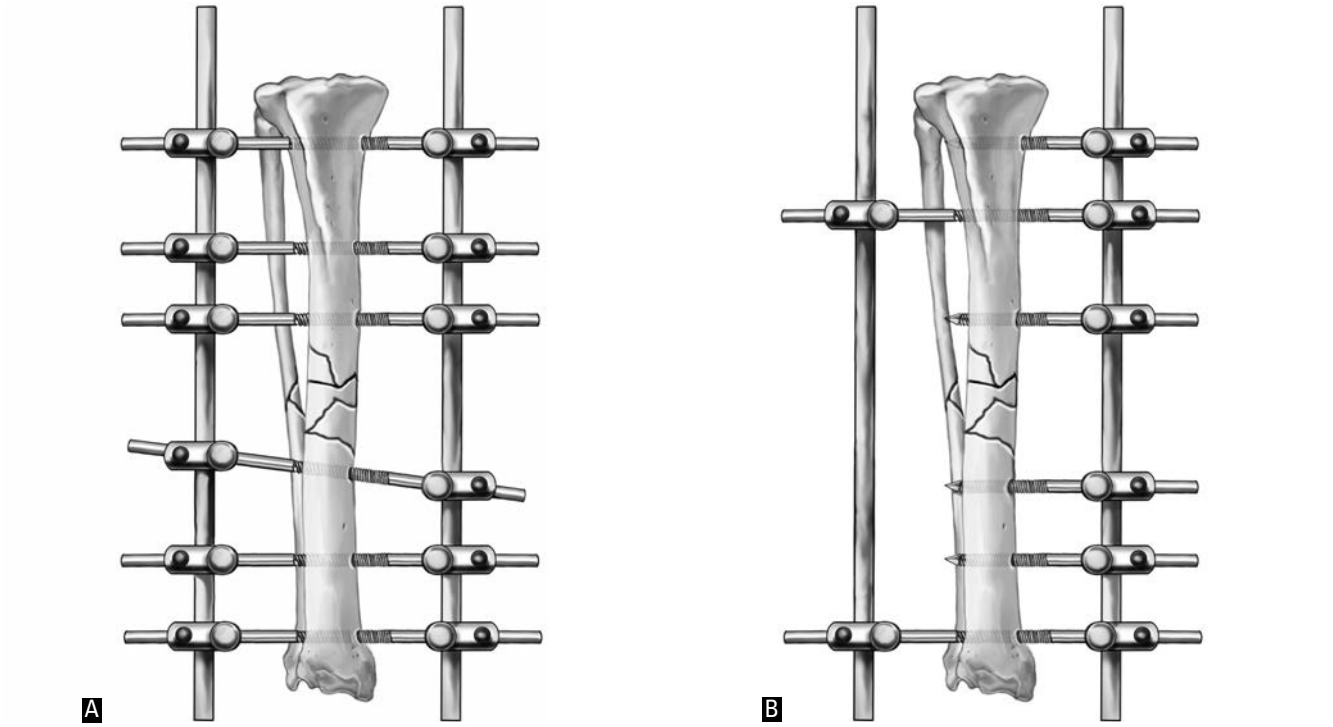

Figure 62-8. A type II external fixator may be applied to the tibia with minimal morbidity. The frame may be filled out with bilaterally secured fixation pins (maximal type II frame) **A.** or unilaterally secured fixation pins (minimal type II frame) **B.**

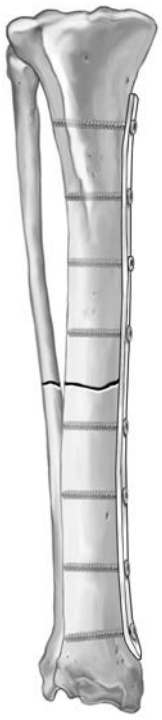

Figure 62-9. Single transverse or short oblique fractures may be anatomically reduced and stabilized using the bone plate as a compression plate.

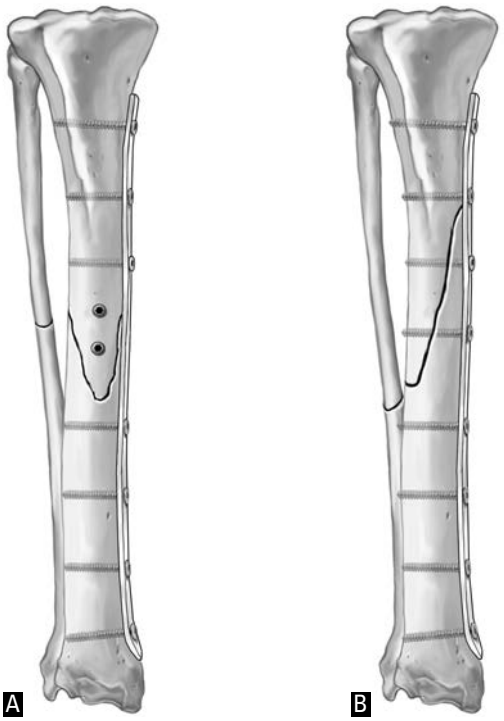

Figure 62-10. Long oblique fractures should be anatomically reduced and compressed with lag screws. Depending on the orientation of the fracture, the lag screws may be inserted outside of the plate **A.** or through the neutralization plate **B.**

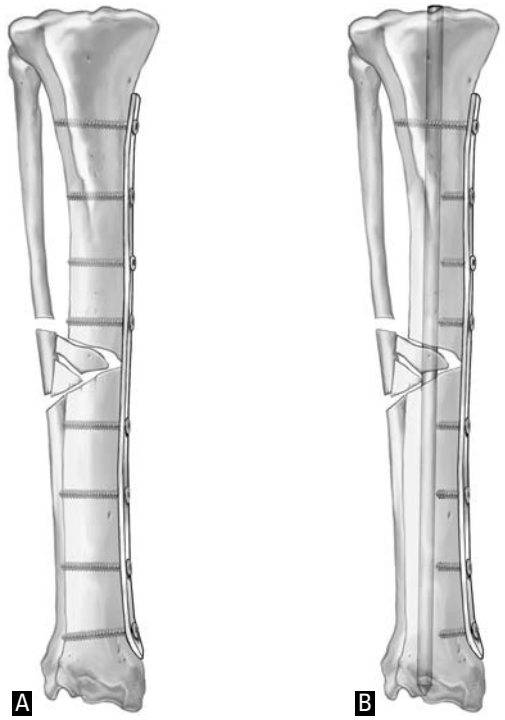

Figure 62-11. Comminuted nonreducible fracture may be realigned and bridged with a bone plate functioning as a bridging plate. **A.** Alternatively, the plate may be combined with an IM pin **B.**

General postoperative management instructions given to clients consist of recommending close confinement of the patient with activity limited to leash walking until there is radiographic evidence of bone bridging the fracture. Radiographic re-evaluations should be made at 6 week intervals.

Animals treated with internal fixation do not require special management of the limb. Animals treated with external fixators require extensive aftercare. Postoperatively, gauze sponges should be packed around the fixation pins and secured with a bandage, which also incorporates the paw, to limit postoperative swelling. External fixator management includes daily pin care and pin packing as needed. Additionally, the external fixator can be destabilized as dictated by the radiographic evidence of bone healing by removing one unilateral frame from a type Ib fixator: removing selected fixation pins from a type Ia or type II fixator; removing the lateral connecting rod of the type II fixator, or downsizing the connecting rods in a frame.

In immature animals, fracture bridging is generally observed by 6 weeks, with additional remodeling occurring in 12 weeks. Mature animals generally are healed in 12 to 18 weeks (depending on fracture configuration and signalment of the animal).

External fixators are removed when there is evidence of bone bridging the fracture site on both radiographic views. Intramedullary pins are generally removed after bone healing because of the morbidity associated with the pin end irritating the insertion site. Interlocking nails, orthopedic wire and lag screws are left in situ unless they are associated with a clinical problem. Plate removal may be necessary after the fracture heals if soft tissues irritation or cold sensitivity occurs.

Distal Physeal Fractures

The most common physeal fractures of the distal tibia are Salter Harris type I and II fractures. If the fracture is nondisplaced, treatment with cast application is generally sufficient. If the fracture is displaced, then a cranial approach to the distal tibia is made to allow anatomic reduction of the fracture.[17] Crossed Kirschner wires or small intramedullary pins are driven from the medial malleolus across the physis, into the tibial metaphyses, seating in the lateral cortex; and from the medial aspect of the distal tibial metaphysis, across the fracture into the epiphysis avoiding the articular surface. Alternatively, the second wire may be driven from the fibular malleolus into the tibia (Figure 62-12).[17]

Postoperative radiographs must be evaluated for accuracy of reduction and implant placement. Generally, a lateral splint is applied for 2 to 3 weeks to support internal fixation. Postoperatively, the patient should be confined to a small area with activity limited to leash walking. Follow up radiographs may be made at 3 and 6 weeks after treatment. Physeal fractures generally heal rapidly, within 3 to 4 weeks. If a cast is used, it should be removed as early as possible. Physical therapy may be necessary to restore range of motion to the hock. Premature closure of the physis usually occurs because of the trauma inflicted on the growing cells during the initial injury. Owners of very immature animals should be warned of the potential for growth deformities. Implant removal may be required if soft tissue irritation occurs.

Figure 62-12. Fractures of the distal tibial physis may be stabilized with crossed Kirschner wires or small intramedullary pins.

Surgical Treatment of Malleolar Fractures

Brian Beale

Fractures of the medial or lateral malleolus of the tibia result in instability of the tarsus because of disruption of the origin of the collateral ligament complex. Subluxation or dislocation may occur if instability is severe. Occasionally, both the medial and lateral malleoli are fractured concurrently. The fractures may be simple and closed, or they may involve loss of bone and soft tissue in cases of shear wounds. External coaptation is usually inadequate because accurate anatomic reduction and rigid stabilization are necessary to decrease the chance of developing degenerative joint disease. Most fractures are best repaired using open reduction and internal fixation. Bone screws and pins and tension bands are the most common implants used to stabilize these fractures (Figure 62-13).

Pin and tension band fixation provides good stability and anatomic reduction in most cases. An approach to the fractured malleolus is performed by incising skin and subcutaneous tissues directly over the fragment. A periosteal elevator is used to expose the distal aspect of the tibia or fibula and the fracture site. The fracture site is cleaned of hematoma and fibrinous debris, to allow better visualization of the articular surface and the edges of the fracture fragments. The fracture is reduced anatomically; this is extremely important because of the intra-articular nature of the fracture. Bone-reduction forceps can be used to provide temporary stability. Two pins are driven in normograde fashion sequentially through the fractured malleolar fragment perpendicularly across the fracture site into the main fragment, with care taken to avoid the articular surface of the tibiotarsal joint. In small fragments, a single pin may be used. The pin size varies, depending on the size of patient and the size of malleolar fragment. Most cats and small dogs can accommodate 0.035- or 0.045-inch Kirschner wires, whereas medium-size and large dogs may accommodate 0.062-inch Kirschner wires or 5/64-inch pins. The tension band wire used is 20 or 22 gauge in cats and small dogs and 16 or 18 gauge in medium and large breed dogs. A hole, large enough to pass the selected wire, is drilled from cranial to caudal in the main fragment approximately 1 cm proximal to the fracture line. A small loop is created in the wire to permit tightening of the wire on the opposite side of the knot formed by twisting the ends of the wire. The wire is passed through the hole and around the Kirschner wires in figure-of-eight fashion.

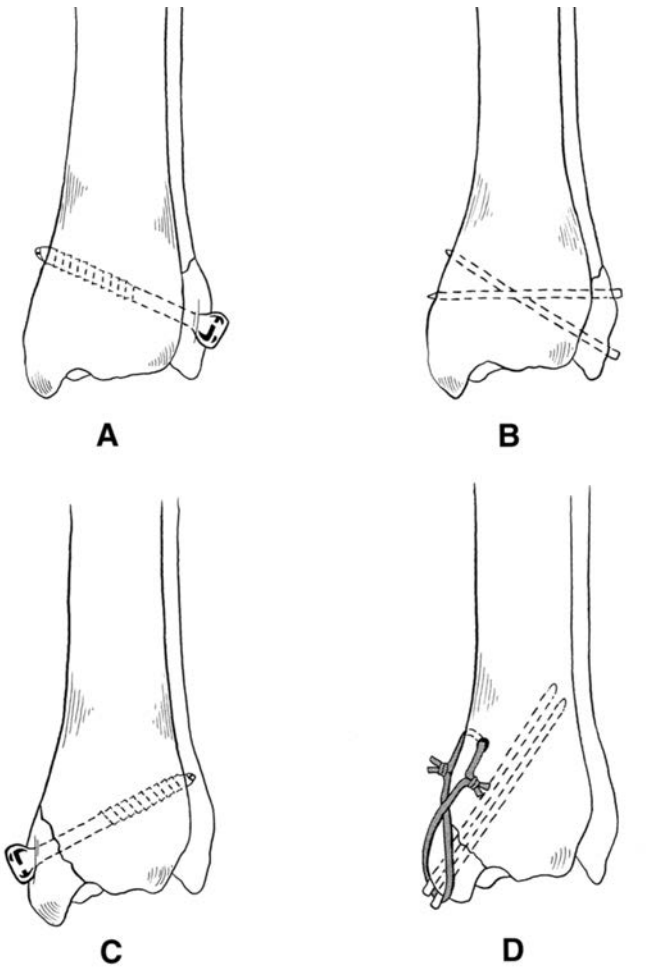

Figure 62-13. Repair of malleolar fractures. **A.** Lateral malleolar fracture stabilized with a partially threaded cancellous screw. **B.** Lateral malleolar fracture stabilized with two divergent Kirschner wires. **C.** Medial malleolar fracture stabilized with a partially threaded cancellous screw. **D.** Medial malleolar fracture stabilized with pins and tension band.

The wire is tightened by simultaneously twisting the loop and ends of the wire while applying moderate traction. This forms a knot on each side of the loop that allows greater and more even wire tension after tightening. The knots should be centered if possible. The wires are tightened onto the surface of the bone, they are cut leaving a minimum of three twists, and they are bent over if irritation of the soft tissues is likely.

Lag screw fixation of the medial malleolus provides excellent stability if the distal fragment is large enough to accommodate a screw. Lag screw fixation of the medial malleolus may be preferred to pin and tension band fixation, especially if the fracture involves a large articular segment. Lag screw fixation of the lateral malleolus usually requires its attachment to the tibia, rather than to the fibula, because of the thin distal fibial diaphysis. The screws should be placed in lag fashion, by either using partially threaded cancellous screws or overdrilling the near cortex when using cortical screws. The size of screw (1.5 to 4.5 mm) selected depends on the size of the fragment size and the patient. One or two screws can be placed; placement of two screws may help to prevent rotation of the fragment. The fracture can be reduced and temporarily stabilized with bone-reduction forceps. The appropriate thread hole and gliding hole (if using a cortical screw) are drilled perpendicularly across the fracture line, with care taken to avoid the articular surface of the tibiotarsal joint. Alternatively, a hole can be pre-drilled in the small fragment to allow more precise centering. The fragment is reduced and temporarily stabilized. The far hole is drilled. After drilling, the hole is measured and tapped, and the screw is inserted and tightened.

External coaptation is recommended for 4 weeks after internal stabilization. A lateral fiberglass splint is inexpensive and easily applied. The splint is applied while placing the tarsus at a functional angle. The bandage is changed if it becomes soiled or wet. After 4 weeks, the splint is removed, and physical therapy is performed several times daily until range of motion is improved. Exercise should be limited to leash walks only for 2 months postoperatively or until radiographic healing is evident. Running and jumping should be prevented. Implant removal is not necessary unless the implant migrates or loosens.

Prosthetic Ligament Repair for Severe Tarsocrural Joint Instability

Dennis N. Aron

Functional Anatomy[1]

Many luxations, subluxations, and shear injuries directly involve the tarsocrural joint. The major ligaments providing stability on the medial side of the joint are the long medial ligaments and tibiotalar short component ligament (Figure 62-14A). The major ligaments providing stability on the lateral side of the joint are the long lateral ligament and the calcaneofibular short component ligament (Figure 62-14B). The components of the medial and lateral ligaments complement each other in maintaining the talus in the mortise provided by the tibia and fibula. Certain parts of the ligament complexes are tighter in extension (long lateral and long medial ligaments) or flexion (calcaneofibular and tibiotalar short component ligaments).

The tibiotalar and calcaneofibular short component ligaments of the medial and lateral sides, respectively, are especially important for maintaining stability when the hock is flexed and should be accorded primary attention with any reconstruction procedure. It is possible that these short ligaments are stressed when the hock is flexed and subjected to concussive forces encountered in jumping or running, thus, needing to be particularly strong to prevent excessive ligament deformation or failure. The joint capsule and malleoli also contribute to joint stability.

The gross anatomy of the medial and lateral collateral ligament complexes is similar (See Figure 62-14). The components cross at the tarsocrural joint space, providing the greatest amount of ligament and an advantageous spatial arrangement directly over the joint.

Mechanism and Diagnosis of Injury

Based on personal experience and published reports protective stenting (augmentation) or prosthetic replacement for severe ligamentous disruption of the tarsocrural joint is indicated.[2] The shear injury produces especially severe disruption and instability of the joint. With this injury, not only are the supporting ligaments lacking, but the support to the respective side of the joint mortise provided by the malleolus and joint capsule are missing. The closed dislocation of the tarsocrural joint also can result in severe ligamentous disruption and joint instability. Most closed injuries cannot be adequately repaired by primary suturing of the joint capsule and collateral ligaments owing to the severity of the tissue damage.

Tarsocrural luxation results from different combinations of injuries including fractures of both malleoli, fracture of one malleolus and damage to the contralateral ligament complex, fracture of the fibula and damage to the medial ligament complex. Uncommonly, damage to both the lateral and medial collateral ligament complexes can occur with no fractures. Tarsocrural subluxation usually results from complete rupture or avulsion of either the lateral or medial collateral ligament complex. In medial ruptures, the paw tilts abnormally toward the lateral direction with a lateral (valgus) applied force. In lateral ruptures, the tilt is in a medial direction with a medial (varus) applied force. Occasionally, there is primary damage to only the long or short components of the medial or lateral ligament complexes. Less joint laxity makes these subluxation injuries more difficult to diagnose. In these situations determine joint laxity by placing lateral and medial tilt forces on the hock at different joint angles. Laxity in extension but not flexion suggests major damage to the long medial ligament, or long lateral ligament; laxity in only flexion suggests that most damage is isolated to the tibiotalar or calcaneofibular short components. Make a dorsoplantar (stress) radiograph while applying lateral and medial tilt forces on the hock. Take the stress radiograph at the tarsocrural joint angle that produces the subluxation. For subtle subluxations, compare

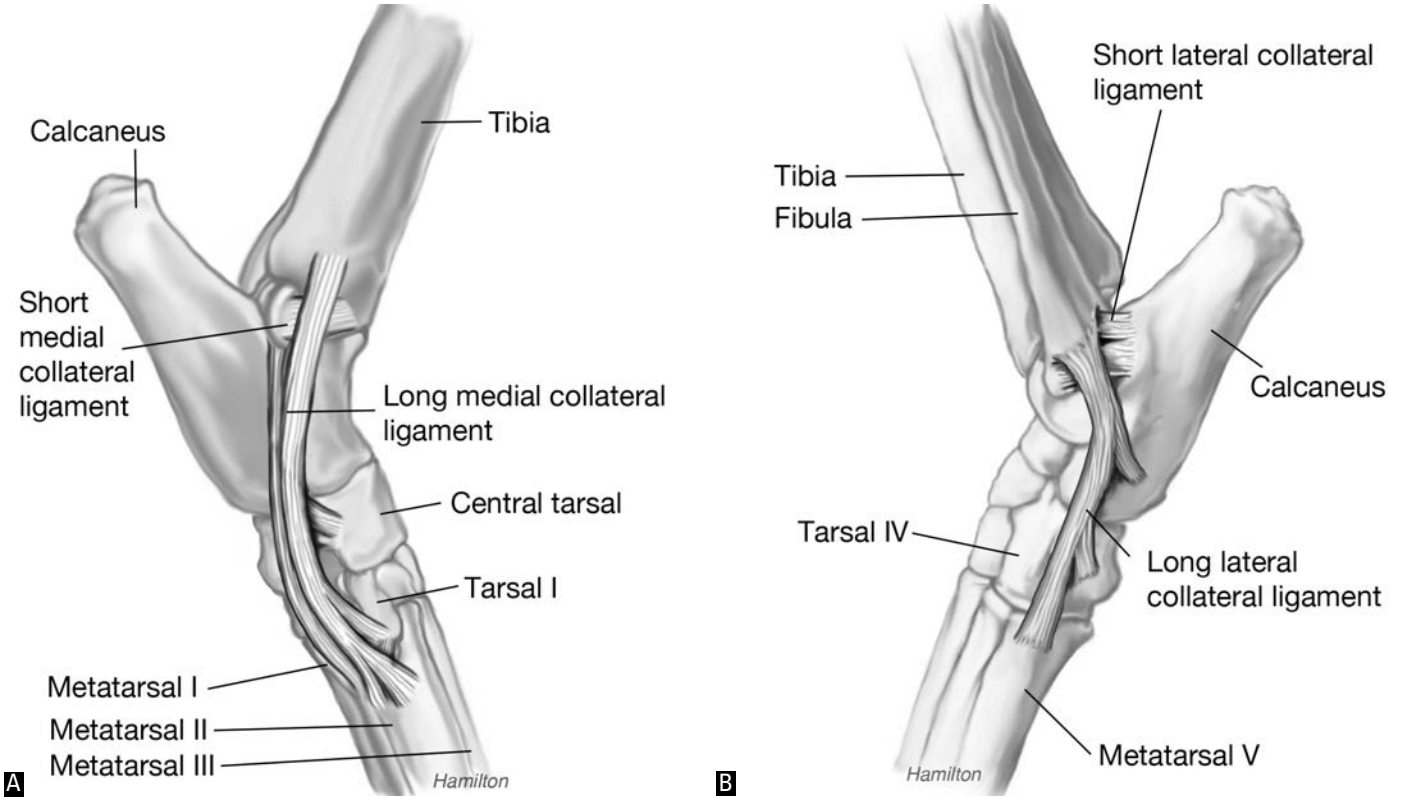

Figure 62-14. A. Medial tarsocrural ligamentous anatomy. **B.** Lateral tarsocrural ligamentous anatomy.

this radiograph with a similar radiograph of the contralateral (normal) hock. Routine dorsoplantar and lateral radiographic views are always needed to check for concomitant tarsal injuries. Stress radiographs are useful to confirm the diagnosis in less straightforward situations but are not always necessary.

Surgical Technique

The double-ligament method closely reproduces the components of the intact medial and lateral collateral ligament complexes, thus, allowing nearly normal joint stability to be maintained throughout a functional range of motion. The double-ligament method provides the surgeon consistent locations for application of the stenting or prosthetic sutures. Further, these locations closely mimic the origins and insertions for the medial and lateral tarsocrural collateral ligament complexes. It has been shown that the stability of both the medial and lateral tarsocrural joint is dependent upon the interaction of the components of the respective collateral ligament complexes. The double-ligament method closely reproduces components of the medial and lateral collateral ligament complexes. This similarity to normal ligament components allows nearly normal joint stability to be maintained throughout a functional range of motion when using the double-ligament method.[1] Similar to the components of the normal collateral ligaments, the stenting or prosthetic sutures becomes taut and lax upon flexion and extension Because of this, wire is not advocated as a useful material with the double-ligament method. Monofilament polybutester[i] (preferred) or braided polyester[ii] sutures are successful with the double-ligament method, seemingly due to the retention of elasticity upon cyclic loading.

Clinically, the double-ligament method gives results superior to conservative management with splints or nonanatomic single-ligament replacement methods. The prognosis is good for long-term function with most closed luxation and subluxation injuries, depending on timely repair (within five to seven days of injury) and absence of articular damage.

Surgical Technique - Closed Injury

Clip the injured limb from the level of the proximal femur, extending distally to include the paw. Include the paw in the sterile field to allow direct manipulation. Place the patient in lateral recumbency, with the injured limb up for lateral replacement or down for medial replacement, and prepare the limb for aseptic surgery. Expose the injury through a curved skin incision centered over the medial or lateral malleolus. Begin from the distal one-fourth of the tibia and continue to the proximal metatarsal bones. Locate the medial or lateral collateral ligament complex along the same line by incising the subcutaneous tissue and deep fascia. Inspect the components of the ligament complexes for damage. To help assess the damage, stress the ligament components with a varus or valgus tilt in both flexion and extension. It is unlikely that there will be a totally isolated injury to only one component of the ligament complex. The ligaments can appear intact but may have lost considerable function owing to internal derangement of the collagen fibers. Usually, the ligament components are too badly damaged to allow primary suturing of the torn ends or reattachment to bone. Replace irreparable ligaments with prosthetic sutures and protect repaired ligaments with stenting sutures. Replace or protect the medial or lateral ligament complexes with figure-eight heavy sutures fastened to the bone directly, with bone anchors,[iii-vi] or with bone

screws. (It is preferred to secure the sutures to the bone directly or with bone anchors as bone screws are too bulky, which can irritate overlying tissue.) Drill bone tunnels in the malleolus in locations similar to the origins of the components of the ligament complex (Figure 62-15). Bone tunnels serve as anchors for the suture prostheses. Secure the suture prosthesis that mimics the lateral or medial short components to tags of the torn ligament at the insertion site. Use a locking loop suture pattern to grip the torn ligament. A bone anchor may be needed to fix the prosthesis to the insertion site (Figure 62-15). Secure the suture prosthesis that mimics the lateral or medial long components to a drill hole in the tubercle of the distal talus or distal calcaneus (Figure 62-15). A bone anchor may be used to fix the prosthesis (Figure 62-15). For each ligament stenting or replacement use one or two (for large patients) strands of #0-2 braided polyester or monofilament polybutester (preferred) sutures for prosthetic replacement or protection. Set the sutures in a figure-eight pattern. Do not use wire, absorbable sutures, or sutures with a high degree of plasticity. Do not use monofilament polypropylene for sutures as it tends to stretch permanently (high plasticity) and is better suited for primary repair of torn ligaments. Do not use monofilament nylon (fishing leeder) as it is very stiff and tends to function like wire. Tie the long and short suture prostheses. Tie the short prosthesis with the tarsocrural joint held in approximately 90° flexion for dogs and 70° for cats. Tie the long suture prosthesis with the joint in a functional standing angle of 135° for dogs (varies with breed) and 120° for cats. After the sutures are tied, tighten the bone anchors against the bone.

Expose and provide stenting or ligament replacement to the luxation injury through separate surgical incisions on the medial and lateral sides of the joint. Fix a malleolar fracture with a tension band technique and replace or protect the contralateral ligaments. To manage luxations due to fracture of the fibula and damage to the contralateral ligament complex replace or protect the medial ligaments and stabilize the fibula to the tibia with K-wires or bone screws.

Shear Injury

Shear injuries usually occur when an animal is trapped by a moving vehicle, resulting in shearing by the road surface of supporting ligaments, bone, joint capsule, and malleolus. The medial side of the joint is injured more commonly than the lateral side of the joint. Perform wound management and ligament replacement when the bone and cartilage damage is isolated primarily to the malleolus. Severe soft tissue damage makes stabilization difficult and prolongs healing. Although a successful ligament replacement gives better results than a tarsocrural joint arthrodesis, consider joint arthrodesis if there is extensive bone and cartilage damage.

Technique – Shear Injury

Before debridement and ligament replacement, cover the shear wound with a temporary sterile dressing and apply a temporary splint to prevent further damage to the unstable joint. Exteriorized material will contaminate deeper recesses if replacement into the wound is attempted before formal debridement. Therefore, do

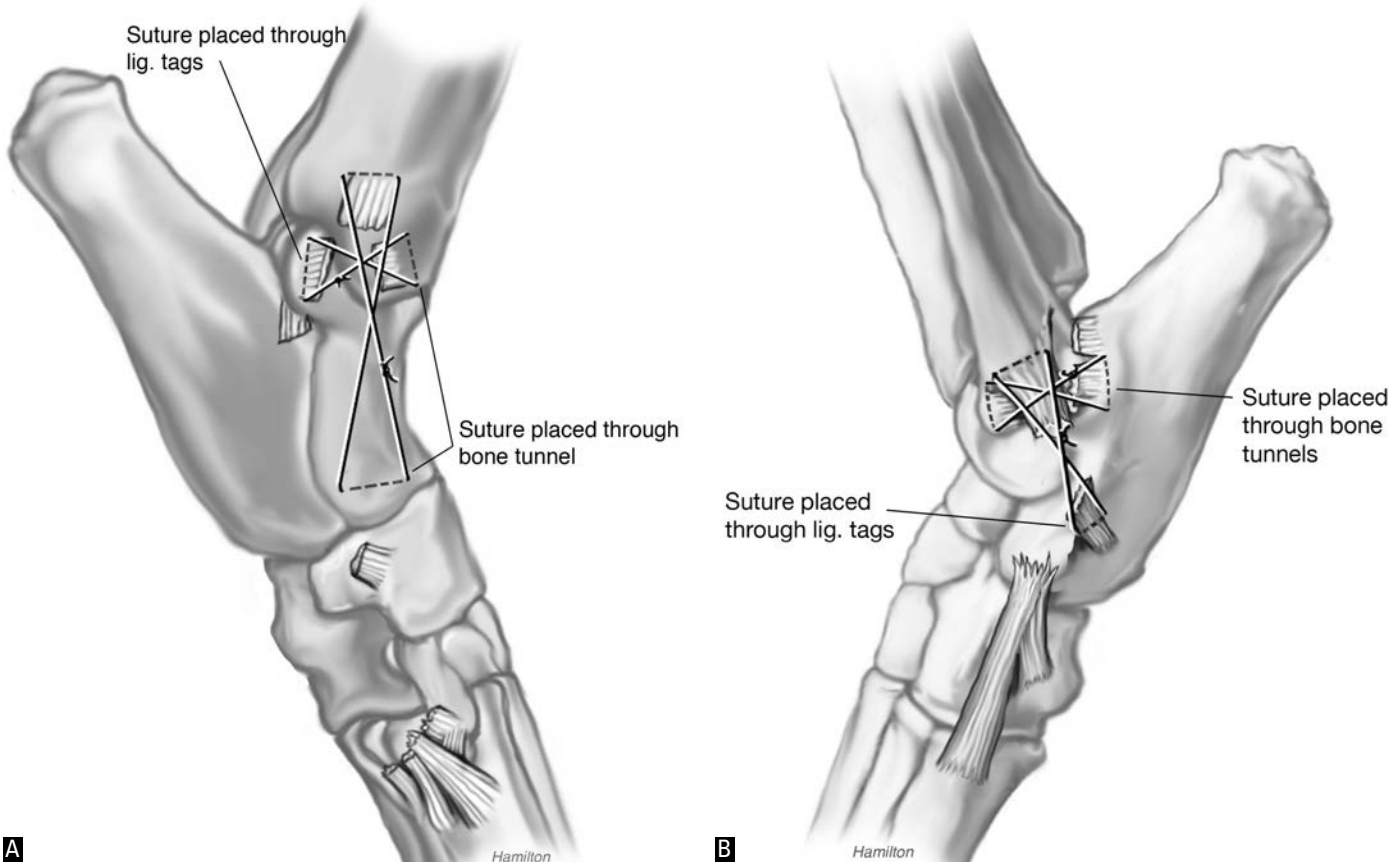

Figure 62-15. A. Stent suture reinforcement of medial ligament injury. **B.** Prosthetic suture replacement of lateral ligament injury. Affix sutures to tags of the ligament. Alternatively, secure the suture to bone tunnels or to bone anchors.

[v]Bone Anchor, SECUROS, Charlton, MA 01507
[vi]Suture Anchor, IMEX™ Veterinary Inc., Longview, TX 75604

not push or "stuff" extruded soft tissue, bone, or cartilage back into the wound. Do not soak the wound. Perform debridement as soon as the animal is a stable candidate for surgery, ideally within 6 hours from the time of injury for moderate wounds, and within or less than 1 to 2 hours for severe wounds. Ligament replacement and wound closure can be delayed but do not delay wound debridement.

Anesthetize the animal and remove the temporary splint. Keeping the wound covered, clip the limb, and cleanse with an appropriate antiseptic. Remove the dressing and thoroughly irrigate the wound with copious amounts of a pre-warmed balanced electrolyte solution. After moving the animal to the operating area, perform a final surgical scrub and drape the limb. Debride the wound of all visible necrotic tissue and debris. Be careful to avoid damage to articular surfaces. During the debridement process, lavage continuously with copious amounts (1 L or more) of a balanced electrolyte solution such as lactated Ringer's, using a moderate amount of pressure, through a 30 to 60 ml syringe and 18 or 19 gauge needle or catheter. Fluid pressure on the tissues should approximate 7 psi. Perform ligament replacement at this time or delay for repeat wound debridement or orthopedic referral. If delaying replacement cover the wound with an absorbent dressing to keep the wound moist and stabilize the joint with a rigid coaptation splint such as a fiberglass slab incorporated into a padded wrap. Change the dressing once a day or more frequently if there is fluid striking through the bandage. Repeat wound debridement if necrotic tissue is left in the wound after the first procedure. Continue this process of serial debridement until only viable tissue is present in the wound.

The prosthetic ligament replacement technique for the shear injury usually requires three bone anchors (preferred) or three bone screws and figure-eight heavy sutures. Bone anchors are required for the shear injury because some bone is usually sheared off, thus, making it difficult to create bone tunnels as with the closed injury. Place the anchors as close as possible to the origin and insertion of the components of the ligament complex (Figure 62-16). Position the origin anchor in the distal tibia for the medial ligament or the distal fibula and tibia for the lateral ligament. Direct this anchor slightly proximal to avoid penetrating joint cartilage and to obtain maximum bony purchase. Position the insertion anchor for the medial tibiotalar short ligament in the proximoplantar quadrant of the medial trochlear facies of the talus. Direct this anchor slightly distal to avoid the trochlear sulcus of the talus. Position the anchor corresponding to the insertion of the medial long ligament through the tubercle at the plantar base of the talus. Direct this anchor slightly proximodorsally. Position the anchor corresponding to the insertion of the calcaneofibular short ligament proximoplantar to the base of the lateral articular facies of the tuber calcis. Position the insertion anchor for the long ligament through the tubercle at the dorsal extent of the base of the calcaneus. Direct this anchor slightly proximoplantar. Using one or two (for large patients) strands of #0-5 polyester sutures or monofilament polybutester sutures as prosthetic replacements, place suture(s) from the origin anchor and the short insertion anchor, and separate suture(s) from the origin anchor to long insertion anchor. Set the sutures in a figure-eight pattern (See Figure 62-16). Tie taut the tibiotalar or calcaneofibular short suture prosthesis with the tarsocrural joint held in approximately 90° flexion for dogs and 70° for cats. Tie

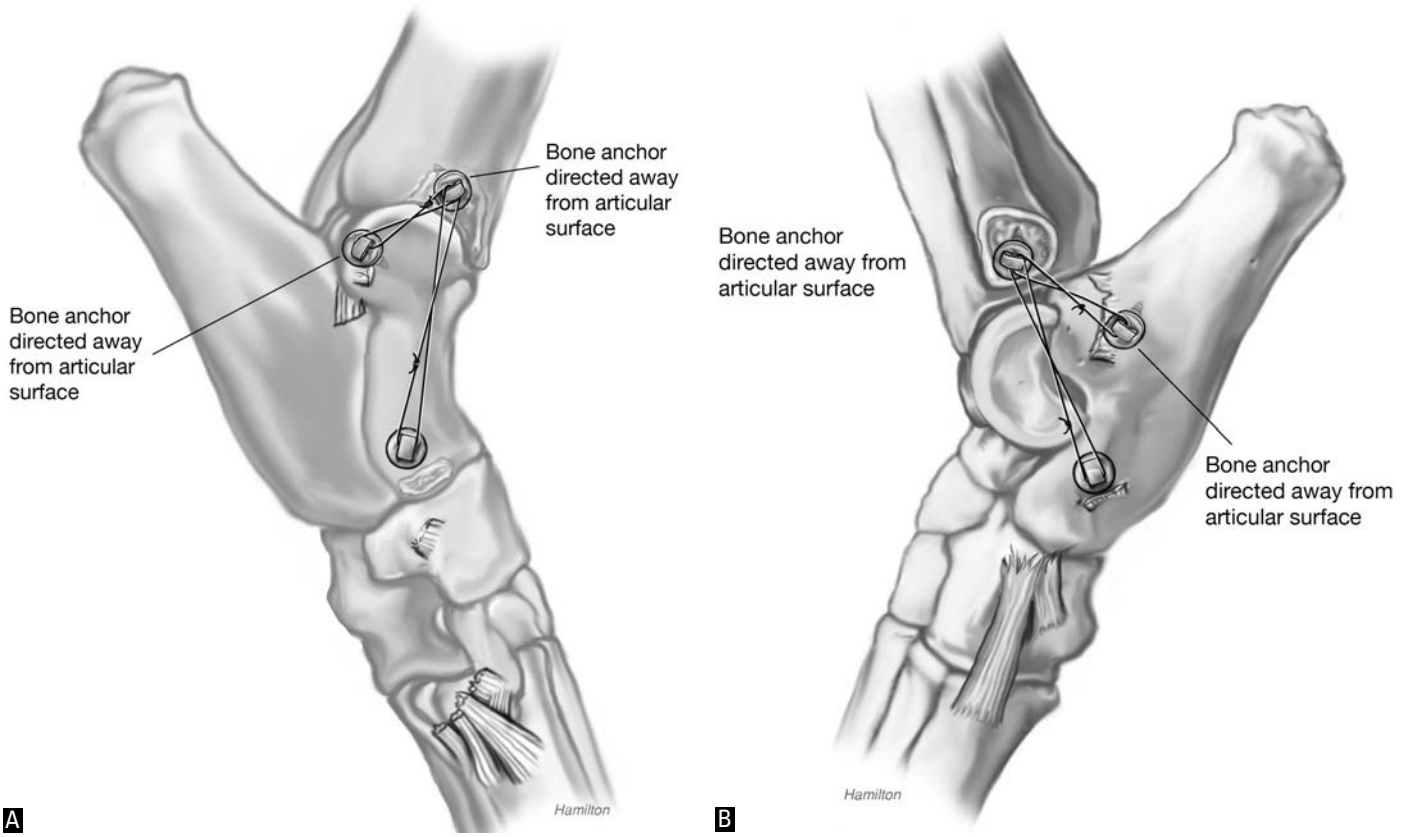

Figure 62-16. A. Prosthetic suture replacement of medial ligament shear injury. **B.** Prosthetic suture replacement of lateral ligament shear injury.

taut the medial long or lateral long suture prosthesis with the tarsocrural joint in a functional standing angle of 135° for dogs (varies for some breeds) and 120° for cats. Tighten the anchors against the bone. Never perform primary soft tissue closure over a shear injury. If possible, allow second intention healing; alternatively, perform delayed closure or apply a skin graft after all surfaces of the wound and prosthetic sutures are covered with healthy granulation tissue.

Postoperative Care

The postoperative rehabilitation is crucial to achieving a consistently high long-term result with these tarsocrural injuries. For both the closed and shear injuries the rehab is similar in that there are three phases: progressive decrease of inflammation and increase of tissue proliferation, gain of muscle strength, and reintroduction of normal activity. A vital point is that all during rehab and beyond, inflammation must not be exacerbated. Whenever activity exacerbates inflammation the rehab activity must be reduced until the inflammation is once again diminished and more healing and strength is attained.

To facilitate clearing the inflammation and promote rapid healing, the first phase of rehab depends on early and strong controlled weight-bearing to stimulate positive physiology of the limb. However, allowing too much tissue strain to occur will be detrimental by adding to the inflammation and risking implant breakdown and tissue damage. During this phase, strain is controlled through coaptation splints (mobilization aids). Immediately after surgery apply a below the knee firm coaptation splint that allows slight strain. This can be done several ways such as with a fiberglass slab or aluminum rod incorporated into a padded wrap. This type of splint will allow periodic bandage changes for the shear wound. Concurrently, perform progressive controlled walking and encourage the animal to bear strong weight. The weight-bearing is as strong as possible but controlled to limit the exacerbation of inflammation as indicated by subtle to gross worsening of weight-bearing. Avoid using a transarticular external skeletal fixator (ESF) during this phase of rehab as this rigid form of immobilization does not allow positive physiology to the limb and is very detrimental to the joint. However, if an ESF must be used it should only be maintained for two weeks or less. Remove the firm coaptation after two to six weeks (shorter time period for closed injury and rapid healing situations and longer for shear injury). Next, place the limb in a mobilization aid that allows progressive strain for three to eight weeks. This is accomplished by using a below the knee four to ten layer soft cast.[vii] The amount of tissue strain produced (moderate to high) can be greatly altered by the number of layers in the soft cast.[3] If the shear wound has not completely been covered by healthy epithelial tissue a "window" can be easily cut into the soft cast. During use of the supple soft cast mobilization aid, perform controlled low impact mobilization by allowing increasingly longer walks and by progressively unwrapping layers from the splint to increase tissue strain as healing advances and muscles gain strength. Once the soft cast is completely removed, initially back down the walking time but continue progressive controlled mobilization by, once again, slowly increasing the animal's walking activity over a four to eight week period. Controlled muscle building techniques (underwater treadmill, exercise ball, etc) are valuable during this stage of rehabilitation. When a high level of muscle strength has been regained, slowly and progressively bring the animal back to normal activity. As all during rehab, if the animal shows signs of increased lameness or pain, progress more slowly with controlled mobilization in a manner that does not create lameness or discomfort.

Prognosis

The prognosis is good for long-term pain-free function if there is no damage to the articular surfaces other than the malleolus and if surgery is timely. Careful rehabilitation through progressive controlled mobilization is critical to success.

Repair of Fractures of the Tarsus

William G. Marshall and Jon F. Dee

Introduction

Fractures of the tarsus, in the authors' experience, occur with greatest incidence in the racing greyhound population, but are also encountered in other working breeds, in pet dogs, and in the cat. Clinical presentation varies depending upon the particular bone or bones involved. Diagnosis and accurate characterization of tarsal fractures can be challenging because the radiographic appearance of the region is complex, with superimposition of the bones. Standard orthogonal studies often must be supplemented by oblique and stressed views. Computed tomography could be considered the modality of choice for detailed imaging of the tarsus[1] (Figure 62-17), though financial considerations often preclude its' use. Successful surgical repair of tarsal fractures demands a comprehensive knowledge and understanding of the normal regional anatomy (Figure 62-18).

Repair of the Talus

Fractures of the medial or lateral trochlear ridge are intra-articular and therefore anatomical reduction and rigid stabilization are imperative. A dorsomedial or dorsolateral approach may be

[vii]Scotchcast™ Soft Cast Casting Tape, 3M™, St. Paul, MN 55144

used if the fracture is restricted to the dorsal part of the trochlea. More proximal fractures can be approached by osteotomy of the relevant malleolus. Accessing the talus by osteotomy of the medial malleolus should be avoided wherever possible however, as significant morbidity in the form of degenerative joint disease is associated with this approach. When a lateral malleolar osteotomy is performed, it is wise to pre-drill the screw holes that will be required for reconstruction of this articular surface. The fracture is reduced with small bone forceps or digital pressure, and fixation achieved through the use of Kirschner wires. Multiple 0.035 or 0.045-inch Kirschner wires driven perpendicular to the fracture line are the fixation method of choice. Alternatively, small (2.0 or 1.5 mm) lag screws can be used. All implants must be countersunk below the articular surface. A lateral malleolar osteotomy is repaired with positional screws as previously alluded to (Figure 62-19), or with a pin and tension band wire. Where osteotomy of the medial malleolus must be performed it is repaired using pin and tension band fixation. In one case where the condylar fragment was too large to simply remove, and too small for internal fixation, a transarticular external fixator was applied which achieved indirect repair and a good functional result (Figure 62-20).

Fractures of the neck of the talus are approached from the medial aspect. There is often a concurrent luxation of the distal segment

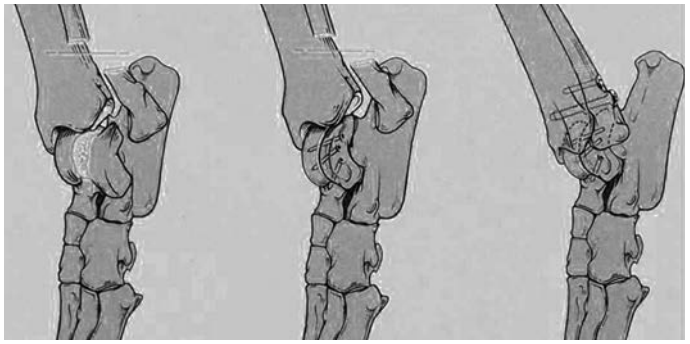

Figure 62-19. Illustration of a fracture of the lateral trochlear ridge of the talus. The fracture has been accessed via a lateral malleolar osteotomy and repaired using countersunk Kirschner wires. The lateral malleolus is reconstructed using positional screws. The screw holes should be drilled before performing the osteotomy. (Reproduced from Dee JF. Fractures of the tarsus. *In:* Johnson AL, Houlton JEF, Vannini R eds. AO Principles of Fracture Management in the Dog and Cat. Switzerland: AO publishing, 2005).

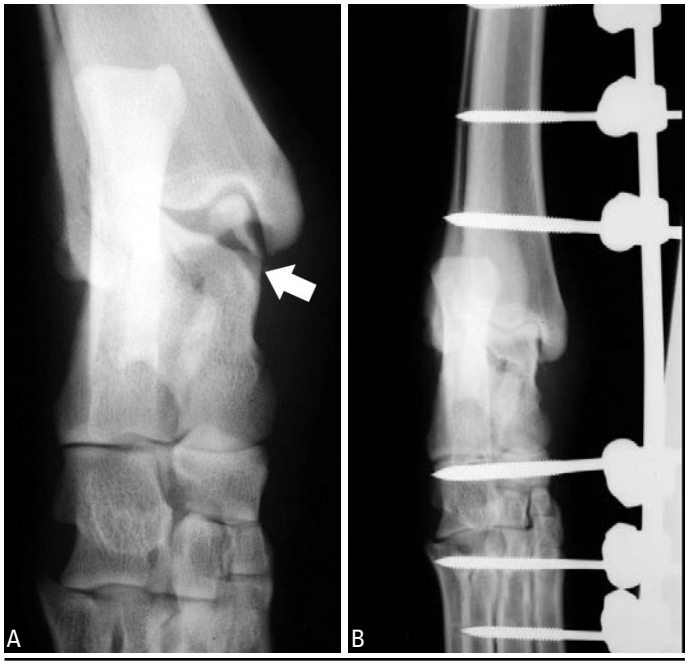

Figure 62-20. Preoperative **A.** and postoperative **B.** dorsoplantar radiographs of a fracture of the medial trochlear ridge of the talus *(arrow)* repaired indirectly by application of a transarticular external fixator.

at the talocentral articulation. Reduction may be facilitated by flexing the tarsus and simultaneously applying pressure to the lateral surface to open the medial aspect of the joint. A Vulsellum forceps can be used to temporarily stabilize the fragments. Talar neck fractures are repaired by Kirschner wire or lag screw fixation. If the fracture has sufficient obliquity, a screw or wire may be directed from the distomedial aspect of the distal fragment into the lateral trochlear ridge. In the case of more transverse fractures, the distal segment is stabilized by directing a lag or positional screw from its dorsomedial aspect in a plantarolateral direction into the body of the calcaneus.

Fractures of the head of the talus are accessed by a medial or dorsomedial approach. They may be extra or intra-articular. An extra-articular, transverse fracture of the head is stabilized

with crossed Kirschner wires or a modified T-plate. Reduction is maintained by the use of forceps or digital pressure – holding the joint in extension may enhance stability. A wire is driven from the plantaromedial aspect of the distal fragment into the dorsolateral aspect of the talar trochlea. The second wire is driven from the plantaromedial aspect of the trochlea into the dorsolateral aspect of the distal fragment. In larger dogs, it is possible to repair this fracture by use of a modified (three hole) T-plate placed on the dorsal aspect of the head and neck. The racing greyhound with a severe (grade IV or V) fracture of the central tarsal bone may, on occasion, suffer a concurrent dorsal or medial slab fracture of the talar head. These are best repaired by the use of a single countersunk lag screw.

Any repair of the talus should be supported by a lateral splint for four to six weeks postoperatively. After removal of the splint, physical therapy should be encouraged to preserve range of motion. Exercise must be restricted to short leash walks for two months postoperatively. Provided there is radiographic evidence of healing, a gradual return to normal activity can then be permitted.

In the case of a severe, comminuted, articular fracture of the talus, a pantarsal arthrodesis should be considered over any attempt to reconstruct the fragments.

The talus is the most frequently fractured tarsal bone in the cat.[2] These fractures can be managed using techniques described for the dog, though internal fixation of the feline talus is a challenging prospect. Small avulsed fragments of the medial or lateral trochlear ridge may be removed to restore joint function, albeit with inevitable progression of degenerative joint disease. Larger fragments are repaired with countersunk Kirschner wires. Fractures of the neck (Figure 62-21) may be repaired with a lag screw or a solitary Kirschner wire (Figure 62-22) but these methods are technically demanding. A more conservative approach is worth considering, because excellent results have followed closed reduction of feline talar neck fractures and application of a transarticular fixator.[3] Transarticular external fixation is a good means of protecting the repair of any feline tarsal injury as this species is often intolerant of bandages and splints. A tarsal injury particular to the cat is luxation of the talus with rupture of the short ligaments of the talocalcaneal and talocalcaneocentral joints (Figure 62-23). The luxation is often accompanied by a distal fibular fracture and avulsion of a fragment from the lateral trochlear ridge. The fibular component is repaired using positional screws (Figure 62-24) or an intramedullary pin and tension band wire. To help prevent reluxation the talus may be fixed by a positional screw to the calcaneus.

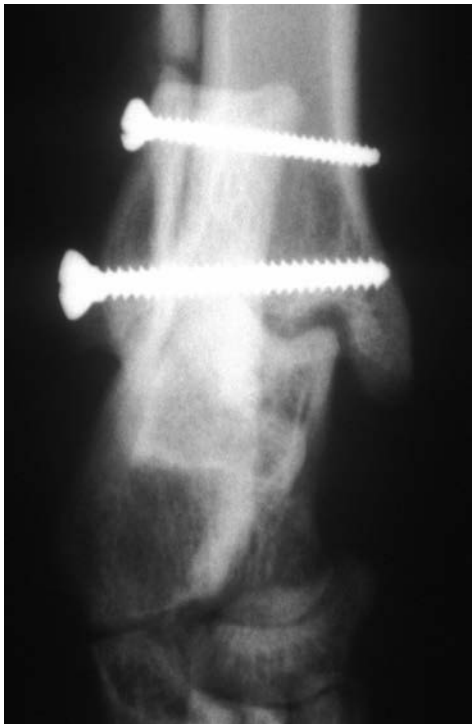

Figure 62-24. Dorsoplantar radiograph of a talar luxation and fibular fracture in a cat that has been repaired by open reduction of the talus and positional screw fixation of the fibula.

Repair of the Calcaneus

Fractures of the calcaneus have a multitude of configurations but all are accessed via a lateroplantar approach. The author prefers to position the patient in sternal recumbency as this negates some of the forces of the extensor mechanism, facilitating fragment reduction.

An avulsion of the medial or lateral insertion of the superficial digital flexor tendon from the tuber calcanei can be managed in two ways depending upon the size of the bone fragment. Small fragments are removed and the insertion of the tendon reconstructed. Larger fragments may be reattached using lag screws. Avulsion of the entire tuber calcanei is usually seen in skeletally immature animals and is repaired using Kirschner wires or a small Steinmann pin, driven from proximal to distal, seated in the base of the calcaneus. Pin fixation is combined with a figure-of-eight tension band wire. In immature animals the implants are removed once the fracture has healed. The pin and tension band method of fixation may be applied to many calcaneal fractures with minor variations in seating of the pin and placement of the wire. Taking a simple oblique midshaft fracture as an example, pin and wire fixation is carried out as follows. The calcaneus is a very dense bone and therefore a hole, slightly smaller than the pin to be used, is drilled from proximal to distal in the proximal fragment. A hole for the wire is drilled through the distoplantar aspect of the base from lateral to medial and a single-loop wire passed, with the loop on the lateral side. Vulsellum forceps are applied to the tuber calcanei and base of the calcaneus to reduce the fragments and the pin is now seated in the base. The wire is wrapped around the proximal end of the pin to form a figure eight and is tightened; the pin is bent over and cut with the proximal end orientated to point dorsally. Some surgeons use two pins, though this has no proven advantage (Figure 62-25). The implants will lie under the superficial digital flexor and may cause some irritation though the clinical significance of this is unknown. If the surgeon prefers to interfere with the superficial digital flexor as little as possible, the wire may be passed through a transosseous tunnel drilled proximally (from lateral to medial), and the pin countersunk (Figure 62-26).

In more distal fractures that approach the base, the pin should be seated in the fourth tarsal bone (T4). The wire may be passed through T4 in the region of the plantar process. The pin and figure-of-eight wire method is also applicable to comminuted

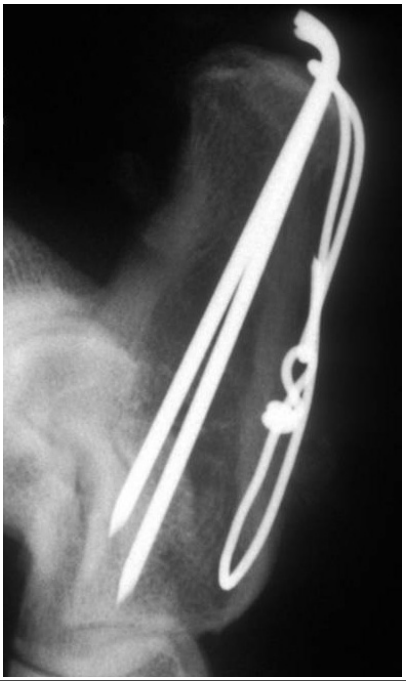

Figure 62-25. Mediolateral radiograph of a calcaneal fracture that has been repaired using two Steinmann pins and a figure-of-eight tension band wire.

Figure 62-26. Dorsoplantar **A.** and mediolateral **B.** radiographs of a calcaneal fracture in a skeletally immature dog, repaired with a countersunk Steinmann pin and a tension band wire. Proximally, the wire has been passed through a transosseous tunnel.

fractures; this may be supplemented by the use of lag screws or cerclage wire to reconstruct the calcaneal shaft. In one case a tension band wire alone was successfully combined with lag screw reconstruction (Figure 62-27). Application of a neutralization or buttress plate to the lateral aspect of the calcaneus has been advocated in comminuted fractures, with or without a supplemental figure-of-eight wire. The authors would suggest that a pin and figure-of-eight wire can be applied to virtually all comminuted calcaneal fractures, with a decreased surgical time and inventory when compared with plate fixation. Fractures with a plantarodistal component benefit from the addition of a "reverse" pin and tension band, with the pin orientated from plantarodistal to dorsoproximal and the wire passed through the calcaneal shaft. Small plantarodistal chip fractures representing an avulsion of the origin of the middle plantar ligament may not be amenable to reconstruction. Such cases are best managed by arthrodesis of the calcaneoquartal joint space. This procedure again utilizes pin and tension band fixation with the pin seated in T4 and the tension band passing through the same bone in the region of the plantar process.

Lateral sagittal fractures of the base and shaft of the calcaneus are repaired using multiple lag screws placed from lateral to medial (Figure 62-28). Dorsomedial slab fractures involving the base and sustentaculum tali are a challenge to diagnose radiographically. Repair is similarly challenging: lag screws have been used in a few instances but often external coaptation must be resorted to.

Post-operatively, simple fractures of the tuber calcanei or shaft do not require external coaptation. Comminuted fractures should be supported by a lateral splint for around 6 weeks. Exercise must be restricted to short leash walks for two months postoperatively, followed by a gradual return to normal activity provided there is radiographic evidence of healing.

Repair of the Central Tarsal Bone

Stress fracture of the central tarsal bone (CTB) occurs in the racing greyhound.[4] Five types of CTB fracture have been described in this breed based on radiographic and intra-operative appearance[5] (Table 62-1). A fracture-luxation of the CTB occurs sporadically in all breeds;[6] the fracture occurs at the plantar process which remains attached to the plantar ligaments. The rest of the bone is displaced dorsomedially.

Table 62-1. Classification of Central Tarsal Bone Fractures in the Racing Greyhound.

Fracture Type	Fracture Configuration
I	Non-displaced dorsal slab fracture
II	Displaced dorsal slab fracture
III	Large displaced medial fragment
IV	Dorsal and medial slab fractures
V	Highly comminuted fracture

Repair of type 4 CTB fractures in the greyhound proceeds as follows,[7] and is illustrated in Figure 62-29. With the patient positioned in dorsal recumbency and the tarsus immobilized parallel to the table surface, the CTB is approached on its dorsomedial aspect. The 5 cm skin incision runs between the dorsal branches of the medial and lateral saphenous veins. The CTB is found, by blunt dissection, just distal to the oblique tendon of the tibialis cranialis muscle (Figure 62-29A). The tendon of the long digital extensor is retracted laterally, and those of the tibialis cranialis and extensor digitorum brevis retracted medially to expose the fracture fragments. The fracture is reduced through hyperextension and eversion of the hock, and reduction is maintained with Vulsellum and/or pointed reduction forceps (Figure 62-29B). The medial fragment is repaired first. A 4.0 mm partially threaded cancellous screw is driven mediolateral,

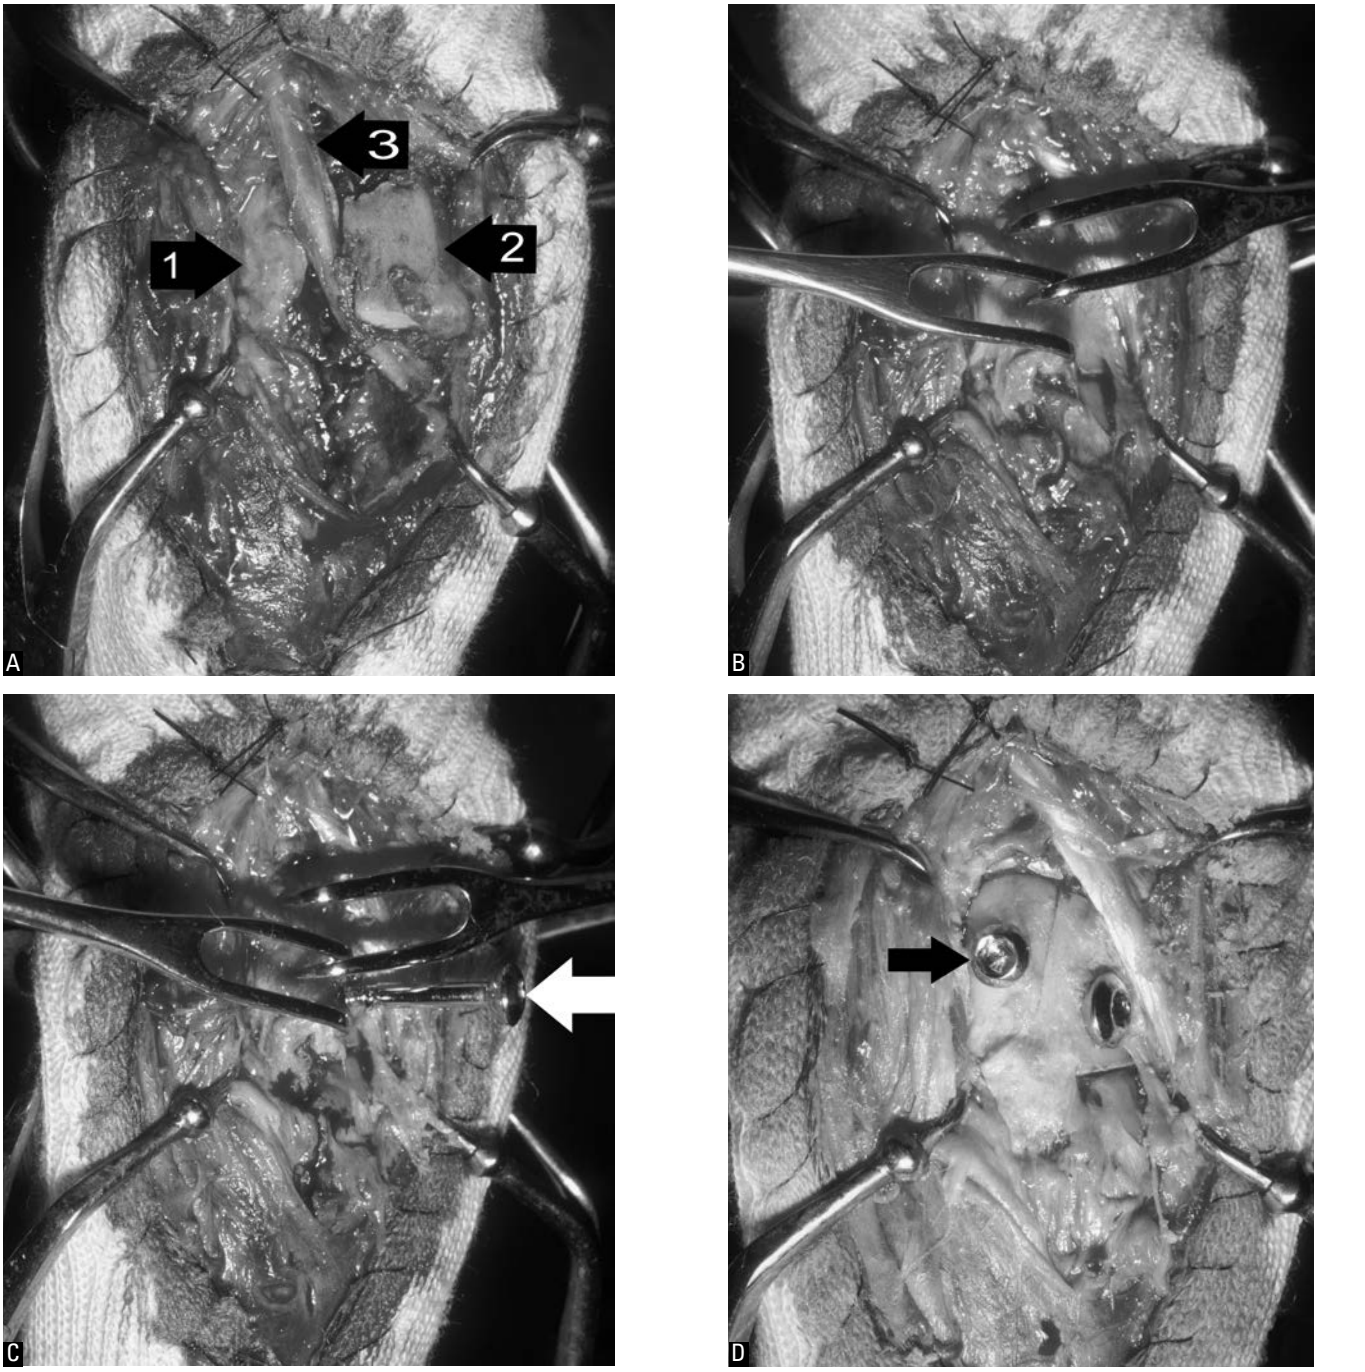

Figure 62-29. Intraoperative photographs of a type 4 central tarsal bone repair. **A.** Dorsal *(1)* and medial *(2)* fragments are identified. The tendon of the tibialis cranialis passed obliquely between the fragments *(3)*. **B.** The tendon has been retracted medially and the fragments reduced using Vulsellum forceps. **C.** A 4.0 mm partially threaded cancellous screw is applied in lag fashion to secure the medial fragment *(arrow)*. **D.** The dorsal fragment is secured with a lagged 2.7 mm cortical screw *(arrow)*. (Reproduced from Boudrieau RJ, Dee JF, Dee LG. Treatment of central tarsal bone fractures in the racing greyhound. *J Am Vet Med Assoc* 184:1492, 1984).

from a point just proximal to the origin of the oblique intertarsal ligament that joins the CTB to the third tarsal bone (T3), and the threads are engaged in the body of T4 (Figure 62-29C). This screw is placed in lag fashion and countersunk. The dorsal slab component is then repaired. A 2.0 or 2.7 mm screw is driven perpendicular and just proximal to the mediolateral screw to seat in the plantar process of the CTB. The screw is lagged and countersunk (Figure 62-29D). Figure 62-30 illustrates optimal lag screw positioning in repair of type 4 fractures. Repair of fracture types I and II is achieved as described for repair of the dorsal component of a type 4 fracture (Figure 62-30). Type III fractures are best managed as if they were type IV because it is possible that a dorsal fragment exists, but is non-displaced, and therefore not visible radiographically. This recommendation has been borne out by experience.[7] The poor prognosis for return to racing that accompanies the type V fracture means that many are treated by external coaptation alone, resulting in a permanent varus deformity though a basically functional limb. Repair may be attempted in a number of ways. If the dorsal and medial fragments are large enough, repair can proceed as for

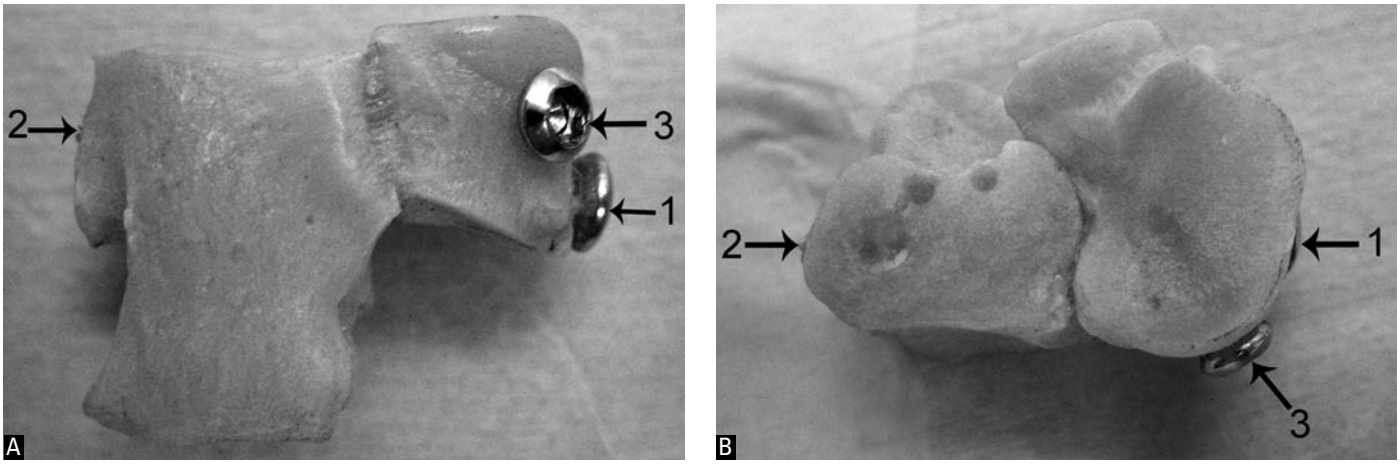

Figure 62-30. The dorsal **A.** and proximal **B.** aspects articulated fourth and central tarsal bones demonstrating optimal lag screw positioning for repair of a type 4 central tarsal bone fracture. *1* = mediolateral screw head, *2* = mediolateral screw threads exiting the trans cortex of T4, *3* = head of dorsoplantar screw. Note the orientation of the dorsoplantar screw required to seat in the plantar process of the central tarsal bone.

type IV fractures though the reconstruction will not be perfect. Alternatively, a buttress plate can be placed on the dorsal aspect of the tarsus from talar neck to T3 and the central tarsal space filled with bone graft. Central tarsal prosthesis or allograft could also be considered. As the level of experience increases and instrumentation improves, a number of type V CTB fractures have been successfully reconstructed by placing up to five lag screws in this bone. One such racing greyhound has returned to win. The most rational course of action for management of type V fractures will depend upon the proficiency of the surgeon, the patients' ability on the track, and the owners' expectations. Repair of the CTB fracture-luxation in non-greyhound breeds is accomplished by directing a lag screw mediolaterally to seat in T46. A threaded Kirschner wire has been used in place of a screw in small toy breeds.

In the author's experience approximately two thirds of fractured CTB's have associated secondary fractures, with fractures of the calcaneus, T4, and avulsion fracture of the lateral aspect of the base of the fifth metatarsal being the most common[5] (See Figures 62-17, 62-27, 62-28, 62-29 62-33, and 62-35). It is important to actively look for secondary fractures when evaluating fractures of the CTB as they have implications for prognosis as well as for management.

Postoperatively, a lateral splint is applied and maintained for six to eight weeks while restricting activity to leash walks. Radiographic evidence of healing is assessed around one month post-operatively. A gradual increase in activity leads into training and finally racing. Overall, prognosis for return to function may be good. In one study, 71 (88%) of 81 greyhounds with a central tarsal fracture that was treated by internal fixation returned to racing.[7]

Repair of the Fourth Tarsal Bone

Fracture of this bone may be considered rare in the general pet population (Figure 62-32). However, around 40% of type IV and V CTB fractures in the racing greyhound are accompanied by a

Figure 62-31. compression fracture of T4[5]. Repair of these fractures is almost always achieved indirectly through repair of the CTB which restores hock length and axial alignment. If required, a second mediolateral screw can be placed through the second and third tarsal bones and seated in T4 to provide additional stability (Figure 62-33).

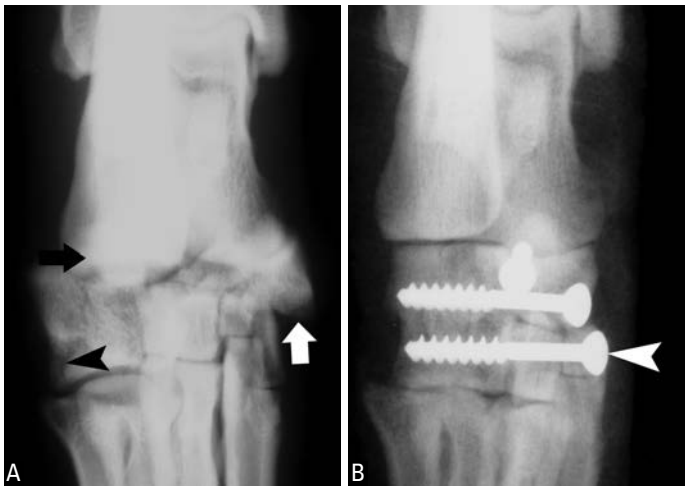

Figure 62-33. A. Dorsoplantar radiographs showing a highly comminuted central tarsal bone fracture with a large medial fragment *(white arrow)* combined with a fracture of the fourth tarsal bone in a racing greyhound. The fourth tarsal bone has been compressed by the calcaneus *(black arrow)*, and the fracture extends through the distal surface of the bone *(black arrowhead)*. In **B.** the central tarsal bone has been repaired by lag screw fixation. A second 4.0 mm lag screw directed through the second and third tarsal bones to seat in the fourth provides additional stability *(white arrowhead)*. (Reproduced from Dee JF, Dee LG, Eaton-Wells RD. Injuries of high performance dogs. *In:* Whittick WG, ed. Canine Orthopedics. 2nd ed. Philadelphia: Lea and Febiger, 1990).

Repair of the Third Tarsal Bone

Dorsal slab fracture of T3 occurs in the racing greyhound (Figure 62-34) though it would be considered uncommon compared with fracture of the CTB. Based on experience, these fractures should be managed by internal fixation where a return to racing is desired. The approach to T3 is a distal extension of the approach to the CTB. Location of T3 is simplified by first identifying the second tarsal bone (T2) and tarsometatarsal joint space. Reduction is achieved by application of Vulsellum forceps. A 2.0 or 2.7 mm cortical screw is driven in a dorsoplantar direction, perpendicular to the fracture line, and seated in the plantar process. The screw is lagged and countersunk. Post-operative management is the same as for CTB fractures.

Repair of the Second Tarsal Bone

Fractures of this bone can be considered extremely rare. When they do occur, repair is by lag screw fixation (Figure 62-35) illustrates a T2 fracture in conjunction with a number of other tarsal injuries in a racing greyhound, and 2.0 mm lag screw repair. Somewhat more common is subluxation of T2, which may accompany fracture of T3 (Figure 62-36) or tarsometatarsal subluxation. To repair a T2 subluxation, the bone is approached on its' medial aspect and a positional or lag screw driven from medial to lateral, seating in T3 and T4.

Injuries of high performance dogs. *In:* Whittick WG, ed. Canine Orthopedics. 2nd ed. Philadelphia: Lea and Febiger, 1990).

Post-operative management will depend upon the nature of any concurrent tarsal injury but in general, external coaptation for six to eight weeks is appropriate.

Repair of the First Tarsal Bone

Transverse fracture of the first tarsal bone (T1) has recently been reported in conjunction with tarsometatarsal subluxation in a small breed dog.[8] It is hypothesized that fracture of this bone represents an avulsion of the long component of the medial collateral ligament from its insertion on T1. Since then, another case with an almost identical injury has been recognized by the authors. Stress radiography was used to accurately characterize the injury (Figure 62-37). Both dogs were successfully treated by external coaptation of the affected limb, for six weeks, in a lateral

splint. The T1 fractures went on to heal (Figure 62-38), stability was restored to the joint, and the dogs were sound two months after the initial injury. A greater number of T1 fractures need to be documented and managed before strong recommendations can be made regarding this injury.

Surgical Treatment of Osteochondritis Dissecans of the Hock

Brian Beale

Lesions associated with osteochondritis dissecans (OCD) of the hock occur on the medial or lateral trochlear ridge of the talus. The lesions may be characterized as small, cartilage flaps or large, osteochondral fragments. Early diagnosis and prompt surgical removal of these fragments are recommended, before the onset of significant degenerative joint disease (DJD). Several approaches have been described to gain access to the flaps. Severance of either collateral ligament allows subluxation of the joint and excellent visualization of the trochlear ridges; however, this approach should be avoided because of the probability of causing iatrogenic joint instability, predisposing the dog to greater DJD. Osteotomy of the medial or lateral malleolus also gives excellent surgical exposure; however, this approach can also be associated with increased morbidity. Medial malleolar osteotomy is technically demanding and requires iatrogenic formation of an articular fracture of the distal tibia. Precise reduction and rigid stabilization is necessary to prevent DJD. Lateral malleolar osteotomy is preferred, but precise reduction and rigid stabilization are necessary to prevent joint instability or nonunion of the osteotomy site. The preferred approaches are the dorsolateral and plantarolateral approaches to the lateral trochlear ridge and the dorsomedial and plantaromedial approaches to the medial trochlear ridge. Accurate radiographic assessment of the location of the OCD lesion is necessary to select the appropriate surgical approach. Most OCD lesions can be accessed through a single approach; however, a combination of the dorsal and plantar approaches is necessary to gain access to some large lesions or lesions located on the midportion of the trochlear ridges. A combined approach to the medial trochlear ridge allows access to all but approximately 5% of the ridge (the midportion). A combined approach to the lateral trochlear ridge allows access to the entire ridge. The advantage of using the combined approaches is the preservation of the collateral ligaments without the need for a technically demanding, time-consuming osteotomy. If these approaches fail to provide sufficient surgical exposure, a malleolar osteotomy can then be performed. Because of the low morbidity associated with these procedures, bilateral lesions can be operated on at the same time.

All four approaches are performed by making a curvilinear skin incision centered over the appropriate region of the trochlear ridge. Subcutaneous tissues are incised and are retracted. Certain anatomic structures should be avoided during each approach. The dorsolateral approach requires lateral retraction of the tendons of the extensor digitorum longus, tibialis cranialis, and extensor hallucis longus muscles, the dorsal branch of the lateral saphenous vein, and the superficial peroneal nerve (Figure 62-39). This approach also requires plantar retraction of the tendons of the peroneus longus, extensor digitorum lateralis, and peroneus brevis muscles. In the plantarolateral approach, the tendons of the peroneus brevis, extensor digitorum lateralis, and peroneus longus muscles must be avoided dorsally (Figure 62-40). The plantar branch of the lateral saphenous vein and branch of the

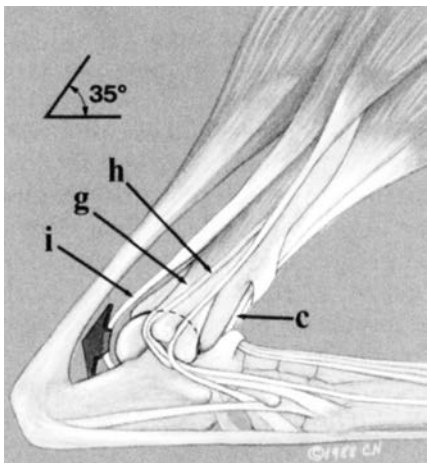

Figure 62-40. Plantarolateral approach to the hock. Flexion of the hock to 35° results in passive dorsal movement of the tendons of the peroneus brevis, extensor digitorum lateralis, and peroneus longus muscles. The tendon of the flexor hallucis longus muscle is retracted medially, resulting in exposure of the lateral trochlear ridge. The lateral collateral ligament (not shown) is preserved, *c,* extensor digitorum longus muscle; *g,* peroneus brevis muscle; *h,* extensor digitorum lateralis muscle; *i,* flexor hallucis longus muscle.

caudal cutaneous sural nerve are retracted in a plantar direction, and the flexor hallucis longus tendon is retracted medially. The dorsomedial approach requires lateral retraction of the tibialis cranialis tendon, saphenous nerve, cranial tibial artery and vein, and dorsal branches of the saphenous artery and vein (Figure 62-41). In the plantaromedial approach, the tendon of the flexor digitorum longus muscle and the distal attachment of the tibialis caudalis tendon are retracted dorsally, and the flexor hallucis longus tendon, tibial nerve, and medial saphenous vein and artery are retracted laterally (Figure 62-42). The collateral ligament complex is preserved in all four approaches. The joint capsule is incised longitudinally, directly over the palpable trochlear ridge, and is retracted. Extension and flexion of the joint allow access to the trochlear ridge for removal of the OCD fragment. Removal is usually simple using a Freer elevator or similar instrument. If present, synovial attachments to the fragment are sharply incised. Reattachment of the fragment with Kirschner wires or lag screws is not recommended because of the typical remodeling of the fragment present at the time of surgery, the technical difficulty of the procedure, and the possibility of implant failure. Gentle curettage of the subchondral lesion can be performed to remove loose debris and undermined edges at the periphery of the lesion. Fibrocartilaginous repair tissue within the defect should be left undisturbed. Forage (drilling of several small holes into the subchondral bone) of the defect to encourage vascular ingrowth has been proposed, but its efficacy is unknown. The joint capsule and subcutaneous tissues are closed in two layers using synthetic absorbable suture. The skin is closed using synthetic nonabsorbable suture. A soft, padded bandage is recommended for 7 to 10 days. Exercise should be restricted to leash walks only for 6 weeks.

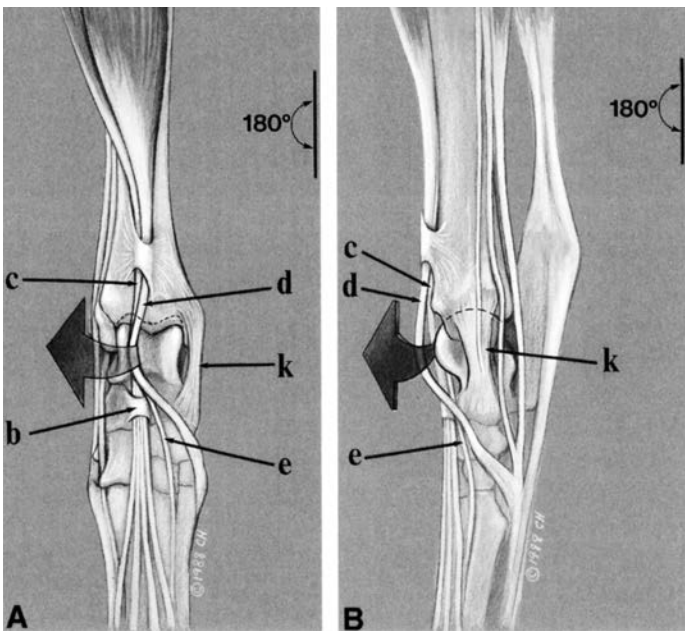

Figure 62-41. Dorsomedial approach to the hock. **A.** Dorsal view of the medial trochlear ridge showing lateral retraction of the tendons of the extensor digitorum longus, extensor hallucis longus, and tibialis cranialis muscles. **B.** Medial view of the medial trochlear ridge showing dorsolateral retraction of the tendons of the tibialis cranialis, extensor hallucis longus, and extensor digitorum longus muscles. Tibiotarsal Arthrodesis and other Tarsal Arthrodesis Procedures

Arnold S. Lesser

Introduction

When performing arthrodesis of the tibiotarsal joint, as in pancarpal arthrodesis, it is recommended to include the fusion of the intertarsal and tarsometatarsal joints. Fusion of the tibiotarsal joint alone creates added stress to these secondary joints. Tibiotarsal arthrodesis has a better prognosis then elbow or stifle arthrodesis for a successful return to function. Dogs and cats can tolerate the loss of motion in the hock and carpus better then a mid limb joint (elbow and stifle). However, arthrodesis is never simple because the surgeon is trying to overcome motion in areas where the body is constructed to maintain motion. Although the lever arm is shorter for the hock than for the stifle or elbow, the angle of the arthrodesis is more acute than for the carpus. A stiff, straight structure is hard to bend but once it is bent, and the more acute the angle, the easier it is to bend. The same is true for a plate-bone composite structure, thus the straighter or more oblique the angle of a joint being fused the more stable it is. Even the plate alone is weaker when bent at more acute angles. The normal standing angle of the hock is 130 to 150°, but if the arthrodesis angle is straighter it will be more stable and more likely to succeed. When the plate is placed on the cranial aspect of the joint, which is most commonly described, it is on the compression side which adds to the instability. Other positions for the plate have been described but are problematic for pantarsal arthrodesis. A plate is now available for placement on the medial aspect of the joint at a fixed angle of 135 degrees to overcome this weakness.

Indications

The tibiotarsal joint is subject to trauma and degenerative disease just as in any other joint. When these conditions lead to chronic pain and dysfunction, arthrodesis is indicated.

Any fracture or luxation where the articular surface cannot be reestablished or is permanently damaged, such as a gunshot or infected nonunion, arthrodesis is indicated. Shearing injuries to the medial aspect of the tibiotarsal joint with ligamentous and bone loss are frequently seen. This occurs when the leg is dragged on the ground. Most of these injuries heal by second intention and the scar tissue or screws (bone anchors) and stainless steel orthopedic wire are enough to provide stability. But, if the bone loss is excessive then arthrodesis is an alternative.

OCD of the talus is probably the most common reason for arthrodesis of the tibiotarsal joint. Even after the osteochondral fragment is removed any improvement tends to be temporary with degenerative joint disease progressing to chronic lameness. When conservative therapy is no longer effective, arthrodesis is indicated. Rheumatoid or polyarthritis also commonly affects the tibiotarsal joint and, as in the carpus, arthrodesis is beneficial for individual joints. But the disease tends to affect multiple joints. Septic arthritis or secondary degenerative arthritis can be severe enough to warrant arthrodesis.

A unique indication for a talocrural fusion is in sciatic nerve paralysis. A muscle transfer of the vastus lateralis to the long digital extensor tendon requires fusion of the tibiotarsal joint providing mechanical advantage to dorsiflex the paw when walking. The fusion helps position the paw and removes a point of motion along the path of the transferred tendon.

A failed repair of the calcanean (Achilles) tendon can be salvaged with a tarsocrural or pantarsal arthrodesis. The rupture of the plantar ligament however, can be repaired with fusion of the proximal intertarsal joint alone. This is a very common injury especially in collies and shetland sheep dogs, but all breeds can be affected. These dogs present with hyperextension of the hock with the tubercalcus more parallel to the tibia then normal. This varies from the complete luxation of the intertarsal joint where the talocentral joint is also unstable. With luxations of the individual joints, such as the intertarsal and tarsometatarsal joints, fusion of the involved joints alone is sufficient. The extent and location of the soft tissue injuries may differ and dictate the repair. This will be discussed later.

Procedure

In all cases the cartilage must be removed from the adjacent surfaces. The articular surfaces of the talocrural joint can be approached by cutting either of the collateral ligaments or by an osteotomy of the medial maleolus or fibula and incising the joint capsule. For the tibiotarsal joint either the cartilage itself can be removed with a power bur or a curette leaving the original saddle shape of the distal tibia and tallus intact. Alternatively, two flat surfaces can be developed with a saw or bur (Figure 62-43). In either case, autogenous cancellous bone should be packed between the surfaces to fill in the gaps. If a significant amount of bone is removed to create flat planes then this will act to effectively shorten the leg and to compensate for this the joint should be fused at a straighter angle which is also more stable. The angle of the cuts will determine the final angle of the arthrodesis. The normal standing angle in dogs is between 130 and 150°, but there are significant differences between individuals and breeds such that measurement of the normal standing angle of the contrlateral limb is the best method for determination of the desired angle. The normal standing angle of this joint in cats is usually 115 to 125°. The cartilage of the intertarsal and tarso- metatrsal joints is removed in a routine manner with a curette or bur.

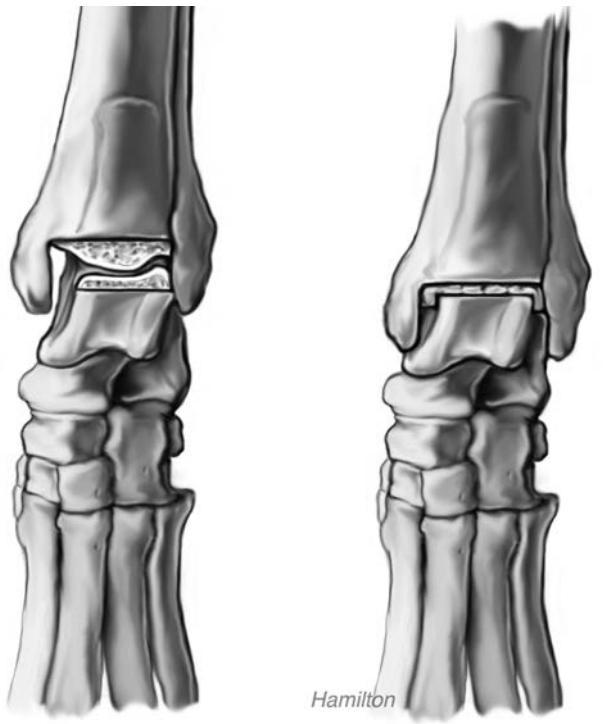

Figure 62-43. When the articular cartilage is being removed, it is advantageous to shape the opposing surfaces to produce the most stable configuration possible as well as locking in the desired angle. Two congruent rectangular surfaces can be shaped and augmented with cancellous bone.

In small dogs or cats the tibiotarsal joint can be fused with compression screws. One screw is generally placed from the sustentaculum tali into the medullary canal of the tibia, and another screw is placed from the tibia calcaneus into the tibia to hold the position of the joint and oppose flexion (Figure 62-44). Once the medulary canal is wider than the thread of the screw, then multiple screws must engage the cortex of the tibia, the talus and fibular tarsal bone. They can either be passed from proximal to distal or vise versa (Figure 62-45). Either orthopedic wire or another screw should go from the calcaneus to the tibia to resist flexion and protect the other screws from bending forces. A Kirschner wire can be used to hold the joint temporarily while the holes for the screws are drilled. The problem with this technique is that only the tibiotarsal joint is fused and although it can be successful (especially when muscle transfer is done for sciatic nerve paralysis) there are some dogs that will develop problems in the other tarsal joints. A study by Gorse and co-workers found better function with pantarsal arthrodesis than for talocrural arthrodesis alone. External coaptation with a

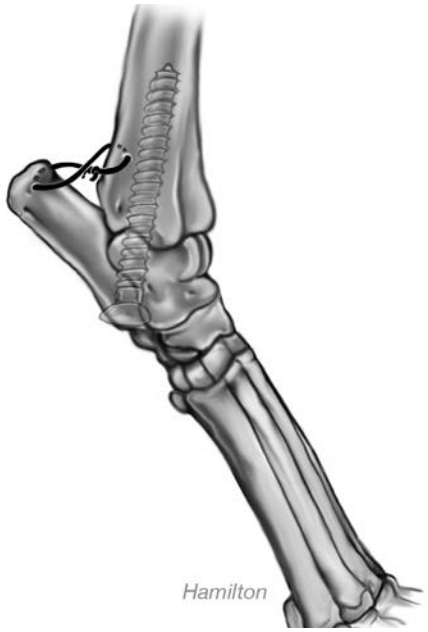

Figure 62-44. A screw can be placed from the calcaneus through the talus up into the medullary canal of the tibia. Once the medullary canal becomes wider than the screw, this placement is no longer viable. A figure-eight wire or screw is placed from the tuber calcei to the tibia to resist flexion.

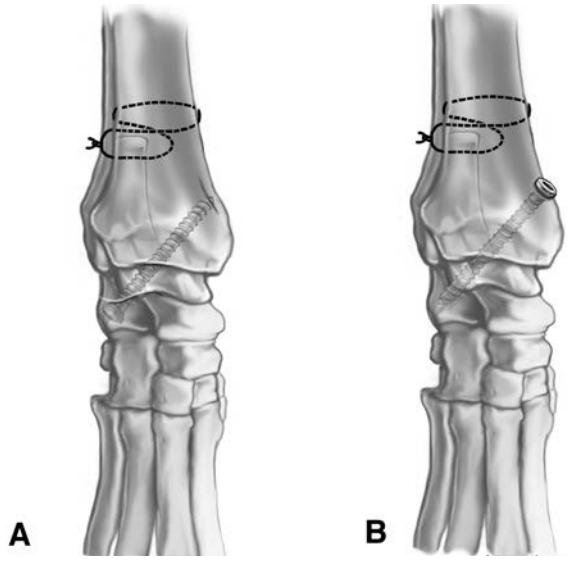

Figure 62-45. The screw can also be placed from the calcaneus to emerge from the medial malleolus **A.** or the opposite **B.** from proximal to distal. A wire or screw should be added from the tuber calcei to the tibia.

splint or cast should be maintained until there are radiographic signs of healing with all screw fixations.

Preferred methods for stabilization of a pantarsal arthrodesis are bone plate fixation or external skeletal fixation (ESF). The most common placement of the plate is along the cranial aspect of the tibia, tarsus and metatarsal bones (Figure 62-46). This is, however, the compression side of the construct and not ideal. A straight plate can be placed caudolaterally, but a new tarsal arthrodesis plate (Jorgensan labs) is available with a built-in angle of 135° which can be placed medially (Figure 62-47). The 3.5mm plate has 2.7mm holes distally for the metatarsal bones and the 2.7mm plate has 2.0 mm holes distally. For medial placement of a plate, the medial maleolus may need to be shaved. Regardless of the aspect of plate placement, three to four screws should be applied to the tibia; one to three screws should be applied to the talus, calcaneus and central tarsal bones; and three screws should be applied to the metatarsal bone. In a cranial plating, one of the screws should be placed across the arthrodesis under compression, and either a screw or wire should immobilize the calcaneus to resist bending. Motion between the calcaneus and talus post arthrodesis can cause lameness. The plate should engage either the 3rd or the 4th metatarsal bone. A separate screw can be used to compress the arthrodesis and grab the calcaneus when the plate is applied medially. Even with plate fixation, some form of splinting should be considered until radiographic signs of healing are evident (usually 2 to 3 months). Since we are not worried about joint stiffness, as would be the case in fracture fixation, extra support is warranted, especially in large active dogs. The complications of soft tissue irritation has to be weighed against this added support. Therefor a ESF can be used for additional support instead of coaptation.

External fixation is also well adapted as primary repair for pantarsal arthrodesis, especially in shearing injuries or open, contaminated, comminuted fractures (Figure 62-48). A type II construct is needed for rigid fixation but a modified type II, using full pins only in the most proximal and distal position or positions, and using half pins in between is technically easier without sacrificing too much stability. Fixation pins with a positive thread profile or Duraface pins should be used. These should be applied using pre-drilling technique and slow speed power insertion. If the older Kirschner Ehmer or newer Securos clamps are used, the stainless steel connecting bars are contoured to the desired angle. A reinforcing bar applied from proximal to distal bilaterally will triangulate the construct and strengthen it. With the SK system, titanium or carbon fiber composite connecting rods are generally used and these cannot

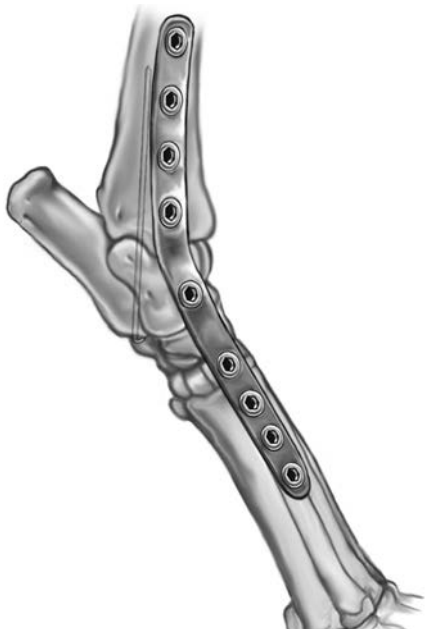

Figure 62-46. A plate can be placed on the cranial aspect of the tibia and tarsus including the third or fourth metatarsal bone. Plates are now available with smaller holes for the metatarsal bones.

Figure 62-47. A plate is available to be placed on the medial aspect of the joint. This does limit the angle of arthrodesis to 135 degrees but removes the plate from the compression side of the fixation. The medial malleolus can be shaved down to accommodate the plate if necessary.

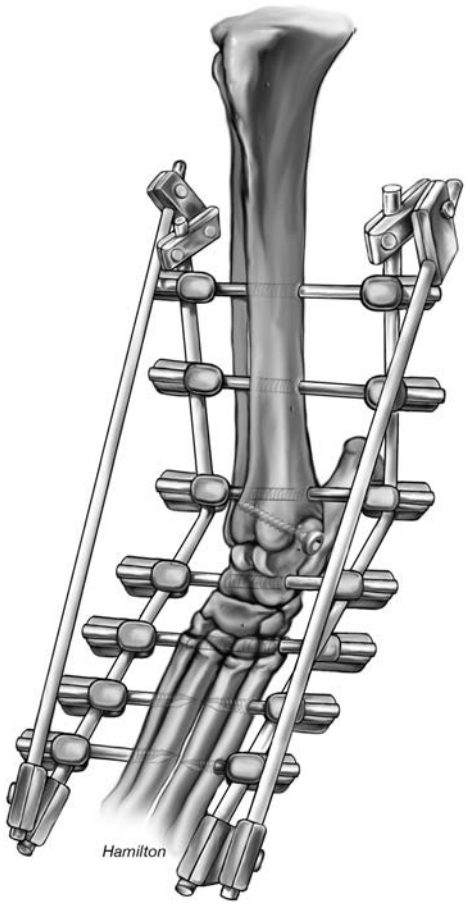

Figure 62-48. A type II external skeletal fixator is well adapted for use in fusing the hock. Compression should be applied across the arthrodesis and the connecting bars can be contoured or linked. Triangulating articulations can be added for bending resistance.

be contoured. Instead, modified SK connecting clamps can be used to create an adjustable articulation to create the desired angle between two connecting rods (Figure 62-49). The metatarsal bones form an arch and it is rarely possible to get a full-pin through all four. It is better to aim for the 2nd and 5th, or the 3rd and 4th metatarsal bones. Half-pins are a simpler way of securing the metatarsal bones. Compression should be placed across the arthrodesis site so ideally a full-pin should be placed in the talus and at least one of the pins in the tibia. Two to three pins should be placed in the tibia. The greater the number of fixation pins used, the less stress there will be on any individual pin and the less chance of pin loosening. As long as the frame is rigid and all the joints are spanned with compression across the arthrodesis site, the surgeon has some leeway in regard to pin placement sites. A third bar can be triangulated, spanning the cranial aspect of the frame for added strength. Ring fixators or hybrids also work well in this joint.

When an injury involves just the intertarsal or tarsometatarsal joints, only the affected joints need to be fused. When the plantar ligament ruptures causing hyperextension of the hock, the cartilage is removed between the fourth tarsal bone and the calcaneus, and a Steinmann pin is placed through the calcaneus, fourth tarsal bone and into the 3rd or 4th metatarsal bone. Cancellous bone is placed in the gap and a 20 or 18 gauge tension band wire is placed from a hole drilled in the calcaneus to a hole in the 4th tarsal or metatarsal bone (Figure 62-50). This bone is very dense and pre-drilling the hole for the pin facilitates pin placement. The proximal end of the pin is either countersunk or bent over but still can cause irritation. A laterally applied plate is a quick and very stable alternative. When there is a complete luxation of the proximal intertarsal joint, bone plate fixation is preferable (Figure 62-51).

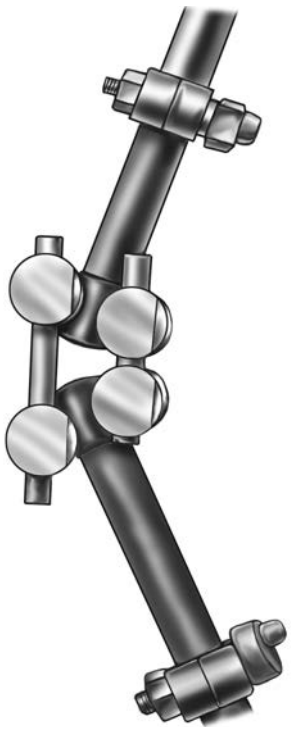

Figure 62-49. If SK clamps with titanium or carbon fiber bars are used a modified clamp can be used to span the joint.

Figure 62-50. Rupture of the plantar ligament can be treated with an intermedullary pin and tension band wire. The wire can be placed through a hole in the tuber calcei or around the proximal end of the pin before it crosses to enter a hole in the taral or metatarsal bone.

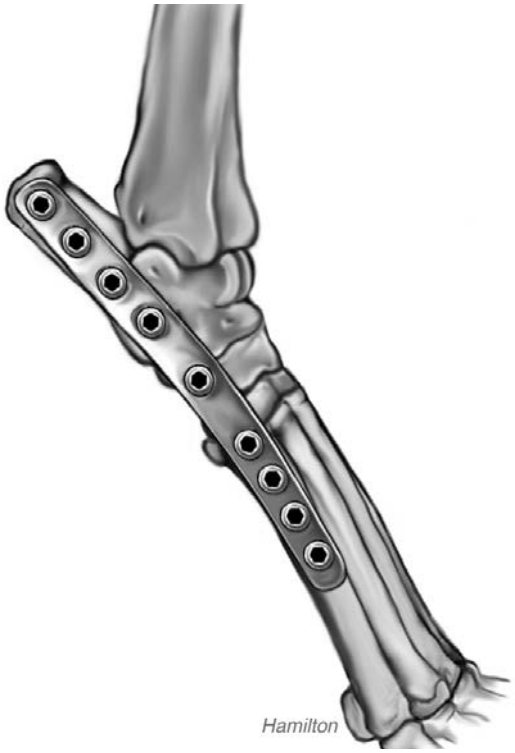

Figure 62-51. For unstable distal tarsal ot tarso-metatarsal luxations a laterally placed plate provides good fixation with little soft tissue irritation and is a good alternative to a pin and tension band.

With luxations or fracture-luxations of the intertarsal and tarsometatarsal joints, stress radiographs are helpful to accurately define the injured structures. Often combinations of pins, wires and screws can be used to stabilize these injuries. If the intertarsal luxation involves only the dorsal ligaments, weight bearing stabilizes the injury and coaptation alone will often suffice. If the instability is in one plane only, then screws and figure eight wire will stabilize the injury, but if two planes are involved, as in tarsometatarsal fracture luxations, cross pins and wire will be necessary for stability. It is always best to remove the cartilage and graft these partial fusions, but if the luxations involve only capsular and ligamentous disruption, it may not be necessary to remove the cartilage especially in smaller patients. Coaptation during healing is also a good idea due to the large weight bearing stresses encountered post operatively. The pins and wire can be removed once healing has occurred, usually in 8 to 12 weeks.

Orthopedic Bandaging and Splinting Techniques

Chapter 63

Commonly Used Bandages and Slings

Application of a Robert Jones Bandage

David W. Knapp

The materials necessary to apply a Robert Jones bandage include one to three 1 -lb rolls of absorbent cotton, 1- or 2-inch white adhesive tape, several rolls of 3- or 4-inch stretch gauze, one to three rolls of 3- or 4-inch elastic tape or self-adherent stretch tape, and a nonadherent dressing when indicated.

Application is begun by placing adhesive tape stirrups medially and laterally from the carpal or tarsal area distally (Figure 63-1A). Dog-earing each end or placing a tongue depressor between the tape ends aids in separating the stirrups later. Placement of a nonadherent dressing on any open wound or surgical incision is done at this time.

The next portion of the bandage is the application of the cotton. One begins distally and wraps proxi-mally, high into the axillary or inguinal regions (Figure 63-1B). The ends of digits 3 and 4 should be left exposed, and the cotton should be wrapped with enough tension to make the bandage tight, but not tense enough to cause the cotton to tear. The final bandage should convert an irregularly shaped leg into a uniform-diameter or stovepipe configuration, thereby allowing the bandage to apply even pressure over the entire length of the leg (Figure 63-1C).

After application of the cotton, even pressure is accomplished by wrapping from distal to proximal with 3- or 4-inch stretch gauze (Figure 63-1D). Each wrap should overlap the previous by about 50% its width, avoiding any formation of ridges and valleys, indications of uneven pressure. When wrapping the stretch gauze, one should apply enough tension to compress or reduce the size of the bandage adequately. In most cases, the final diameter of the bandage after the stretch gauze is applied is 40 to 50% of the original diameter.

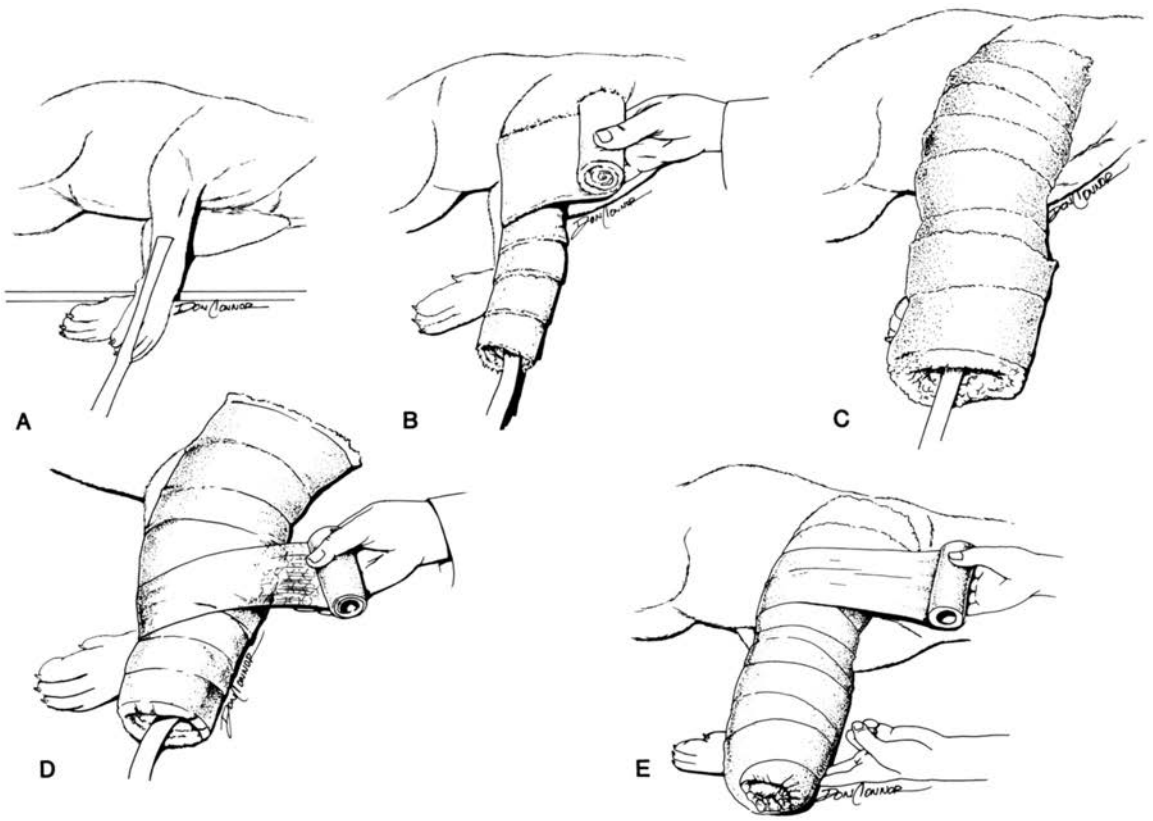

Figure 63-1. Application of a Robert Jones bandage. **A.** Placement of stirrups on medial and lateral aspects of paw. **B.** Wrapping with rolled cotton starting at distal end. **C.** Cotton padding in place. **D.** Application of stretch gauze, compressing cotton. **E.** Application of elastic tape or self-adherent stretch tape after stirrups are folded up, leaving only digits 3 and 4 exposed.

To complete the bandage, the tape stirrups are separated and are placed along the appropriate medial and lateral sides. Using either elastic tape or self-adherent stretch tape, the final layer is started, again distally, wrapping proximally and continuing to overlap each layer by 50% while taking care to maintain even compression. When this layer is completed, only the distal ends of digits 3 and 4 should be exposed (Figure 63-1E). If the toes are not visible, adequate amounts of the surrounding cotton should be removed to allow exposure of the digits.

The goal of the Robert Jones bandage is to provide immobilization while maintaining even compression over the length of the limb. Compression can be evaluated by tapping over the length of the bandage; a properly applied bandage sounds like a ripe watermelon when it is thumped. To obtain even compression may require several applications of the stretch gauze, beginning each wrap distally and continuing proximally to either the axillary or inguinal region. In smaller dogs and cats, cotton cast padding may be substituted for the roll cotton, thereby achieving a more uniform fit to the leg. A more uniform fit may also be accomplished by removing the paper insert in the cotton roll, tearing the roll in half, and wrapping with 6-inch widths rather than 12-inch widths of cotton strips. All layers of the bandage are wrapped in a lateral-to-medial rotation to allow for a neutral to slightly internally rotated position of the limb.

Postbandaging care should include keeping the bandage clean and dry and observing the exposed digits for swelling or coolness to the touch. If problems are noted, the bandage may have been improperly applied and should be removed and the leg reevaluated. If no signs of problems are evident, the Robert Jones bandage may be left in place for up to 3 weeks.

Ehmer Sling (Figure-of-Eight Sling)

Paul W. Dean

The Ehmer or figure of eight sling is a non weight bearing sling for the pelvic limb. A properly applied Ehmer sling maintains the leg in a flexed position with the coxofemoral joint abducted and inwardly rotated.

Indications

The Ehmer sling is used primarily to maintain the coxofemoral joint in a stable position following closed reduction of craniodorsal coxofemoral luxation. Maintenance of the coxofemoral joint in an inwardly rotated and abducted position provides for maximal coverage of the head of the femur by the acetabulum while periarticular fibrosis stabilizes the coxofemoral joint. Use of an Ehmer sling may also be beneficial in maintaining stability of the hip joint in the immediate post operative period following certain surgical procedures such as repair of fractures of the femoral head and neck, acetabular fractures, and to provide stability following open reduction of coxofemoral joint luxations.

Application Technique

The only material necessary to apply an Ehmer sling is a roll of porous, adhesive tape. I prefer to use 2" porous tape (Curity®, Kendal Healthcare Products Company, Mansfield, MA 02048) rather than elastic adhesive tape (Elastikon, Johnson and Johnson, Somerville, NJ 08876), as the elastic type tape is more prone to create a constriction if not applied loosely. Regardless of the type of tape material used, it is advisable to first unroll, or strip off, a length of tape then re-wrap it loosely so that when the tape is applied, there is less of a tendency to tape too tightly around the foot or thigh.

To begin placement of an Ehmer sling, the tape is first anchored to the metatarsal region of the foot by wrapping the tape loosely around the metatarsals. The tape is begun on the dorsal metatarsus, proceeds to the lateral and then plantar aspect of the metatarsus. The limb is then flexed, taking care not to hyperflex the hock joint, and the tape is continued up the medial aspect of the tibia, medial to the stifle joint and medially over the thigh muscles (Figure 63-2). The tape should not be passed up the medial aspect of the tibia, caudal to the stifle joint and over the lateral side of the thigh muscles as this predisposes the tape to slipping off the cranial thigh muscles (Figure 63-3). After the tape is passed up the medial aspect of the thigh muscles, it is brought over the cranial thigh muscles to the lateral side of the thigh and continues distally caudal to the stifle joint, medial to the distal tibia and hock, and passes under the plantar aspect of the metatarsals from medial to lateral (Figures 63-4 and 63-5).

Figure 63-2. Tape placed loosely around lateral metatarsus and brought up the medial side of the leg adhesive surface of tape facing skin.

Figure 63-3. Incorrect placement of tape predisposes the sling to slippage off the cranial aspect of the stifle.

Figure 63-4. Tape is continued from medial to lateral over the cranial quadriceps muscles to pass caudal to the stifle.

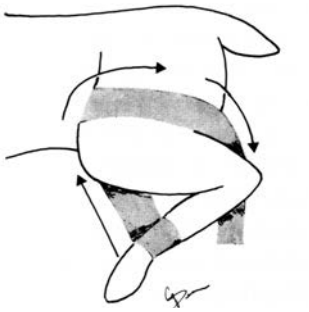

Figure 63-5. Tape continued from lateral aspect to pass medial to the hock and metatarsus and is then brought around the plantar surface of the metatarsus to the lateral side.

Two or three wraps of tape are continued in a manner similar to that previously described. Properly applied, the toes should point slightly inward, the hock joint should be rotated outward and the stifle and coxofemoral joint should be rotated internally. To provide maximal coverage of the femoral head by the acetabulum, abduction of the limb is provided by passing a length of tape from the plantar metatarsal region, over the lateral aspect of the flexed limb and around the abdomen where it is attached to a pre placed bellyband (Figure 63-6). Care should be taken to stay cranial to the prepuce with the bellyband in male dogs. If using an Ehmer sling to stabilize a ventral coxofemoral luxation, the limb is not abducted as this will predispose to re-luxation.

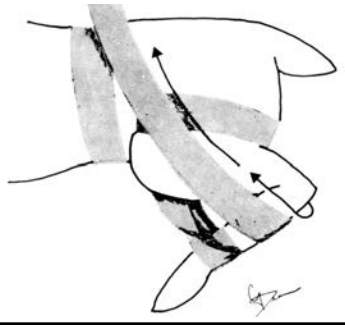

Figure 63-6. After completion of two to three wraps of the tape as previously described, the tape is brought up the lateral side of the leg and attached to the pre placed bellyband in order to maintain abduction of the hip joint.

Aftercare and Potential Complications

A properly applied Ehmer sling is well tolerated by most dogs. The sling should be left in place for 2 to 3 weeks following closed reduction of coxofemoral luxations and following open reduction of coxofemoral luxations using the trans acetabular pinning technique.[1] Immobilization of joints beyond 4 weeks should be avoided as potentially irreversible changes such as capsular and pericapsular contracture, proliferation of intracapsular connective tissue, and major cartilage alterations may occur.[2] Owners should be instructed to check the sling daily for slippage and to observe the toes daily for potential swelling. Should swelling of the toes be observed, the owner should be instructed to return the animal immediately to have the sling removed and re applied correctly.

The primary complication from a properly applied Ehmer sling is skin irritation from the tape. This is most noticeable over the cranial aspect of the thigh musculature, and will resolve with conservative management once the sling is removed. Occasionally, a short course of antibiotic therapy is used. In male dogs, the bellyband may produce irritation cranial to the prepuce or cause preputial swelling if it slips caudally; it should be monitored and adjusted as needed.

90°-90° Flexion Splint for Femoral Fractures

Dennis N. Aron

Introduction

Compromised stifle joint function is a frustrating complication of surgery on fractures of the femur. This process develops most readily when the limb is carried or is splinted in extension. This may be a result of tension created in the quadriceps muscle group after fracture reduction or splinting. The resulting abnormal gait and decreased weight-bearing of the limb can induce disuse osteoporosis, muscle atrophy, and articular changes. Periarticular connective tissue contracture and abnormal joint motion lead to irreversible degenerative joint disease of the stifle. In addition to these changes, growth disturbances such as hip subluxation and bone hypoplasia may develop when quadriceps contracture affects immature animals. A review of femoral fracture cases supports the type of circumstance considered to be high risk for development of stifle joint stiffness.[1] These "at risk" fractures are those that involve the immature patient and/or those with considerable bone comminution and soft tissue damage. When these situations exist and involve the distal third of the femur the risk is quite high. In addition, risk is high when multiple trauma results

in involvement of other bones and joints in the same limb and/or other limb(s) in conjunction with the femoral fracture.

Various treatment modalities have been used for correction of this problem. For the most part these treatments have been active and passive physical therapy modalities and surgical manipulations. The goals of these treatments are restoration of stifle joint and limb function, but significant clinical improvement is unpredictable and costly. Especially common for these types of cases is to attempt manual passive flexion and extension of the stifle after the development of stiffness. It has been suggested in a research study in rabbits that passive therapy only prevents stiffness if it is conducted continuously for more than 16 hours a day for three weeks. Further, it was noted that to do passive therapy for less time per day would actually produce more stiffness.[2]

Because of the great difficulty in treating stifle stiffness once it has occurred it is important to use techniques that contribute to prevention of stiffness. Undoubtedly, providing a stable osteosynthesis will encourage early weight-bearing and contribute to prevention of joint stiffness. However, even situations with stable fracture repair can develop joint stiffness.[1] This has been of clinical importance in humans; as a result, the Association for the Study of the Problems of Internal Fixation has recommended that all fractures of the middle and distal femur be held for the first five postoperative days with the knee positioned in 90 degrees of flexion.[3] A similar technique (90-90 flexion splint) has been evaluated in the dog and cat and appears to be a strong deterrent to the development of stifle stiffness with these types of cases.[1]

The 90-90 flexion splint needs to be applied in the immediate postoperative period to be effective and is not generally helpful if applied after development of stifle joint stiffness.[1] The amount of time the splint should be used for prophylaxis is empirical. However, to avoid the risk of developing stiffness in flexion the joint should not be held by the prophylactic splint for more than seven days. The splint is usually used for three to five days. Gravity may play an important role in allowing the good extension noted after only a day or two following removal of the flexion splint.

Technique

(Figure 63-7)

The only material necessary for application of the 90-90 flexion splint is a roll of elastic tape.[i] One can use a small amount of gauze under the tape to cover an incision. Using too much padding of any type will tend to lead to slippage of the splint. Apply the 90-90 flexion splint in a similar fashion to an Ehmer sling. However, unlike the Ehmer sling place both stifle and hock joints in approximately 90° of flexion, not maximal flexion. While holding the hock and stifle 90° begin by applying adhesive tape loosely around the metatarsal area. Direct the tape up the medial aspect of the tibia. Pass the tape to the medial side of the thigh then around the cranial femur onto the lateral thigh and return to the starting point. Repeat this two or three times attempting to place the tape high in the inguinal region at the top to prevent it from slipping off the cranial aspect of the thigh. Last, place tape strips perpendicular to the already applied tape to encircle the tibia from cranial to caudal to squeeze the tape and further prevent it from slipping. There is no effort, however, to maintain hip abduction as is recommended for the Ehmer sling. A properly applied 90-90 splint is well tolerated by most dogs and cats. Monitor the splint for areas of irritation and especially the toes for swelling. If the toes or distal limb starts to swell, the splint must be removed immediately. Irritation of the skin in the groin region may occur. This is usually minor and is managed conservatively following splint removal.

Chapter 64

Commonly Used Splinting and Casting Techniques

Splinting Techniques

Douglas N. Lange and Kenneth E. Bartels

External fixation by coaptation implies the use of casts, splints, or bandages to provide immobilization of an injured limb. These devices approximate the shape of the limb to which they are applied, and they provide stable fixation of bone fragments without the need for surgical implants at the fracture site.

External fixation for orthopedic injuries in veterinary medicine offers distinct advantages over open reduction and internal fixation. In most instances, tissue and vascular trauma is reduced, the risk of infection is decreased, and the cost of application can be much lower than that of surgery.[1] Careful case selection is required to achieve successful treatment of fractures with external coaptation. In general, these devices are best used in young patients (less than 1 year of age) that tend to heal rapidly with transverse or incomplete fractures distal to the elbow or stifle. External coaptation best neutralizes bending forces on fractures away from joints, rather than near joints, and requires stabilization of the joint above and the joint below the fracture.[2] Therefore, coaptation does have disadvantages resulting from long-term limb immobilization that can cause severe disuse atrophy and possible "fracture disease." The use of a below-the-knee cast bracing (Sarmiento-type) system has been advocated; if properly used for certain tibial fractures, this type of system may reduce problems associated with total immobilization of the hind limb.[3,4] If a coaptation device is incorrectly applied, loosens, or becomes wet, skin necrosis and even gangrene can result. Certain cases of multiple or severely comminuted fractures are best managed by internal fixation techniques, because precise anatomic reduction and adequate neutralization of forces acting on the fractures cannot be achieved with external coaptation.

Indications

Coaptation splints are commonly used for immobilization of simple transverse fractures of the radius, ulna, fibula, metacarpals, metatarsals, and phalanges. They can also be useful for immobilization of certain joints, such as the stifle, after traumatic injuries or surgical stabilization.[2,5] With most fractures, however, use of both internal fixation and external coaptation combines the disadvantages of both and, in general, should be avoided whenever possible.[1]

Temporary coaptation devices usually are indicated in the acutely traumatized animal for prevention of edema, relief of pain, reduction of subsequent damage to soft tissue, wound protection from further contamination, prevention of development of closed fractures into open fractures, and fracture stabilization. Robert Jones bandages, coaptation splints of various materials, Schroeder-Thomas splints, tape hobbles, Ehmer slings, Velpeau slings, and nonweightbearing slings have been described for temporary immobilization as well as for definitive immobilization of certain orthopedic injuries.

The choice of coaptation device depends on each individual case and circumstance. The coaptation device may serve as a temporary splint for traumatic injuries while waiting for definitive internal fixation, as a primary treatment of certain fractures, or as an adjunct to internal fixation or ligament repair.[1,2] Cost is another important aspect that must be considered as well as the availability of materials required for different coaptation devices.

General Application Guidelines

A few general guidelines are relevant to application of all types of coaptation splints and casts. Depending on the animal's physical condition and the severity of the orthopedic problem, application of coaptation splints or casts is best performed with the patient sedated or under general anesthesia. When the patient's physical status precludes the use of chemical restraint, traction and excessive manipulation of the limb must be kept to a minimum.

Use of Stirrups

Application of adhesive tape on the cranial and caudal surfaces of the foot to form "stirrups" is usually necessary so the limb can be attached to the splint or cast securely (Figure 64-1A). In some instances, one should fix the strips of adhesive tape medially and laterally on the limb; this has been recommended for application of a full-encircling cast.[6] When lateral and medial stirrups are used, they must be incorporated into the lateral and medial sides of the cast, respectively, to avoid excessive pressure and possible skin necrosis over the outer distal metatarsal or metacarpal epiphyseal areas.[7] Encircling bands of tape should never be used on an animal's foot because they can cause irreparable vascular damage and skin necrosis.

If problems are encountered in attaching the tape to the foot, the skin can be dried with alcohol to increase the holding capacity on the foot. Some veterinarians spiral a piece of adhesive tape around the cranial and caudal tape pieces to increase fixation of stirrups to the skin.[8] Two to three overlapping layers of elastic gauze (Kling or Sof-Kling, Johnson & Johnson Medical, Inc., Arlington, TX) applied snugly and evenly over the stirrups has also been used without problems to prevent the tape stirrups from slipping (Figure 64-1B). Good judgment must be used during application of these gauze layers to prevent vascular compromise. Tape application over the carpal pad can cause mild irritation to this structure at the time of tape removal, but it is usually not severe.

A technique described specifically for cats uses longitudinal "anchor" strips of adhesive tape applied medially and laterally on the leg, with the tape ends extending proximal and distal to the bandage or splint. The exposed ends of the tape anchor strips are reflected back on the bandage and then are covered with a second layer of bandaging material, which locks the anchor strips on the bandage.[9]

Use of Padding

The padding layer of the bandage provides protection, absorbency, and minimal support to the limb, depending on the thickness of the padding layer. The use of padding before cast or splint application may ensure patient comfort, but when used inappropriately or in excess, it may actually decrease a device's ability to provide adequate immobilization. Excessive padding, hair, and soft tissue structures increase the distance between the rigid part of the coaptation device and the rigid part of the limb (bone), and this can decrease the stiffness and effectiveness of the cast or splint. Therefore, long hair should be clipped, but not shaved, before bandage placement, and adequate cast padding should be applied to provide comfort and to prevent skin irritation. Hohn has stated that properly applied cast padding actually enhances fracture fixation by compensating for slight tissue shrinkage after cast application.[6]

One or two layers of orthopedic stockinette often are adequate; in some cases, incorporation of hair with the encircling plaster during the cast application may provide enough padding to prevent chafing and pressure sores as well as slippage. Removal of a plaster cast in which hair is securely incorporated can be difficult, however. Although some veterinarians apply small pieces of cotton between the toes before cast or splint application, an excess of padding can lead to additional vascular compromise.

Cast padding is applied, beginning at the toes, by overlapping half of the roll's width as it is unrolled; it should be wrapped snugly but not tightly (See Figure 64-1B). Cast padding applied in this manner provides two layers of padding, which is normally adequate. Pressure points over humeral or femoral condyles, olecranon, tuber calcis, or carpal pad may be padded with an extra piece or two of padding, although Swaim and colleagues noted that applying full-length cast padding provided the best form of protection from dermal pressure injury.[10]

Limb Positioning

During application of any coaptation–in particular plaster, fiberglass, and thermolabile plastic casts–for immobilization of a front or rear leg, the limb should be placed in a functional position while the material is still moldable. The rear leg should be kept in a normal position with the hock slightly flexed. When the casting material is conformed to the shape of the front leg, the carpus should be placed in slight flexion (15°) and deviated medially by 15° (Figure 64-2). This positioning helps to prevent a valgus deformity, which otherwise could occur during manipulation because of the normal laxity of the radial carpal joint or as a result of eccentric growth of the radius and ulna in the immature patient. External rotation of the metacarpus should be avoided, and the foot should be kept in a neutral position.[4,11] The old adage expressed by some experienced clinicians, "crooked leg in, straight leg out; straight leg in, crooked leg out," succinctly summarizes the preceding guidelines concerning proper limb position during cast application.

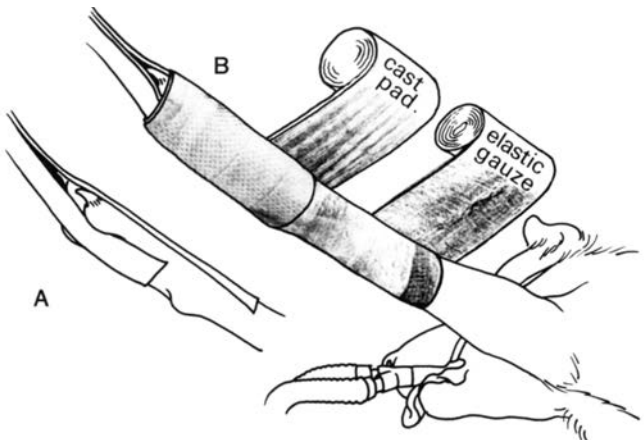

Figure 64-1. A. Application of adhesive tape stirrups on the cranial and caudal surfaces of the foot. **B.** Application of elastic gauze over the adhesive tape stirrups followed by overlapping layers of cast padding.

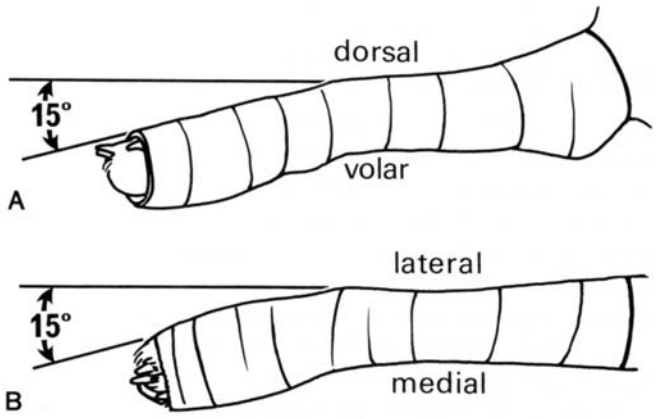

Figure 64-2. Proper positioning of the front leg for application of a fully encircling cast. The carpus is flexed slightly and is deviated medially.

Coaptation Splints

Coaptation splints consisting of various rigid materials are used to approximate the shape of the limb to which they may be applied. In general, they should not be used for immobilization of the humerus or femur. Pre-made commercial splints consisting of plastic or aluminum are known as Mason metasplints or spoon splints. They are applied over padding on the caudal aspect of the limb. Because the limb is curved and the splint is straight, adequate padding is necessary to avoid soft tissue problems, but it may result in poor immobilization. Molded splints of plaster, water-activated fiberglass, or thermolabile plastic can be fitted to the limb almost perfectly. For this reason, they seem to be tolerated better by the patient and cause fewer soft tissue problems during long-term use than Mason metasplints.

Preformed Splints

Indications

Metasplints for the front or rear leg are primarily indicated for fractures of the distal radius and ulna, fracture-dislocations of the carpus or tarsus, and fractures of the metacarpal or metatarsal bones or phalanges. Stabilization of proximal radial or ulnar fractures usually is not adequate with these devices. Generally, the elbow joint cannot easily be immobilized without using a spica configuration over the shoulder.

Application Technique

Adhesive tape stirrups are applied on the cranial and caudal aspects of the paw, with the cranial tape extending beyond the paw 2 to 3 inches farther than the caudal tape. The tape ends are then pressed together. A piece of precut cotton is applied to the back of the paw and antebrachium, or the leg is wrapped with at least two layers of cast padding, even if the splint is foam padded. The splint is snugly secured to the limb with elastic gauze by wrapping the leg with firm conforming pressure beginning at the toes and extending proximally up the limb. The stirrups are reflected up the caudal aspect of the splint and are secured with tape or another layer of elastic gauze (Figure 64-3A). The "gauze-covered" splint is covered with adhesive tape, elastic tape (Elastikon, Johnson & Johnson, Medical, Inc.), or conforming elasticized tape (Vetwrap bandaging tape, Animal Care Products/ 3M, St. Paul, MN) (Figure 64-3B). If the splint extends only to the elbow joint, a V-shaped section can be cut from the cranial aspect of the bandage material just below the joint to prevent pressure necrosis in that area (Figure 64-3C).

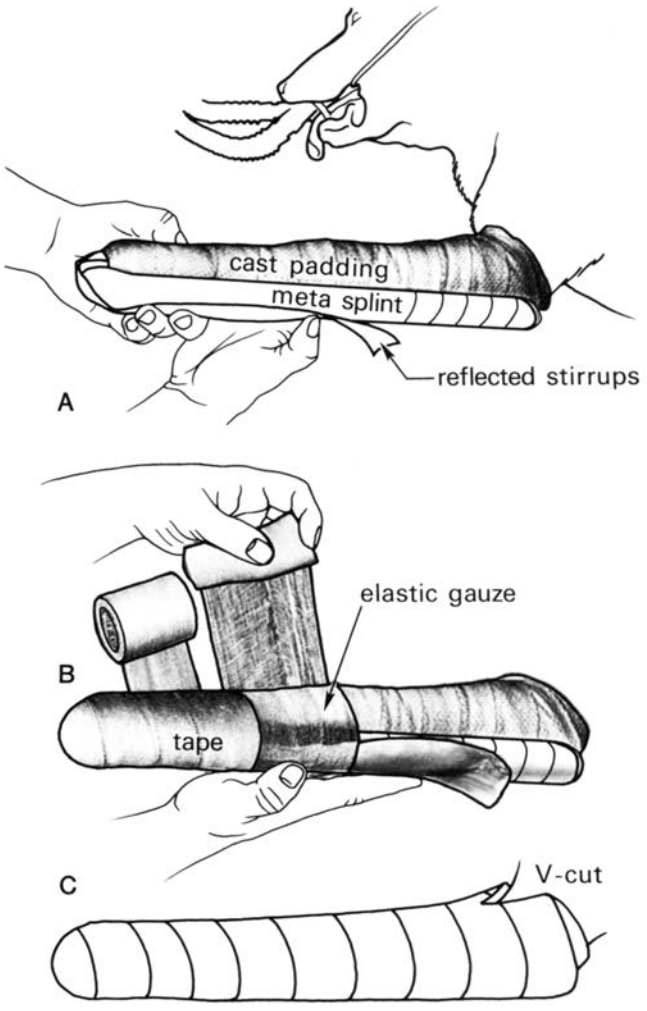

Figure 64-3. Application of aforeleg Mason metasplint. **A.** Stirrups are reflected proximally and are secured to caudal aspect of metasplint. **B.** Metasplint is secured to the limb with overlapping layers of elastic gauze followed by application of adhesive or elastic tape. **C.** A V-shaped section is cut from the cranial aspect of bandage material at the elbow joint to prevent pressure necrosis.

Some clinicians apply metasplints by an alternative method that does not involve use of tape stirrups. With this method, slippage of the splint is prevented by wrapping tape proximally around the elbow to prevent flexion (Figure 64-4). The toes are left exposed, so circulation can be assessed.

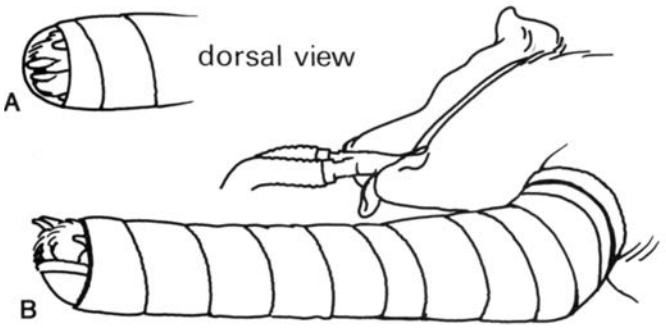

Figure 64-4. A. and **B.** Application of a foreleg Mason metasplint without the use of adhesive tape stirrups.

Molded Lateral Splints

Indications

A molded splint applied laterally on either the forelimb or the rear leg can provide immobilization of the elbow joint or stifle, respectively. It can also stabilize less severe fractures of the radius, ulna, tibia, and fibula. This type of coaptation can be particularly helpful in providing protection from bending forces after internal fixation or joint stabilization. The casting material can be extended over the shoulder or hip as a modified spica to provide partial joint immobilization.

Application Technique

Adhesive tape stirrups may not be necessary for application of this type of splint, especially if it extends proximally to include the shoulder or hip. The patient is placed in lateral recumbency with the injured limb positioned uppermost. The limb is padded with two layers of cast padding beginning at the toes and ending at the axilla or inguinal area.

If the shoulder or hip is to be immobilized through the use of a modified spica splint, the layers of padding should encircle the chest wall or pelvis, respectively. For splint application on the front leg, the padding creates a figure-of-eight pattern around the thorax and the affected limb, but the padding and the next layer of conforming gauze are carried behind the opposite axilla (Figure 64-5A). For a hip spica, the cast padding and conforming gauze applied to the affected leg and the opposite limb create a figure-of-eight pattern and can incorporate the proximal half of the opposite leg. When this configuration is used, the resulting coaptation device is called a "one-and-a-half leg" spica.[4] Care must be taken when applying a hip spica on a male dog so the prepuce is not included in the bandage. Spica splints are also restrictive, and some animals may not be able to stand without assistance.

Cast materials that can be molded to form a lateral splint are plaster, water-activated fiberglass, thermola-bile plastic,

or yucca board. Rolls of plaster, water-activated fiberglass materials, or thermolabile plastic can be cut to proper length or shape before application on the lateral aspect of the limb after activation. Elastic gauze is used to conform the softened splint material to the limb and to attach the splint to the shoulder and chest wall or the hip and thigh area. The gauze-covered splint is then bandaged with elastic tape applied in a pattern similar to that of the gauze (Figure 64-5B and 64-6).

Conformable materials used for molded lateral splints should be applied according to the manufacturer's directions and as each individual case dictates. A splint thickness of four to five layers of fiberglass or plaster casting material is usually adequate for the small animal patient. Prepackaged fiberglass splints are commercially available (Ortho-Glass Splinting System, Parker Medical Associates, Charlotte, NC) as well as unitized plaster splints (Specialist J-Splint plaster roll immobilizer, Johnson & Johnson Orthopaedics, Rayn-ham, MA). These products consist of multiple layers (8 to 15) of casting tape enclosed in a stockinette, which is packaged in a roll and can be cut to any length. Sheets of fabric impregnated with a thermolabile plastic (Orthoplast Splint Johnson & Johnson Orthopaedics) can be shaped according to a paper pattern of the affected limb and then softened in hot water (170°F) before application. Rolls of casting material composed of loosely knitted fabric impregnated with thermolabile plastic (Hexalite, Kirschner All Orthopedic Appliances, Marlow, OK) can be cut into splints as described earlier. The rigidity of this material requires that a flve-to six-layer splint be used to immobilize a limb adequately. To provide as much strength as possible, splint width of each coaptation material should be approximately one-third to one-half the outside circumference of the affected limb. In other words, the splint configuration is similar to a full-encircling cast cut in half in a cranial-to-caudal direction, with the lateral half of the cast used as the coaptation device.

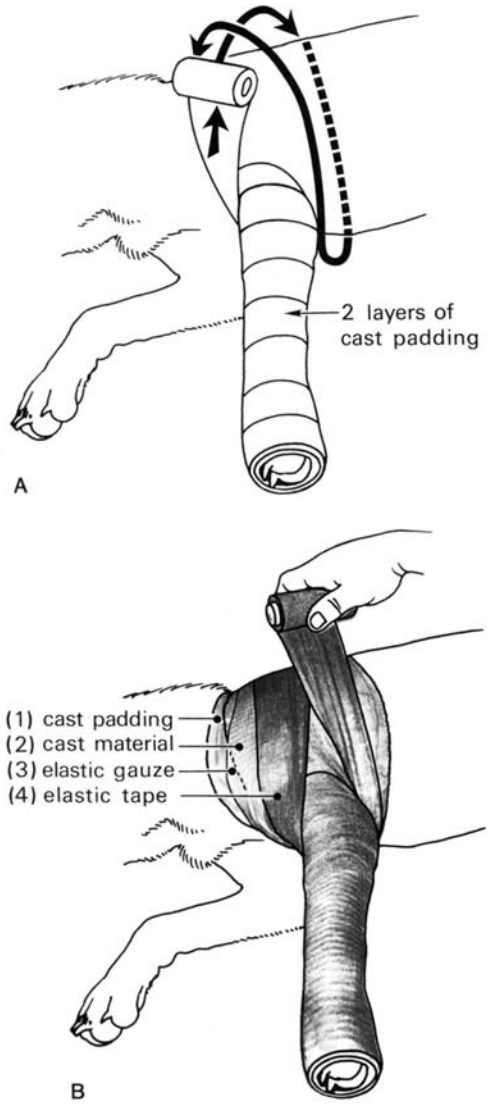

Figure 64-5. Application of a molded foreleg lateral splint. **A.** Cast padding encircles the affected limb and thorax. **B.** Molded conformable material is secured to limb with elastic gauze and elastic tape.

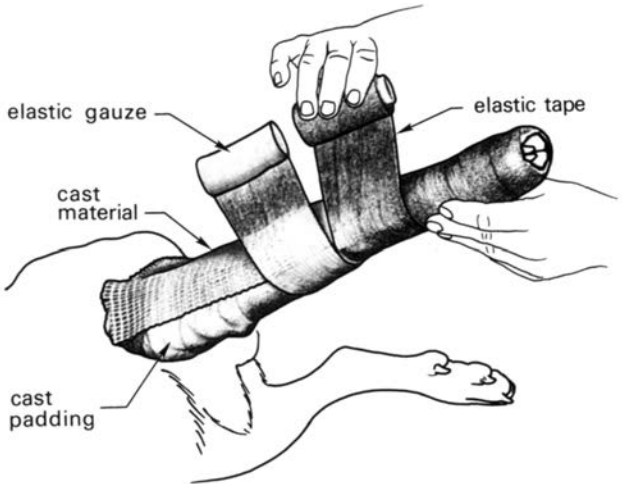

Figure 64-6. Application of a molded lateral splint to the rear leg.

Schroeder-Thomas Splints

Probably the most misused and misunderstood coaptation device today is the Schroeder-Thomas splint. When correctly applied, this splint can be an excellent means for immobilizing joints postoperatively surgery and for immobilizing certain fractures. This traction device can provide accurate and continued fixation of bone fragments by counteracting muscle forces and immobilizing parts of the skeleton. Under certain circumstances, skeletal traction can be provided when transfixation pins located in the areas of the femoral or humeral condyles are incorporated into the splint so traction from the splint on the distal end of the affected limb controls the distal fracture fragment.

Indications and Possible Complications

The use of Schroeder-Thomas splints may be indicated for some fractures of the radius, ulna, and tibia; avulsion fractures of the tibial tuberosity and distal malleolar fractures are exceptions. These splints have been used for fractures of the distal humerus (distal one-third), although not for condylar fractures, which require precise reduction of the joint surface to avoid degenerative joint disease. Nonarticular fractures of the distal femur (distal one-third) are considered by some clinicians to be amenable to reduction and immobilization with a Schroeder-Thomas splint, although supracondylar or condylar fractures must receive superb postreduction care because immobilization can

be difficult to maintain. The splint has been used for temporary immobilization of the stifle and elbow joints postsurgically.

Although a Schroeder-Thomas splint can be used successfully for more orthopedic conditions than are mentioned here, its inappropriate use can have disastrous consequences.

Application to a fracture of the proximal humerus or femur is definitely contraindicated because the ring of the splint must support and rest on the proximal fracture fragment. If the splint is used for proximal femoral and humeral fractures, the ring rests in the fracture site and acts as a fulcrum point, whereas the limb serves as the lever resulting in movement at the fracture site. In these circumstances, fracture disease (nonunion, quadriceps tiedown, joint stiffness) results. The splint often loosens with time because of the dynamic nature of its application. Circulatory problems causing tissue necrosis can develop as a result of loosening, swelling of the limb, or improper application. Pressure necrosis under the ring of the splint, edema of the scrotum, severe limb edema, and strangulation of the foot can occur.

Application Technique

Schroeder-Thomas splints should be custom-made for every individual case. Obviously, splint rods can be reused if they are the appropriate length for an individual patient. Because this type of splint is a dynamic traction device, it requires careful attention by the owner and periodic adjustment by the clinician. A Schroeder-Thomas splint is constructed of aluminum rods (1/8-, 3/16-, or 3/8-inch diameter) available in 6-foot lengths or 12-foot coils. For small dogs or cats, regular coat-hanger wire has been used. An average-size dog (30 to 40 lb) requires the 3/8-inch diameter aluminum rod. Commercially available plastic or wooden "ring" blocks usually are used to form the elliptic ring at the proximal end of the splint. Adhesive tape and combine roll or elastic gauze are used for application of the stirrups and the traction slings, respectively. A vise is helpful in shaping the rod, and bolt cutters or a hacksaw are necessary for cutting the rod. The shape of the splint is modified in relation to the specific leg injured, the bone that is fractured, or the joint that is involved. Traction application also varies according to the fracture, so the fragments can be separated and aligned (Figure 64-7).

The first step in construction of a Schroeder-Thomas splint is the formation of the upper ring at the proximal end of the splint. For the rear leg, the diameter of the ring is determined by measuring the distance between the cranial aspect of the wing of the ilium and the caudal point of the ischium; for the foreleg, the ring diameter can be determined by measuring the length of the scapular spine.[4] The bottom of the ring should be flattened to conform to the animal's axillary area or thigh. The bottom of the ring must bend medial to the vertical bars at a 45° angle at the middle of the ring. The ring can be bent, or the vertical bars can be bent to accommodate this angle. The lower half of the ring should be padded; however, excessive padding may cause irritation and circulatory problems and should be avoided. Applying tape to the ring with the adhesive side facing outward and then wrapping the lower half of the ring with thin strips of cotton or cast padding work well. The tape with the adhesive side inward is applied over the cotton loosely so the padding is soft and conforms to the inguinal or axillary region.

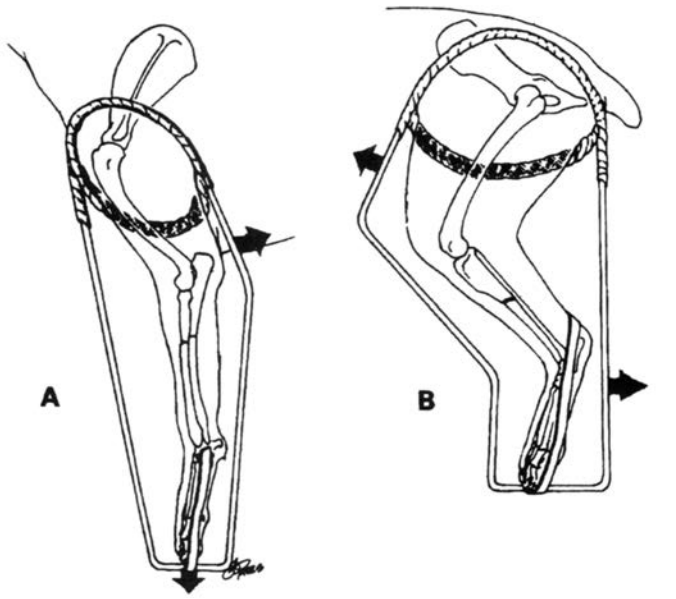

Figure 64-7. Configurations of a foreleg and hind leg Schroeder-Thomas splint and traction application for radioulnar fractures **A.** and tibial fractures **B.** (From Tobias TA. Slings, padded bandages, splinted bandages, and casts. In: Olmstead ML, ed. Small animal orthopedics. St. Louis: CV Mosby, 1995:108.

The vertical bars of the splint are sometimes left straight to accommodate certain fractures. However, each case should be considered on an individual basis and the splint configuration varied accordingly. For the rear leg, the front bar is bent to conform to the normal angulation of the stifle and hock; the rear bar is left straight. The angles of the front bar are varied according to the injury (See Figure 64-7). For the fore-limb, both bars are bent to conform to the angulation of the elbow. Although various configurations for humeral and radioulnar fractures have been described,[4,8,12] the configuration illustrated in Figure 64-7A has been used successfully and seems to be well tolerated by most animals.

The vertical bars are bent and connected with adhesive tape at the bottom of the splint. The length of the splint is determined by gently extending the limb so the end of the splint coincides with the end of the toes. The limb should not be stretched taut in a Schroeder-Thomas splint. The middle of the horizontal bar formed by connecting the vertical bars can be bent into an inverse-V shape so the adhesive tape stirrups fastened there will not be worn away by walking. A separate piece of aluminum rod can also be added to the bottom of the splint to protect the tape. The width of the distal end of the splint should be approximately three times the width of the paw. The finished splint should be completely wrapped as smoothly as possible with adhesive tape for cosmetic purposes. More important, this procedure prevents slippage of traction slings. The completed splint is applied to the leg carefully, with the ring snugly placed in the axillary or inguinal area. The splint is secured initially to the distal end of the foot by means of an adhesive tape stirrup. For additional support, a spiral of tape ("barber pole") can be applied over the foot to help

secure the vertical stirrups. Wrapping tape circumferentially around the foot usually causes swelling and should be avoided. Cotton can be used to pad between the toes. The adhesive tape stirrups should not be used to apply traction.

Traction is applied by means of the combine roll or wide elastic gauze used to secure the leg to the vertical bars of the splint. Both products, but especially the elastic gauze, must be used with caution, because the application of excessive tension can cause necrosis or edema. Positioning of the traction slings depends on the nature of the fracture. For fractures of the tibia, the traction slings are placed around the hock joint first and then in the femoral area to provide traction on the tibia (See Figure 64-7B). For distal femoral fractures, the first traction sling is applied around the hock joint, and then one is applied around the proximal tibia to provide traction on the femur. Traction slings should be applied in such a manner that they provide adequate medial support to both the tibia and femur and avoid a valgus deformity of the limb.[4] For fractures of the front leg, a traction sling is first applied at the level of the elbow, pulling the humerus caudally. The second sling is applied at the level of the carpus, pulling it cranially, which increases the traction on the radius, ulna, or humerus. As Figure 64-7A illustrates, tension can be applied caudally on the radius and ulna; a support sling placed in the area of the distal humerus maintains even pressure on the limb and reduces motion.

The entire Schroeder-Thomas splint can be covered with orthopedic stockinette to protect the device.

Postapplication Care

Excellent client and professional care is essential in maintaining a Schroeder-Thomas splint after application. The limb must be kept dry and clean, and the animal must be confined. Scheduled rechecks should be performed on a weekly basis, and clients must be diligent in evaluating the device for loosening, irritation, or swelling of the limb. If mild edema does occur, the animal must be monitored carefully for the next 24 to 48 hours; the splint may have to be adjusted or removed if this swelling persists or becomes more severe. Clients must be informed that reevaluation of the device whenever one suspects a problem is essential for proper splint management.

Tape Hobbles

Tape hobbles have been advocated as a method of protecting an injured limb and preventing additional trauma. This device can limit rotational stress on the limb and can aid in preventing stresses to proximal humeral or femoral fractures. It can also prevent excessive adduction or abduction of limbs with scapular or pelvic fractures. Hobbles must be used with caution when any possibility of vascular impairment or swelling in the areas of the metatarsus or metacarpus exists. The first step in application of tape hobbles is wrapping of two or three layers of cast padding around the metatarsal or metacarpal areas. Adhesive tape, 1 or 2 inches in width (depending on the size of the dog), is carefully wrapped around the paw to form a sling. One must not wrap the tape tightly around the paws. Overlapping the tape ends unevenly to form a "tab" from each foot should be the desired goal. The two tape tabs are joined with additional stirrups of tape. Usually, the distance between the feet is about that of a normal standing position for that animal, which should allow for proper freedom of movement (Figure 64-8).

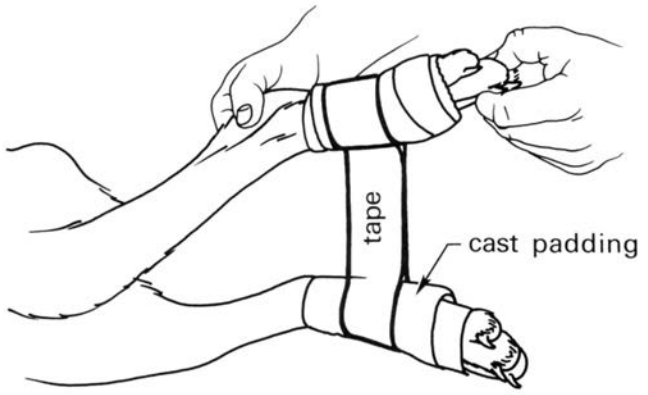

Figure 64-8. Application of hind leg tape hobbles.

Velpeau Sling

The Velpeau sling is used for immobilization of the shoulder joint postsurgically, for stabilization of the shoulder joint after closed reduction of luxations, for immobilization of scapular fractures, and for other conditions that require a front leg to be non-weight-bearing. A Velpeau sling should not be used on animals with oblique fractures of the distal humerus because compression by the sling may result in overriding of the fractured fragments and damage to the radial nerve. Olecranon fractures are also not amenable to this type of sling. A Velpeau sling is made of elastic gauze (2, 3, or 4 inches wide, depending on the size of the animal) or combine roll. It is started by loosely wrapping the conforming material around the paw in a lateral-to-medial direction. The wrap is continued laterally over the affected limb and shoulder and is placed around the thorax and behind the opposite axilla (Figure 64-9A). With the elbow, carpus, and shoulder joints flexed, the wrap is continued to the starting point. Several more layers of conforming material are applied in a similar pattern, but these layers enclose the elbow and paw (Figure 64-9B). Covering the entire limb prevents the lower limb or elbow from being forced out of the bandage if the animal tries to extend or flex the leg. The entire bandage is then covered with elastic tape in a similar manner.

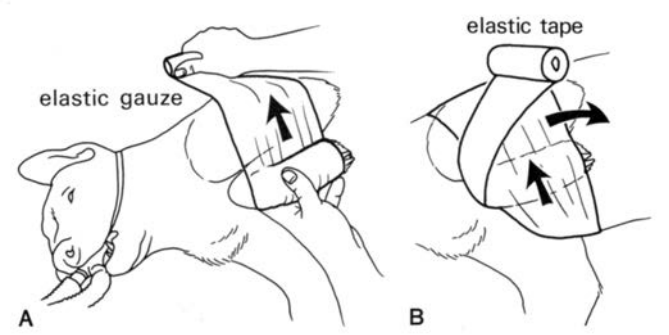

Figure 64-9. Application of a Velpeau shoulder sling. **A.** Elastic gauze is wrapped around the paw and is continued laterally over affected limb with flexed elbow, carpus, and paw. **B.** Several additional layers of elastic gauze are applied and enclose the elbow and paw; the sling is then covered in a similar manner with elastic tape.

The clinician must make the client aware that if the sling loosens and slips, besides the loss of immobilization, disastrous vascular impairment can occur. The animal should be strictly confined for the duration of the bandage's application. Animals usually tolerate the sling well, but it should be checked on a weekly basis. If it is used more than 2 weeks for immobilization, joint contracture can occur because the shoulder, elbow, and carpal joints are held in severe flexion.

Postapplication Management of Splints, Casts, and Slings

After application of any splint, cast, or sling, the limb should be observed every 4 to 6 hours to be certain that the device has been applied correctly. If it is constricting vasculature or lymphatic drainage and causing the proximal or distal aspects of the limb to swell, the device should be removed immediately and reapplied. At the time of discharge, clients must be educated in the proper care of the coaptation device. The splint or cast should be kept dry at all times. Cornstarch or talcum powder can be used to prevent chafing and pressure sores where the device irritates the axillary or inguinal areas.

Clients must feel free to seek professional advice concerning the coaptation device. If any of the following problems should develop, the animal must be examined as soon as possible:[4]

1. Any sign of excessive discomfort
2. Any changes in position or shape of the splint or cast on the leg
3. Any unusual foul odors coming from the splint or cast
4. Any unexplained soiling of the splint or cast that was not present previously
5. Any sores that develop at the top of the splint or cast that do not respond to talcum powder or cornstarch application
6. Swelling of the toes or the leg above the coaptation device
7. Inappetence, depression, or fever in the animal
8. Any excessive chewing of the splint or cast

No splint or cast can be worn in complete comfort by an animal. Minor licking and chewing can be expected; however, when an animal continues to mutilate the device, the device should be rechecked. If it has been properly applied and the animal continues to chew the splint or cast excessively, properly applied chemical or mechanical restraint devices may be needed separately or in combination.[13]

Principles and Application of Synthetic and Plaster Casts in Small Animals

Douglas N. Lange and Kenneth E. Bartels

The purpose of a cast is to provide rigid external coaptation to a reduced fracture or tenuous ligament repair so proper alignment and support are maintained during healing. Since 1851, the traditional plaster of Paris cast has been used when rigid external coaptation is required. Plaster casts provide an inexpensive means of providing molded external support, but they have the disadvantages of prolonged drying time, relative heaviness, decreased porosity, deterioration if exposed to moisture, and brittleness.[1] Synthetic casting materials have been developed and are available to veterinarians. The newer synthetic materials include polyurethane resin-impregnated fiberglass or polyester-cotton knit, and thermolabile plastic. These materials have the advantages of being lightweight, less bulky, immersible, radiolucent, and quickly "set," but they are more expensive and can be difficult to mold. Although newer methods of internal fixation (bone plates and screws) are indicated for most complicated orthopedic problems, closed reduction and external coaptation can be the treatment of choice for selected fractures and ligamentous injuries. Long leg casts are most appropriate for fractures below the elbow and stifle that only require bending and

rotational stability, such as incomplete or transverse fractures. The joint should be immobilized above and below the fracture in most cases, although functional below-the-knee casts have been used successfully.[2] Fractures of the humerus and femur require a cast in a "spica" configuration that immobilizes the shoulder or hip, respectively.

Plaster Casting Material

Characteristics

Plaster of Paris can be shaped and molded with ease and should usually be chosen for immobilizing severely displaced or unstable fractures that require a closer fit when coaptation is indicated. Because plaster is less expensive than the newer synthetic materials, it is indicated if frequent changes of casts are required. It is suitable for an initial or primary cast after fracture reduction when mild edema or swelling of a limb can be expected, because a change of cast is usually necessary after the edema subsides or becomes more severe.[3] Synthetic casts should be used with small patients requiring a lighter cast, with patients likely to abuse or moisten the cast, or when a plaster cast is likely to fail within the required time of immobilization.

Plaster of Paris is made of calcium sulfate crystals that have been reduced to powder and subjected to intense heat to expel the water. The resulting chalky white powder is then incorporated into gauze bandages. When water is added to the plaster, a crystallization process occurs, and the material hardens in an exothermic reaction. The time from which water is added to the plaster bandage until the material becomes hard is called its setting time. Plaster sets in 3 to 8 minutes, depending on whether it is fast or extrafast setting, the temperature of the water used, and the amount of water left in a roll after immersion. As the cast dries, the interlocking of the calcium sulfate crystals gives the plaster its strength. Further molding after a plaster cast has begun to set can prevent this interlocking of the crystals and may weaken the cast.

After the cast sets, the excess water must evaporate from the surface before the cast attains maximal strength. This period (curing time) while the cast is still "green" varies from 8 to 48 hours, depending on how large and thick a cast is, the type of plaster used, humidity, and air temperature. Excessive weight-bearing during drying of the cast should be avoided. A plaster cast is heavy at first, but it becomes lighter as the water in the plaster evaporates. The strength of a plaster cast is proportional to its thickness, but the smallest possible amount of plaster should be used. Placement of plaster "splints" or reinforcing strips of cast material along one surface strengthens a cast without increasing its entire mass; this technique is especially useful over areas where angulation occurs and the cast is susceptible to stress and fracture.

Application Technique

No special equipment is required for preparation and application of a plaster cast, and a standard cast cutter can be used for removal. Gloves should be worn during application, because plaster can be irritating to the hands. The patient and casting area in the hospital should be protected from dripping plaster by the liberal use of newspaper or a plastic drop cloth.

Preparation of plaster bandages involves immersing them in tepid water (70 to 75°F) for a few seconds until the bubbling from the roll has stopped; the plaster rolls then are squeezed to remove excess water. A plaster bandage should be unrolled on the leg, as it is applied, in an encircling manner with overlapping of half of the roll's width; it should never be stretched or tightened around the limb. It should be applied in a smooth, conforming manner so no thick or thin spots result. Tucks can be made in the rolls to change directions or to contour the plaster smoothly. Molding the cast by rubbing each section with wet hands before the plaster is set is essential for proper lamination, to produce a smooth surface, and for conforming the material to the proper configuration of the affected limb. During application, the cast should be supported by the palms of the hands and not indented with the fingers, because the "dimples" that result could produce pressure points on the interior, which can lead to skin excoriation.

Once the cast is dry, any rough edges should be covered with adhesive tape. The cast should not be washed, although a damp cloth can be used to remove excessive dirt if the residual moisture is wiped away afterward. Immersion of the plaster cast can cause deterioration of the plaster, resulting in skin irritation and maceration.

Some manufacturers (Duracast, Duraflex, Carapace, Caraflex, Cellona, Carapace, Inc.. Tulsa, OK; Gypsona, IMEX Veterinary, Inc., Longview, TX) supply plaster casting material in various widths (2, 3, 4, and 6 inches) and setting times (slow, medium, fast, and extrafast). For small animals, the 2- and 4-inch widths are the most versatile; fast or extrafast setting times are more appropriate for veterinary patients. Various setting times can be achieved by adjusting the temperature of the water in which the plaster bandages are immersed before application. Use of colder water increases setting times, and use of warmer water decreases it. Because plaster of Paris products are significantly less expensive than the newer synthetic materials, they will continue to be an essential moldable coaptation material.

Synthetic Casting Materials

Characteristics

Several newer synthetic cast materials are available as alternatives to plaster of Paris. These newer materials are recommended for use as primary casts for nondis-placed fractures with minimal swelling or for longterm wear when multiple cast changes are not required.[1,3-7] They can be divided into three classifications according to their composition: polyester-cotton knit, fiberglass, and thermolabile plastic. Manufacturers are introducing new materials every year, and each product obviously is recommended over a competitor's for many different reasons. Clinicians should be aware of the advantages and disadvantages of several of the materials and should choose the one with the characteristics they regard as the most important.

Polyester-cotton casting materials consist of a polyester and cotton, knitted, open-weave fabric impregnated with a water-activated polyurethane resin (Delta-Lite Fabric Casting Tape, Johnson & Johnson Orthopaedics, Inc., Raynham, MA). After immersion in cool tap water, this material is applied as casts or protective bandages. Casts formed from these products are lightweight, immersible, porous (permeable to water vapor), and fairly strong. Their biggest advantage is that they are virtually radiolucent.[4]

Fiberglass casting tapes consist of a knitted fiberglass fabric impregnated with a polyurethane resin that is activated by water (Delta-Lite Conformable Casting Tape and Delta-Lite "S" Fiberglass Casting Tape, Johnson & Johnson Orthopaedics, Inc.; Synthocast, Kirschner All Orthopedic Appliances, Marlow, OK; Scotchcast II, Orthopedic Products, Surgical Products Division/3M, St. Paul, MN; and Vet Cast and Vet Cast II, Animal Care Products/3M) The water-activated fiberglass casting tapes have met with success in veterinary medicine despite their expense. Differences among the products involve mainly their "handling" ability during application and the final "finish" or smoothness of the cast after it has set. Both these characteristics are primarily influenced by the knitted weave of a product; closely knitted materials generally are more conformable and easier to apply. Casts made from the fiberglass products are strong, lightweight, radiolucent, permeable to water vapor, and immersible in water.

The third type of synthetic casting material is an open-weave cotton fabric coated with high-density thermoplastic resin (Hexcelite, Kirschner All Orthopedic Appliances). A roll is immersed in hot water (65.5°C) for approximately 30 seconds until soft, it is drained of water, and it is applied when comfortable to the touch. The material begins to harden in approximately 3 minutes and achieves rigidity in 10 minutes. Specific areas can be remolded by application of heat with a 1000-watt portable hair dryer until the material is pliable. Thermolabile casting material is permeable to water vapor because of its open weave and does not exhibit an exothermic reaction while curing; it has a rough finish after application.

Bartels and associates evaluated some synthetic casting materials for their tensile strength, fatigue strength, exothermicity (evolution of heat during polymerization), permeability, radiolucency, and cost.[4] Although statistically significant differences were found for some of the criteria, no one material was best in all categories tested. Other "clinical" studies have revealed similar results.[8,9] They confirm that no one material is best in all areas because the newer synthetic casting materials, although easier to handle, are not as strong as the previous, tackier synthetic cast materials.

Packages of water-activated casting tape should be opened one at a time and used within 2 to 3 minutes because exposure to humidity in the air hardens the tape. Because unused packages can deteriorate on the shelf, sealed, unused rolls should be stored in a refrigerator to retard premature hardening. Most manufacturers date their products and recommend that the rolls of dated cast material be used within 6 months.

Application Technique

Water-activated synthetic casting products should be immersed in cool water (21 to 27°C), because warmer water temperatures greatly decrease setting time, and the heat produced during polymerization can be uncomfortable to the patient during cast application. Immersion in water can vary from 5 to 15 seconds, and the cast rolls should be drained of excess water. Gloves should be worn when handling any of the water-activated materials to protect the hands from any residue, which is difficult to remove. Four to five layers of material should be used, according to manufacturer's recommendations for weight-bearing casts in small animals.[4]

Techniques for applying synthetic casting materials differ from those usually recommended for plaster casting material. To change directions during application, tucks are made in plaster and thermolabile materials while fiberglass material is twisted. Synthetic materials are molded only in a horizontal motion to ensure lamination. Maximum bonding of the cast layers can be achieved by firmly blotting the exterior of the cast with the open palms in a rolling motion. Molding is achieved by maintaining a desired position for about 1 minute during the last few minutes of the setting period, which varies from 2 to 6 minutes, depending on the temperature of the water for activation. One manufacturer (Vet Cast, Vet Cast II, Animal Care Products/3M) supplies a hand cream to facilitate smoothing and molding of the cast, but water-soluble lubricating jelly (K-Y Lubricating Jelly, Johnson & Johnson Products, Inc., New Brunswick, NJ) can also be used for this purpose. Another manufacturer includes casting gloves that give the polyurethane resin-impregnated fiberglass substrate tack-free working properties (Johnson & Johnson Orthopaedics, Inc.).

Synthetic casts are lighter than their plaster counterparts and, when applied using polypropylene stockinette and polyester padding, they can be immersed in water. Synthetic casts are easier to keep clean because they can be washed with mild soaps, and hydrotherapy for postoperative orthopedic rehabilitation is possible with them. If inadequate drying of the cast occurs and the skin remains wet, irritation and possible skin maceration can occur. Hair dryers can be used to dry wet fiberglass casts.

Long Leg Cylinder Cast

Application Technique

If external coaptation is chosen for fracture repair, the fracture must be reduced before cast placement. Manipulation of the cast after placement causes creases and pressure points in the cast. General anesthesia facilitates fracture alignment and prevents the animal from disrupting reduction while the cast becomes rigid. At least 50% of the fracture ends should be in contact with each other to expect fracture healing, although perfect reduction is the goal for every fracture.[1] In addition, the limb should be reduced in a normal walking position to facilitate early usage of the casted limb and normal limb function after cast removal. The leg should be clipped and aseptically prepared as for surgery in case a closed fracture becomes an open fracture during

manipulation. The animal should be placed in lateral recumbency with the affected limb down; this positioning helps to prevent a valgus deformity at the fracture site during cast application.[2] The following description of application of a long leg cylinder cast to the front leg emphasizes points that can be recommended when using either plaster or synthetic casting materials:

Adhesive tape stirrups are applied to the cranial and caudal surfaces of the foot with the ends of the tape fixed to a tongue-depressor blade to facilitate separation later. The leg is elevated, and the stirrups can be fastened to an intravenous stand or held in an elevated position by an assistant. One or two layers of orthopedic stockinette are rolled up over the entire limb with no wrinkles and are snugly held by an assistant at the proximal end (Figure 64-10). The stockinette should be long enough to extend distally beyond the toes and into the axillary or inguinal region proximally. Synthetic cast padding that repels moisture is wound around the leg from distal to proximal as snugly as possible.

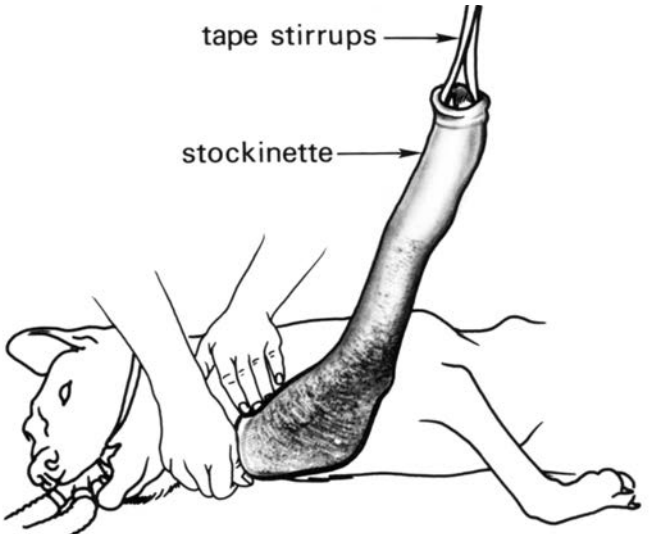

Figure 64-10. Animal placed in lateral recumbency with the affected limb down. Adhesive tape stirrups are applied to cranial and caudal surfaces of the foot; an orthopedic stockinette is rolled over the entire limb.

Wrapping the padding from cranial to caudal around the medial aspect of the limb helps to prevent supination when wrapping the forelimb.[10] Two layers are usually adequate, although extra padding may be needed at the proximal and distal aspects of the cast. Uniform full-length padding provides the best protection against dermal injury.[11] The cast material is rolled around the leg beginning at the distal end and overlapped by half the width of the roll. The material should be applied smoothly using even conforming pressure; smooth application is facilitated by rolling continuously around the limb in a spiral fashion and not raising the roll away from the skin.[5] Regardless of the casting material used, a cast should be supported with the palms of the hands and not the fingertips because indentations from the fingers may result in pressure sores. If applied properly, four layers of material are usually adequate for the average-size dog. The pads and toenails of the two central toes may be left exposed if there is no weight-bearing on the foot. If the animal is weightbearing on the limb, an aluminum rod walking bar can be applied to the end of the cast to prevent excoriation of toes and excessive wear to the cast.[1,2]

Longitudinal splints of cast material can be applied medially and laterally or cranially and caudally to strengthen the cast before the final layer of casting material is applied (Figure 64-11).

After application of the cast and while the material is still moldable, the leg must be positioned properly as described. The stockinette and padding at the ends of the cast and the tape stirrups are reflected over the ends of the cast. These are secured to the proximal and distal aspects of the cast with circular wraps of tape (Figure 64-12).

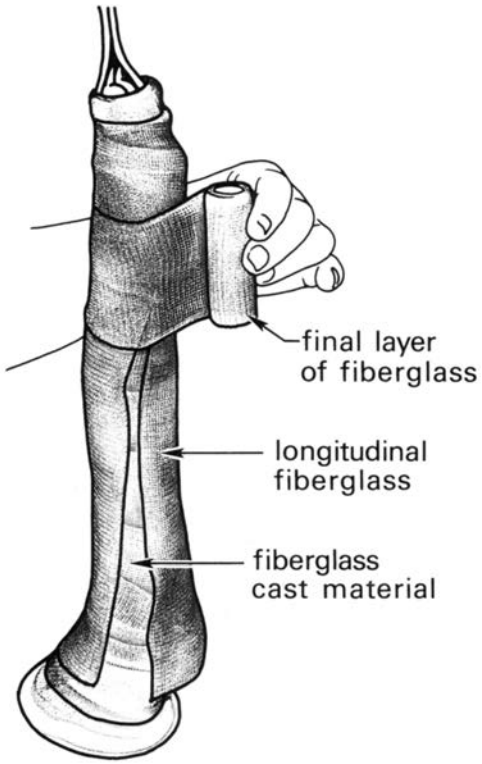

Figure 64-11. Longitudinal splints of cast material are applied cranially and caudally to strengthen the cast before rolling final layer of material. Layers of cast material are applied as shown.

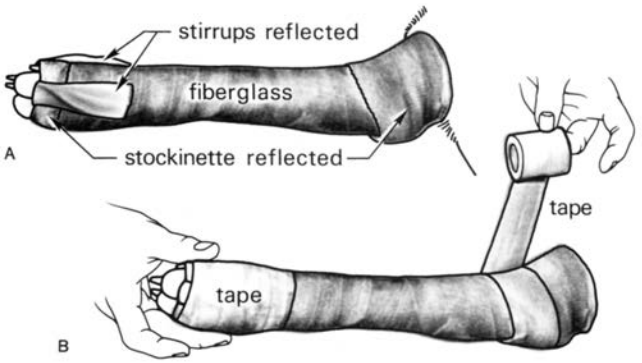

Figure 64-12. Final steps in cast application. **A.** Tape stirrups and stockinette are reflected back over the completed cast. **B.** Reflected stirrups and stockinette are taped to the distal and proximal aspects of the cast.

Postapplication Care

For plaster casts, the animal should be hospitalized for at least 24 hours after application to allow for adequate drying. Synthetic materials such as fiberglass can bear weight in as little as 20 minutes, but the animal should be observed closely for at least 12 to 24 hours to be certain that cast application has been correct and is being tolerated well. While the animal is in the hospital, the cast can be covered with a piece of stockinette to prevent soiling before discharge. Care of a cast is similar to care provided for any splint. The cast should be kept dry and as clean as possible. Routine rechecks should be scheduled, and particular care should be taken to educate the owner on cast management. At removal, the cast should be split longitudinally using a cast saw with short bites made perpendicular to the long axis of the cast, rather than sliding the cast saw down the length of the cast. Cutting a cast in this manner helps to reduce chances of damaging the underlying structures. Cuts should be made on either side of the limb, and the two "half-casts" should be removed carefully. Cast spreaders widen the groove made by the cast saw to facilitate cutting the deeper bandage layers with scissors. Windowing of casts should be avoided because of the danger of edematous tissue herniating through the window.[1,12] If the cast loosens, it should be removed and replaced, because immobilization is lost and pressure necrosis occurs as the cast slips and moves.
